Design Details to Minimize Corrosion

Peter Elliott, Cortest Engineering Services Inc.

Introduction

GOOD ENGINEERING DESIGN is fundamental to reliable and effective material use, given adequate data and the availability of a suitable material in a suitable form. Designing to minimize corrosion can be reliable only if it is part of an overall design philosophy.

Design can never be absolute. There will often be a tendency for compromise based on cost and the availability of materials and resources. For example, one designer may recognize a potential corrosion hazard and may plan for early replacement or more regular maintenance. Such design options may be relatively inexpensive. Designers may have little experience with regard to corrosion and the subtleties of material fabrication and assembly. In these cases, incorrect decisions can be extremely costly.

A designer cannot be a corrosion engineer; therefore, it is necessary to convey a basic knowledge of corrosion to the designer. This information must relate to the total design requirements. In some cases, the process conditions may not be known with sufficient exactness to permit a technical design decision.

The basic principles of corrosion control by design to be discussed in this article are based on practical situations. Texts are available on the subject (Ref 1, 2, 3), but several of them are confined to simplistic geometric shapes that may not always be readily applicable to the design of process plants or operating equipment. It is important to be aware of design details that can lead to early deterioration. These fine details of design, often compounded by human error, account for many significant failures. Therefore, corrosion engineering design must be an integral part of the total design, which in turn includes aspects ranging from appraisal of the design concept to inspection and quality control in installation and operation. In addition, it cannot be overemphasized that poor design may render corrosion-resistant materials susceptible to premature corrosion.

Figure 1 illustrates the frequency of failures attributed to design errors. The results, based on the responses of personnel in the chemical-processing industries, support the importance of being aware of the circumstances that relate a material to its specific environment.

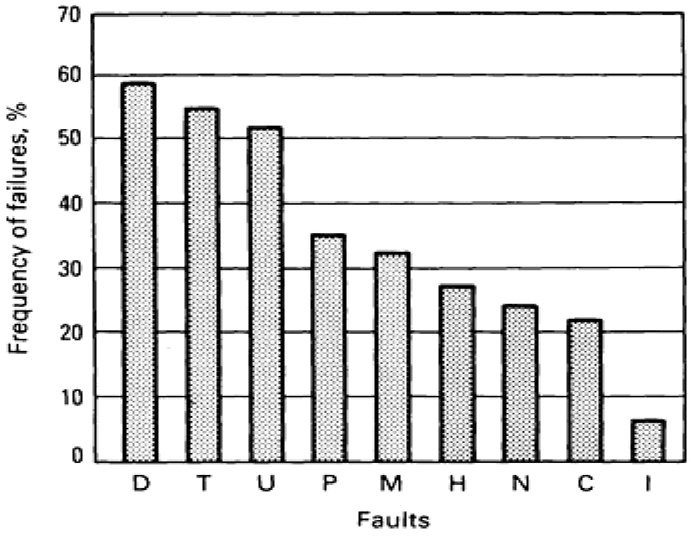

Fig. 1 Results of a survey of causes of failure in the chemical-processing industry showing that plant design faults (D) were the most frequently cited cause of failure. Other causes: T, incorrect application of protective

treatment; U, unforeseen operating conditions; P, poor process control; M, materials faults; H, human errors; N, lack of awareness of corrosion risk; C, contamination of product; I, instrument failure. Source: Ref 4

Why Failures Occur

In the context of design, there are several areas that relate to material/component failure:

- *Overload* suggests a weakness in plant control instrumentation or operation
- *Abnormal conditions* can result from a lack of process control or variations in raw material
- *Poor fabrication* may relate to inadequate instructions or inspection, for example, excessive cold work, overmachining, and excessive torque loading
- *Poor handling.* Scratches or machine marks can result from poor detailing or instruction
- *Assembly,* if incorrect (for example, welds and fastening) can seriously affect stress, flow, and compatibility
- *Storage and transportation* can be significant for many ultimate applications. Some structures or components may not be accessible for remedial work even if a corrosion risk is recognized. Proper design should accommodate these aspects of material handling.

Design Function

Good engineering design attempts to provide a product that satisfies the user and is profitable to the manufacturer and the distributor. The objective is a maximum return on capital expended in the shortest return period.

Optimum designs are a direct function of the limits of an organization, the available resources, equipment, manpower, and the experience and expertise of the designer. It is necessary to be aware of specifications and working codes of practice and to recognize that quality control and assurance procedures are basic to reliability and therefore to efficiency and safety.

Corrosion control by design is not necessarily effective for the variety of factors described above. Corrosion data must be interpreted carefully and must be relevant to plant or process conditions. The designer is in the most effective and logical position to provide ideal and realistic options. Versed in technical, political, and economic strategies, the designer can achieve most of the total requirements of design. In reality, there must be a systematic approach involving direct input from multidisciplinary sources. The communication channels include not only the design stage and operation but also failure analysis and monitoring of maintenance procedures.

Design and Materials Selection

Materials are selected to perform a basic function or to provide a functional requirement (see article "Materials Selection" in this Volume). Therefore, in many cases, a corrosion-resistant alloy or metal may not satisfy such primary requirements as strength, reflectivity, wear resistance, and dimensional stability. Tungsten, for example, may be a strong, high melting point metal, but its impact properties make it delicate for handling. Furthermore, any temperature excursion would render the material nonresistant to oxidation, because the products that form above about 750 °C (1380 °F) are loose and powdery.

Corrosion data sources tend to overemphasize chemical properties and make less reference to those parameters that affect material suitability for a particular service condition. Some of these are given in Table 1.

Table 1 Functional requirements of materials

Characteristic	Functional requirements
Strength under actual service conditions	**Tensile strength; strength in torsion, compression, shear, etc.**
Toughness	**Ability to cope with an overload, impact, etc.**
Dimensional stability	**Practical assembly; stiffness of structure; effect of sustained loading, etc.**
Wear and abrasion	**Lubrication or low friction; loss of surface products (passive films) of benefit in corrosion control**
Physical properties	**Design may require certain properties peculiar to the material (thermal, electrical, acoustic, optical, magnetic, etc.)**
Machinability	**Related to mechanical properties; notches, work hardening, scratches, etc.**

Design Details

The following sections will demonstrate the aspects of design detail that may accelerate corrosion (Ref 5).

Shape. Geometrical form is basic to design. The objective is to minimize or avoid situations that worsen corrosion. These situations can range from stagnation (for example, retained fluids and/or solids) to sustained fluid flow (for example, erosion/cavitation in components moving in or contacted by fluids as well as splashing or droplet impingement).

Common examples of stagnation include nondraining structures, dead ends, badly located components, and poor assembly or maintenance practices (Fig. 2). The general problems include localized corrosion associated with differential aeration (oxygen concentration cells), crevice corrosion, and deposit corrosion.

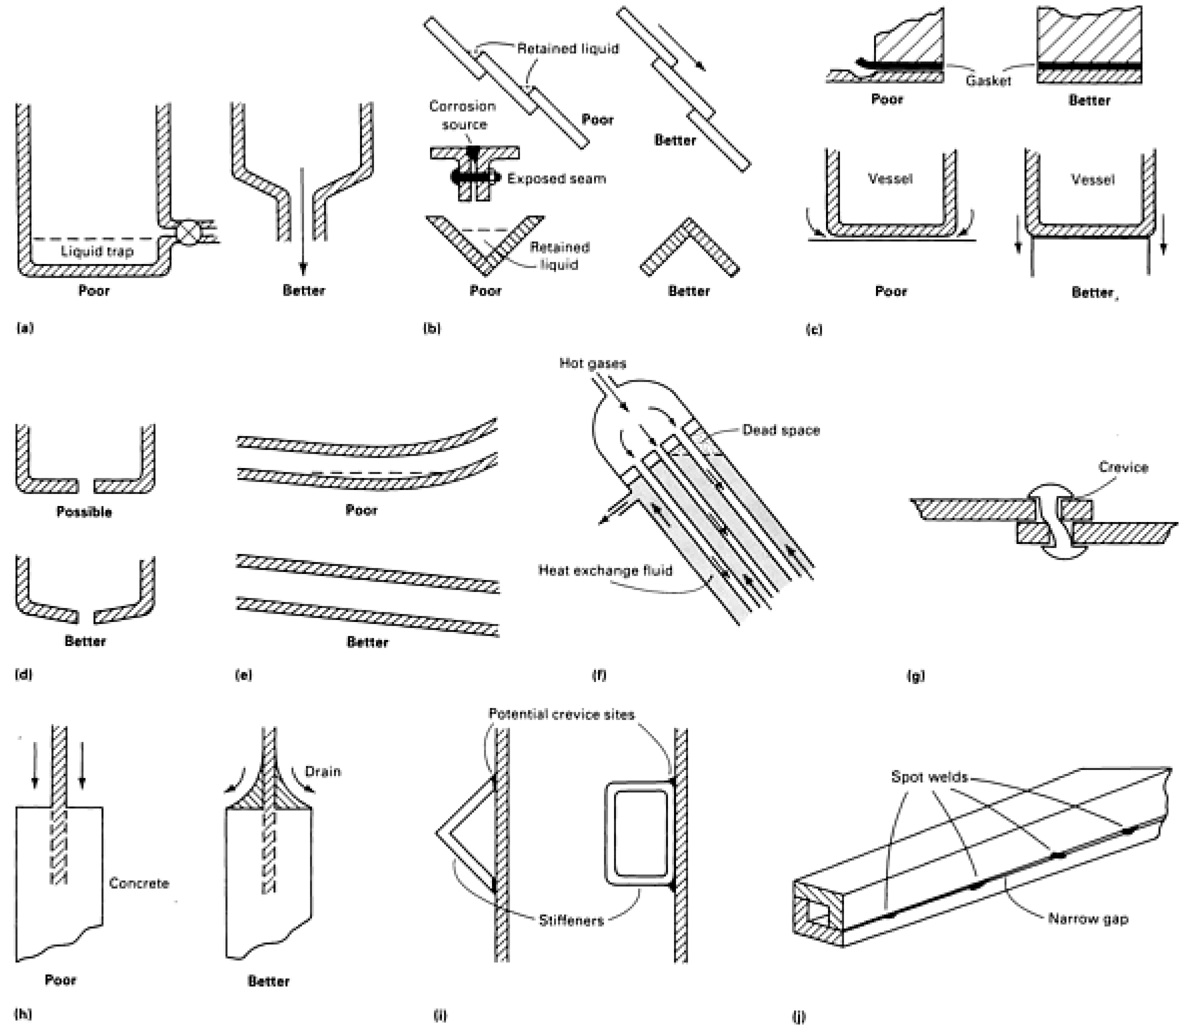

Fig. 2 Examples of how design and assembly can affect localized corrosion by creating crevices and traps where corrosive liquids can accumulate. (a) Storage containers or vessels should allow complete drainage; otherwise, corrosive species can concentrate in bottom of vessel, and debris may accumulate if the vessel is open to the atmosphere. (b) Structural members should be designed to avoid retention of liquids; L-shaped sections should be used with the open side down, and exposed seams should be avoided. (c) Incorrect trimming or poor design of seals and gaskets can create crevice sites. (d) Drain valves should be designed with sloping bottoms to avoid pitting of the base of the valve. (e) Nonhorizontal tubing can leave pools of liquid at shutdown. (f) to (j) Examples of poor assembly that can lead to premature corrosion problems. (f) Nonvertical assembly of heat exchanger permits a dead space that may result in overheating if very hot gases are involved. (g) Nonaligned assembly distorts the fastener, which creates a crevice and may result in a loose fitting that can contribute to vibration, fretting, and wear. (h) Structural supports should allow good drainage; use of a slope at the bottom of the member allows liquid to run off, rather than impinging directly on the concrete support. (i) Continuous welding is necessary for horizontal stiffeners to prevent the formation of traps and crevices. (j) Square sections formed from two L-shaped members require continuous welding to seal out the external environment.

Fluid movement need not be excessive to damage a material. Much depends on the nature of the fluid and the hardness of the material. A geometric shape may create a sustained delivery of fluid or may locally disturb a laminar stream and lead to turbulence. Replaceable baffle plates or deflectors are beneficial where circumstances permit their use. They effectively resolve the problem of impingement damage to the structurally significant component.

Careful fabrication with inspection will alleviate the effects of such factors as poor profiles (welding, bolting), rubbing surfaces (wear, fretting), and galvanic effects due to incompatible assembly of components. Figure 3 shows typical situations in which geometric detail is significant to flow.

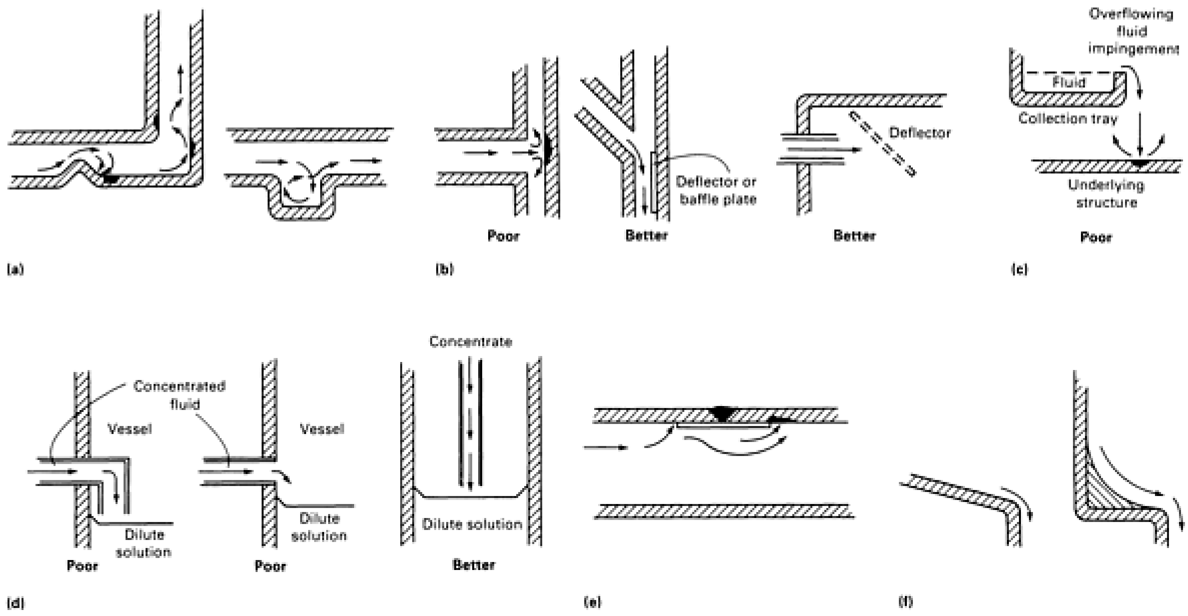

Fig. 3 Effect of design features on flow. (a) Disturbances to flow can create turbulence and cause impingement damage. (b) Direct impingement should be avoided; deflectors or baffle plates can be beneficial. (c) Impingement from fluid overflowing from a collection tray can be avoided by relocating the structure, by increasing the depth of the tray, or by using a deflector. (d) Splashing of concentrated fluid on container walls should be avoided. (e) Weld backing plates or rings can create local turbulence and crevices. (f) Slopes or modified profiles should be provided to permit flow and minimize fluid retention.

Accessibility may become important in cases in which shape could have been better considered at the design stage. Common engineering structural steelwork requires regular preventive maintenance, and access may often be restricted. Figure 4 shows situations in which surface cleaning and/or painting is difficult or impossible. Condensation in critical areas may also contribute to corrosion. Typical structures susceptible to this phenomenon include chimneys or exhausts to high-temperature plants, boilers, or incinerators.

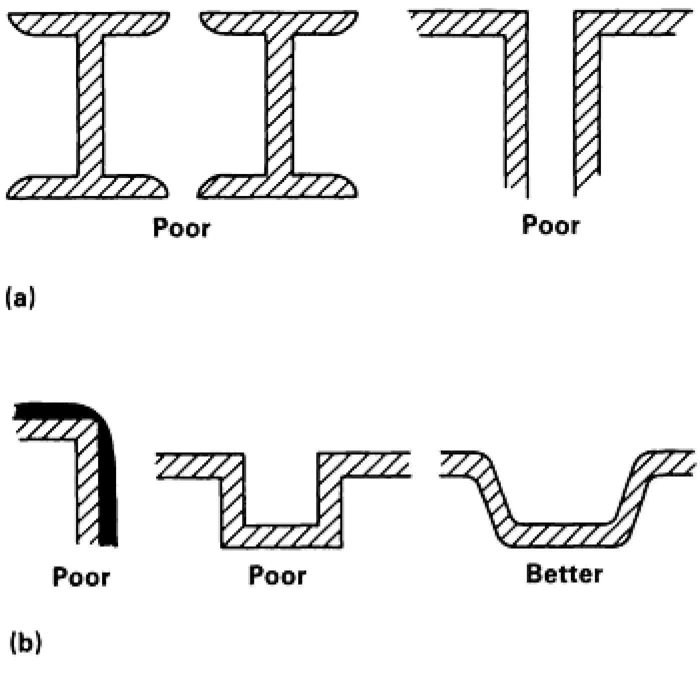

Fig. 4 Effects of design on cleaning or painting of equipment. (a) Poor access in certain structures makes surface preparation and painting difficult; access to the types of areas shown should be maintained at a minimum of 45 mm ($1\frac{3}{4}$ in.) or one-third of the height of the structure. (b) Sharp corners and profiles should be avoided if the structure is to be painted or coated.

Site location relative to winds and airborne particulates can lead to adverse deterioration of structures. The significance of pollution and the synergistic efforts on corrosion are illustrated in Fig. 5, which demonstrates poor layout relative to geographic topography. Design geometries that leave structures exposed to the elements should be carefully reviewed because atmospheric corrosion is significantly affected by temperature, relative humidity, rainfall, and pollutants. Also related to this aspect are the date and location of on-site fabrication, assembly, and painting. Codes of practice must be adapted to the location and the season.

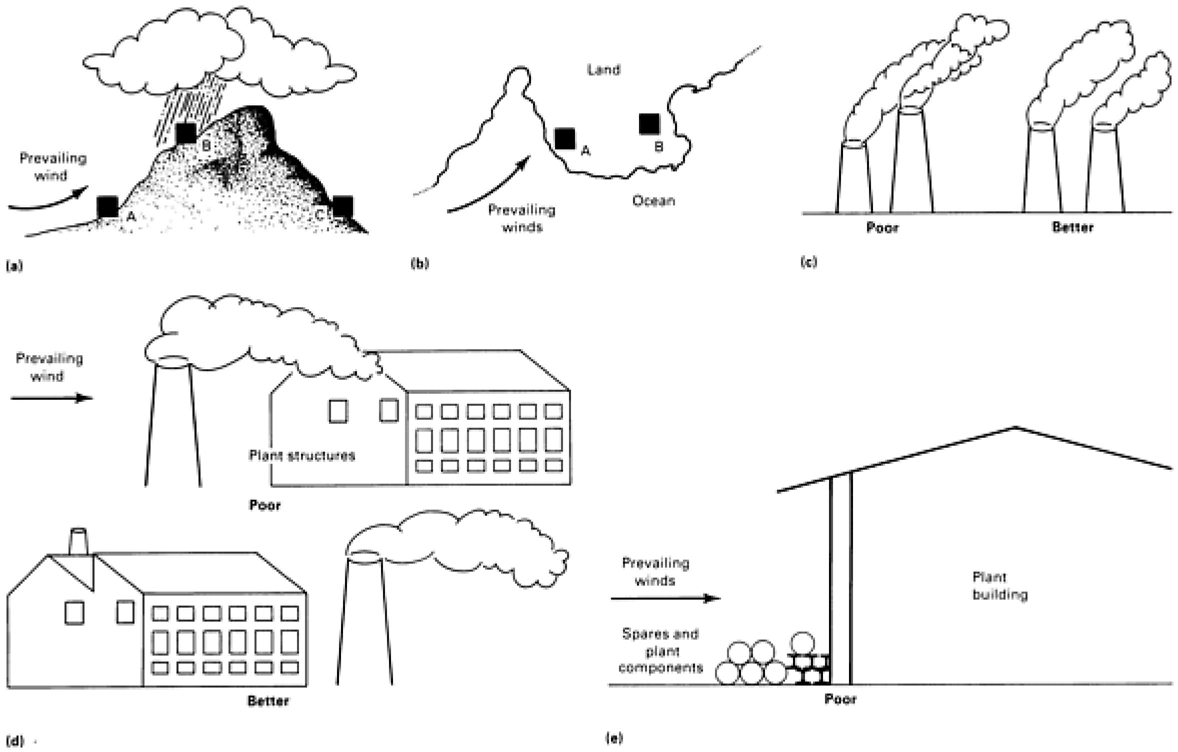

Fig. 5 Site location as a design consideration. (a) Topographic features must be considered in choosing a site. Location C would be the preferred site. (b) In marine atmospheres, prevailing winds should be taken into account; location B is the preferred site. (c) Local industry can affect corrosion of chimney stacks and similar structures. "Lick-over" of gases, which relates to stack height, location, and prevailing winds, should be avoided. (d) Plant structures should be located upwind from stacks. (e) spares and components should be stored away from the prevailing wind.

Insulation represents another area for potential corrosion attack, although the form and requirements for insulating media differ considerably. Moisture-absorbing tendencies will vary, as will the extent of crevicing from compaction and shrinkage or chloride buildup for certain materials. Wet-dry cycling can lead to concentration effects that may result in stress-corrosion cracking (SCC) of certain stainless steels or pitting on other materials, such as aluminum, that contact the insulation barriers. Figure 6 shows some typical examples in which design and installation procedures could have been improved.

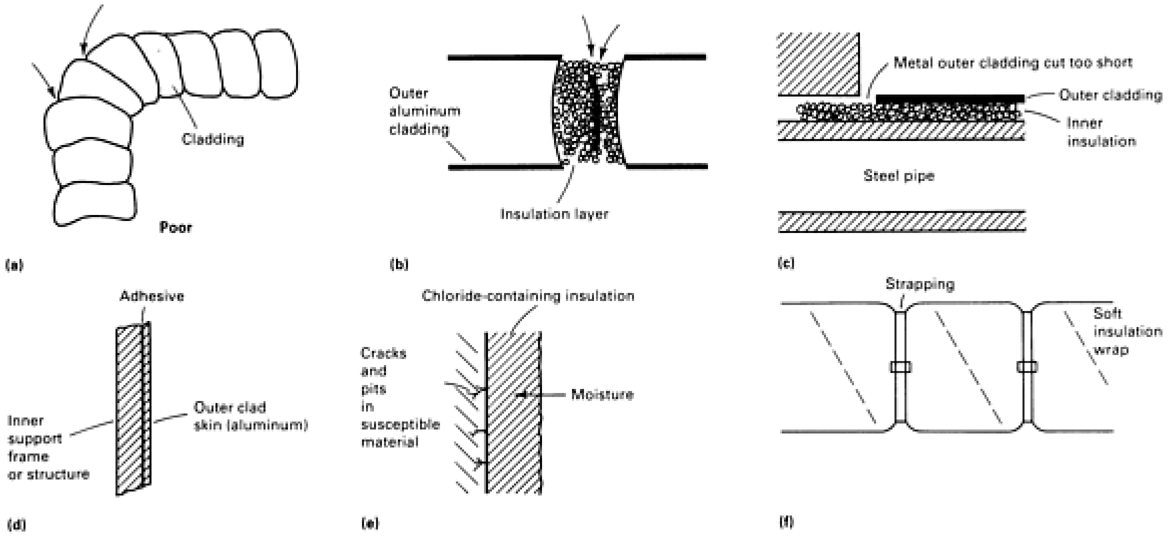

Fig. 6 Corrosion problems associated with improper use of insulation and lagging. (a) Incorrect overlap in lobster-back cladding does not allow fluid runoff. (b) Poor installation left a gap in the insulation that allows easy access to the elements. (c) Outer metal cladding was cut too short, leaving a gap with the inner insulation exposed. (d) Poor or noncontinuous contact of adhesives can lead to a crevice or capillary entry of fluid; also, adhesives may not have sealing properties. (e) Insufficient insulation may allow water to enter; chloride in some insulation can result in pitting or SCC of susceptible materials. (f) Overtightened strapping can damage the insulation layer.

Compatibility. In plant environments, it is often necessary to use different materials in close proximity. Direct contact of dissimilar metals introduces the possibility of galvanic corrosion, and small anode areas should be avoided wherever this is apparent (see the section "Galvanic Corrosion" of the article "General Corrosion" in this Volume). Components that perhaps were designed in isolation may end up in direct contact in the plant. In such cases, the ideals of a total design concept become especially apparent in hindsight.

Galvanic corrosion resulting from metallurgical sources is well documented. Problems such as weld decay and sensitization can generally be avoided by material selection or suitable fabrication techniques. Less obvious instances include end-grain attack and stray-current effects, which can render designs ineffective.

Designers, when aware of compatibility effects, need to exercise their ingenuity to minimize the conditions that most favor galvanic corrosion (Ref 1). Table 2 provides some relevant parameters in this context.

Table 2 Galvanic corrosion sources and design considerations

Source	Design considerations
Metallurgical sources (both within the metal and for relative contact between dissimilar metals)	**Difference in potential of dissimilar materials; distance apart; relative areas of anode and cathode; geometry (fluid retention); mechanical factors (for example, cold work, plastic deformation, sensitization)**
Environmental sources	**Conductivity and resistivity of fluid; changes in temperature; velocity and direction of fluid flow; aeration; ambient environment (seasonal changes, etc.)**
Miscellaneous sources	**Stray currents; conductive paths; composites (for example, concrete rebars)**

The most common design details relating to galvanic corrosion include jointed assemblies (Fig. 7). Where dissimilar metals are to be used, some consideration should be given to compatible materials known to have similar potentials (Ref 6) (for more information see the article "Materials Selection" and the Section "Specific Alloy Systems" in this Volume). Care should be exercised in that galvanic series are limited and refer to specific environments. The confusion of terminology can also be problematic; such terms as mild steel, stainless steel, Hastelloy, and Inconel are too vague and do not provide sufficient assurance about material performance in a corrosive environment.

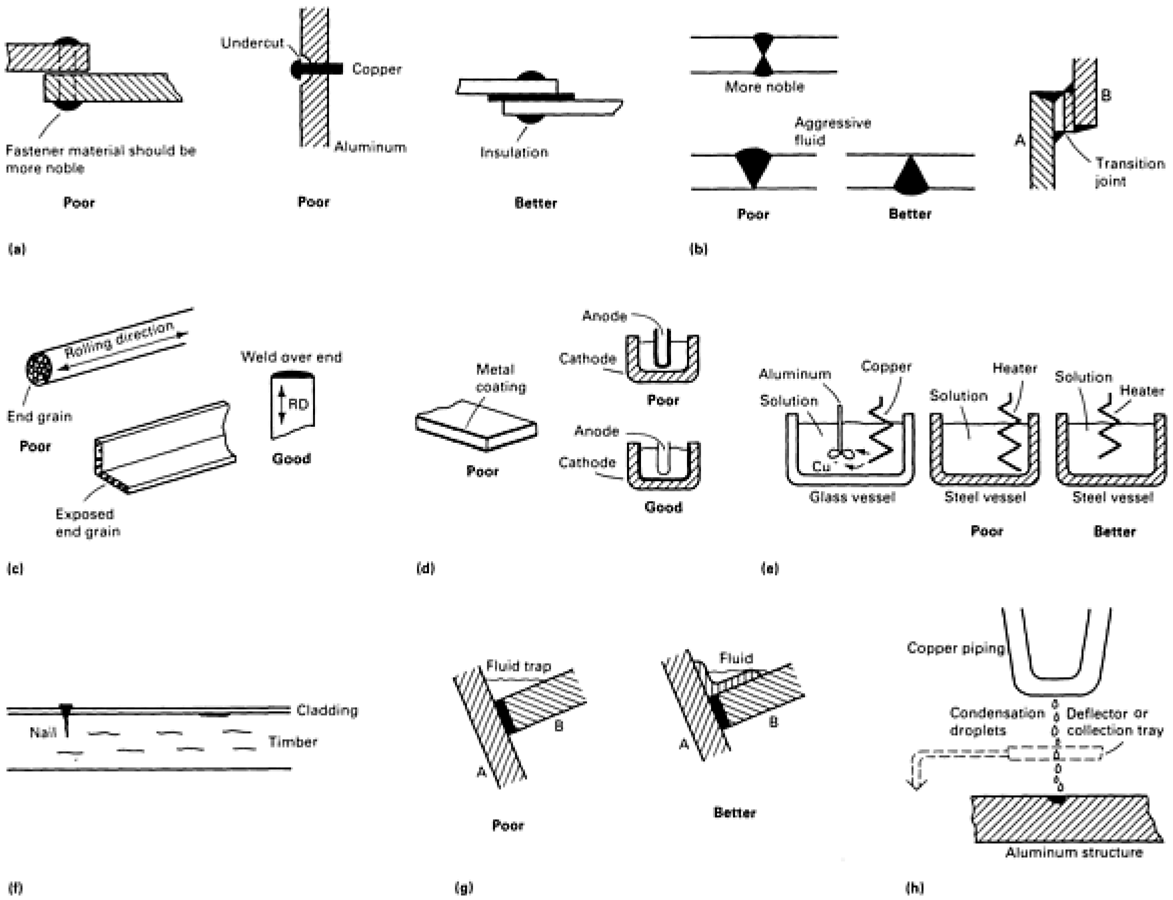

Fig. 7 Design details that can affect galvanic corrosion. (a) Fasteners should be more noble than the components being fastened; undercuts should be avoided, and insulating washers should be used. (b) Weld filler metals should also be more noble than base metals. Transition joints can be used when a galvanic couple is anticipated at the design stage, and weld beads should be properly oriented to minimize galvanic effects. (c) Local damage can result from cuts across heavily worked areas. End grains should not be left exposed. (d) Galvanic corrosion is possible if a coated component is cut. When necessary, the cathodic component of a couple should be coated. (e) Ion transfer through a fluid can result in galvanic attack of less noble metals. In the example shown at left, Cu^+ ions from the copper heater coil could deposit on the aluminum stirrer. A nonmetallic stirrer may be necessary. At right, the distance from a metal container to a heater coil should be increased to minimize ion transfer. (f) Wood with copper preservatives can be corrosive to certain nails, especially those with nobility different from that of copper. Aluminum cladding may also be at risk. (g) Contact of two metals through a fluid trap can be avoided by using an extended seal, mastic, or a coating. (h) Condensation droplets from copper piping can impinge on an underlying aluminum structure; such contact can be avoided by the use of collection trays or deflectors.

Where noncompatible materials are to be joined, it is necessary to use a more noble metal in a joint (Fig. 7). Effective insulation can be useful if it does not introduce crevice corrosion possibilities. Some difficulties arise in the use of adhesives, which may not be sealants.

The relative surface areas of anodic and cathodic surfaces should not be underestimated, because instances of corrosion failure may result from a combination of galvanic and crevice attack. Corrosion in a small anodic zone can be several

hundred times greater than that in similar bimetallic components of similar area. Anodic components may on occasion be overdesigned (thicker) to allow for the anticipated corrosion loss. In other cases, easy replacement is a cost-effective option, given an awareness by the designer of such information.

Where metallic coatings are used, there is always a risk of galvanic corrosion, especially along the cut edges. Rounded profiles and effective sealants or coatings can be beneficial. Transition joints can be introduced when different metals will be in close proximity. These and other situations are illustrated in Fig. 7. Another aspect is the coating of the cathodic material for corrosion control. Ineffective painting of an anode in an assembly can significantly reduce the desired service lifetime because local defects will effectively multiply the risk of anodic sites and localized corrosion.

Mechanical Factors. Environments that promote metal dissolution can be considered more damaging if stresses are involved (see the section "Stress-Corrosion Cracking" of the article "Environmentally Induced Cracking" in this Volume). In such circumstances, materials may fail catastrophically and unexpectedly. Safety and health may be significantly affected.

Figure 8 shows cases in which design detail is used to minimize stress. Perfection is rarely attained in general practice, and some compromise on materials limitations, both chemical and mechanical, is necessary. The difficulty is that mechanical fault can contribute to corrosion and that corrosion (as a corrosive environment) can initiate or cause mechanical failure. Quality control and assurance can eliminate the former.

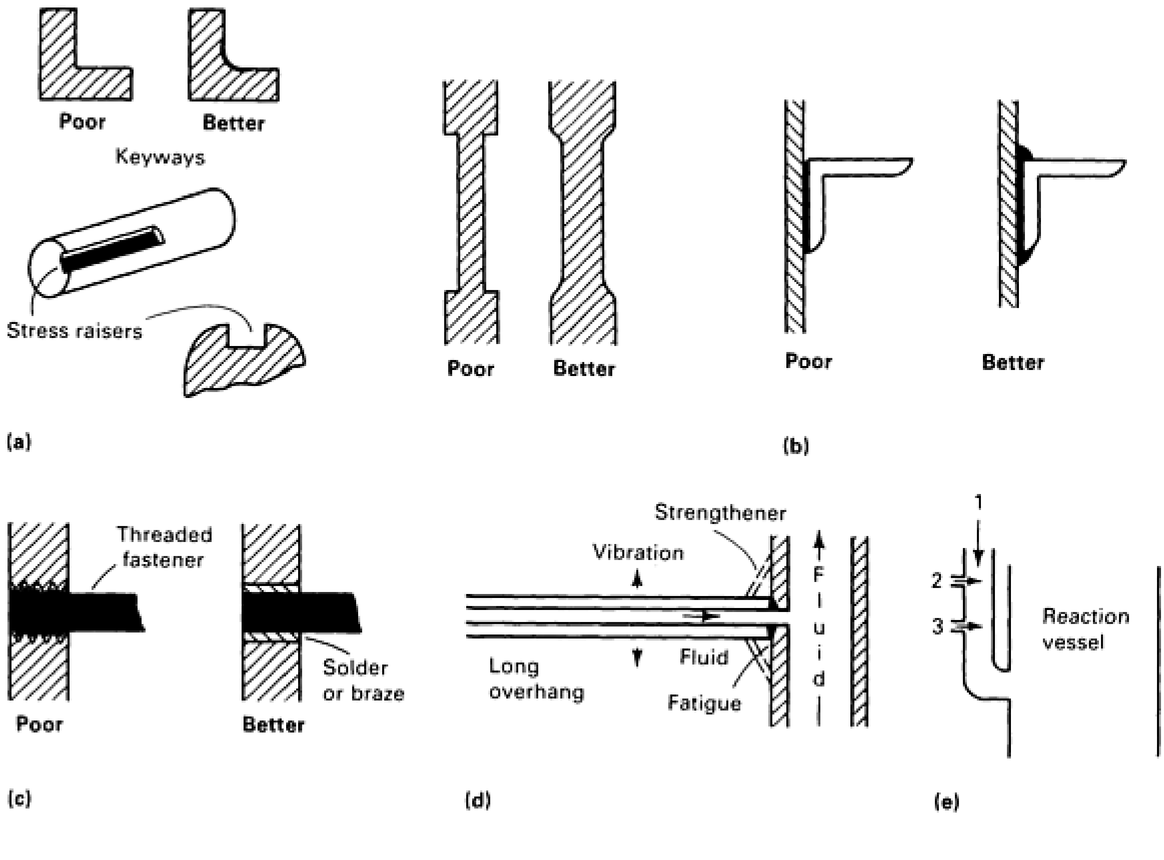

Fig. 8 Design details that can minimize local stress concentrations. (a) Corners should be given a generous radius. (b) Welds should be continuous to minimize sharp contours. (c) Sharp profiles can be avoided by using alternative fastening systems. (d) Too long of an overhang without support can lead to fatigue at the junction. Flexible hose may help alleviate this situation. (e) Side-supply pipework may be too rigid to sustain thermal shock from air under pressure (1), steam (2), and cold water in sequence (3).

Designs that introduce local stress concentrations directly or as a consequence of fabrication should be carefully considered. Of particular importance are stress levels for the selected material; the influence of tensile, compressive, or shear stressing; alternating stresses; vibration or shock loading; service temperatures (thermal stressing); fatigue; and

wear (fretting, friction). Profiles and shapes contribute to stress-related corrosion if material selection dictates the use of materials susceptible to failure by SCC or corrosion fatigue.

Materials selection is especially important wherever critical components are used. Also important is the need for correct procedures at all stages of operation, including fabrication, transport, startup, shutdown, and normal operation. Less obvious cases of failure can arise from vibration transfer, poor surface finish, nonuniform application of surface coatings, or the application of coatings to poorly prepared surfaces.

Surfaces. Corrosion is a surface phenomenon, and the effects of poorly prepared surfaces, rough textures, and complex shapes and profiles can be expected to be deleterious. Figure 4 shows some examples in which design specification could have considerably reduced the onset of corrosive damage. Design limitations include surfaces exposed to deposits, retained soluble salts (because of poor access for preparation before painting), nondraining assemblies, poorly handled components (distortion, scratches, dents), and poorly located components (relative position to adjacent equipment, and so on).

Painting and surface-coating technology have advanced in recent years and have provided sophisticated products that require careful mixing and application. Maintenance procedures frequently require field application; in such cases, control is not anticipated. This is significant, for example, in the offshore locations of the oil and gas industry. Inspection codes and procedures are necessary, and total design should incorporate these wherever possible. In critical areas, design for on-line monitoring and inspection will also be important. The human factor in such procedures is often overlooked. The need for better techniques, standardization, and mechanization or full automation has been stated, and adequate training and motivation are of primary importance. Reporting and assessment may sometimes be inaccurate (Ref 7).

Corrosion of Weldments

The ASM Committee on Corrosion of Weldments

Introduction

IT IS NOT UNUSUAL to find that, although the wrought form of a metal or alloy is resistant to corrosion in a particular environment, the welded counterpart is not. Further, welds can be made with the addition of filler metal or can be made autogenously (without filler metal). However, there are also many instances in which the weld exhibits corrosion resistance superior to that of the unwelded base metal. There also are times when the weld behaves in an erratic manner, displaying both resistance and susceptibility to corrosive attack. Corrosion failures of welds occur in spite of the fact that the proper base metal and filler metal have been selected, industry codes and standards have been followed, and welds have been deposited that possess full weld penetration and have proper shape and contour.

It is sometimes difficult to determine why welds corrode; however, one or more of the following factors often are implicated:

- Weldment design
- Fabrication technique
- Welding practice
- Welding sequence
- Moisture contamination
- Organic or inorganic chemical species
- Oxide film and scale
- Weld slag and spatter
- Incomplete weld penetration or fusion
- Porosity
- Cracks (crevices)
- High residual stresses
- Improper choice of filler metal
- Final surface finish

Metallurgical Factors

The cycle of heating and cooling that occurs during the welding process affects the microstructure and surface composition of welds and adjacent base metal. Consequently, the corrosion resistance of autogenous welds and welds made with matching filler metal may be inferior to that of properly annealed base metal because of:

- Microsegregation
- Precipitation of secondary phases
- Formation of unmixed zones
- Recrystallization and grain growth in the weld heat-affected zone (HAZ)
- Volatilization of alloying elements from the molten weld pool
- Contamination of the solidifying weld pool

Corrosion resistance can usually be maintained in the welded condition by balancing alloy compositions to inhibit certain precipitation reactions, by shielding molten and hot metal surfaces from reactive gases in the weld environment, by removing chromium-enriched oxides and chromium-depleted base metal from thermally discolored (heat tinted) surfaces, and by choosing the proper welding parameters (Ref 1).

Weld Solidification. During the welding process, a number of important changes occur that can significantly affect the corrosion behavior of the weldment. Heat input and welder technique obviously play important roles. The way in which the weld solidifies is equally important to understanding how weldments may behave in corrosive environments (Ref 2).

A metallographic study has shown that welds solidify into various regions, as illustrated in Fig. 1. The composite region, or weld nugget, consists of essentially filler metal that has been diluted with material melted from the surrounding base metal. Next to the composite region is the unmixed zone, a zone of base metal that melted and solidified during welding without experiencing mechanical mixing with the filler metal. The weld interface is the surface bounding the region within which complete melting was experienced during welding, and it is evidenced by the presence of a cast structure. Beyond the weld interface is the partially melted zone, which is a region of the base metal within which the proportion melted ranges from 0 to 100%. Lastly, the true HAZ is that portion of the base metal within which microstructural change has occurred in the absence of melting. Although the various regions of a weldment shown in Fig. 1 are for a single-pass weld, similar solidification patterns and compositional differences can be expected to occur in underlying weld beads during multipass applications.

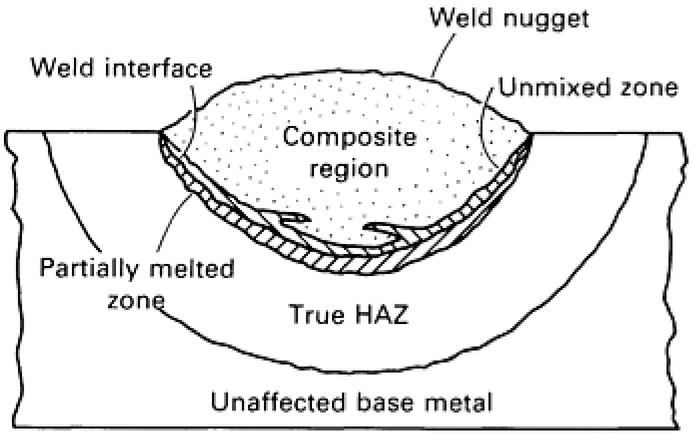

Fig. 1 Schematic of a weld cross section. Source: Ref 3

Corrosion of Aluminum Alloy Weldments

Variations in microstructure across the weld and HAZ of aluminum weldments are known to produce susceptibility to corrosion in certain environments (Ref 4). These differences can be measured electrochemically and are an indication of the type of corrosion behavior that might be expected. Although some aluminum alloys can be autogenously welded, the use of a filler metal is preferred to avoid cracking during welding and to optimize corrosion resistance.

The variations in corrosion potential (equilibrium potential) across three welds are shown in Fig. 2 for alloys 5456, 2219, and 7039. These differences can lead to localized corrosion, as demonstrated by the corrosion of the HAZ of an as-welded structure of alloy 7005 shown in Fig. 3. In general, the welding procedure that puts the least amount of heat into the metal has the least influence on microstructure and the least chance of reducing the corrosion behavior of aluminum weldments.

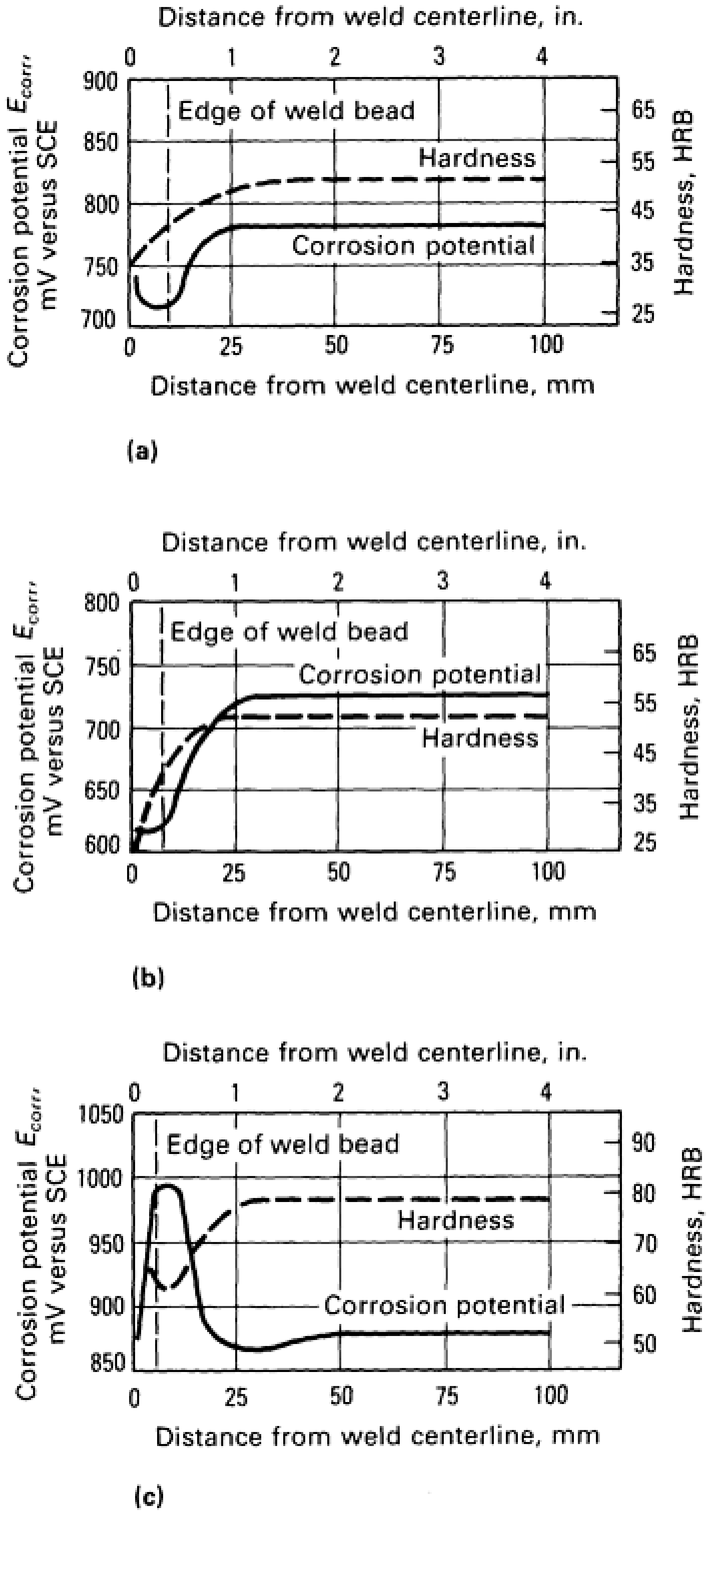

Fig. 2 Effect of the heat of welding on microstructure, hardness, and corrosion potential of welded assemblies of three aluminum alloys. The differences in corrosion potential between the HAZ and the base metal can lead to selective corrosion. (a) Alloy 5456-H321 base metal with alloy 5556 filler; 3-pass metal inert gas weld. (b) Alloy 2219-T87 base metal with alloy 2319 filler; 2-pass tungsten inert gas weld. (c) Alloy 7039-T651 base metal with alloy 5183 filler; 2-pass tungsten inert gas weld. Source: Ref 4

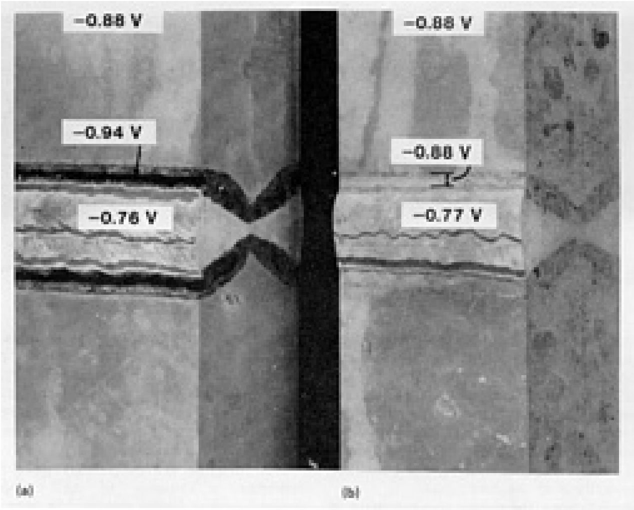

Fig. 3 Welded assemblies of aluminum alloy 7005 with alloy 5356 filler metal after a 1-year exposure to seawater. (a) As-welded assembly shows severe localized corrosion in the HAZ. (b) Specimen showing the beneficial effects of postweld aging. Corrosion potentials of different areas of the weldments are shown where they were measured. Electrochemical measurements performed in 53 g/L NaCl plus 3 g/L H_2O_2 versus a 0.1 *N* calomel reference electrode and recalculated to a saturated calomel electrode (SCE). Source: Ref 4

Tables are available in Ref 4 that summarize filler alloy selection recommended for welding various combinations of base metal alloys to obtain maximum properties, including corrosion resistance. Care must be taken not to extrapolate the corrosion performance ratings indiscriminately. Corrosion behavior ratings generally pertain only to the particular environment tested, usually rated in continuous or alternate immersion in fresh or salt water. For example, the highest corrosion rating (A) is listed for use of filler alloy 4043 to join 3003 alloy to 6061 alloy. In strong (99%) nitric acid (HNO_3) service, however, a weldment made with 4043 filler alloy would experience more rapid attack than a weldment made using 5556 filler metal. With certain alloys, particularly those of the heat-treatable 7*xxx* series, thermal treatment after welding is sometimes used to obtain maximum corrosion resistance (Fig. 3) (Ref 5, 6, 7).

As with many other alloy systems, attention must be given to the threat of crevice corrosion under certain conditions. Strong (99%) HNO_3 is particularly aggressive toward weldments that are not made with full weld penetration. Although all of the welds shown in Fig. 4 appear to be in excellent condition when viewed from the outside surface, the first two welds (Fig. 4a and b), viewed from the inside, are severely corroded. The weld made using standard gas tungsten arc (GTA) welding practices with full weld penetration (Fig. 4c) is in good condition after 2 years of continuous service.

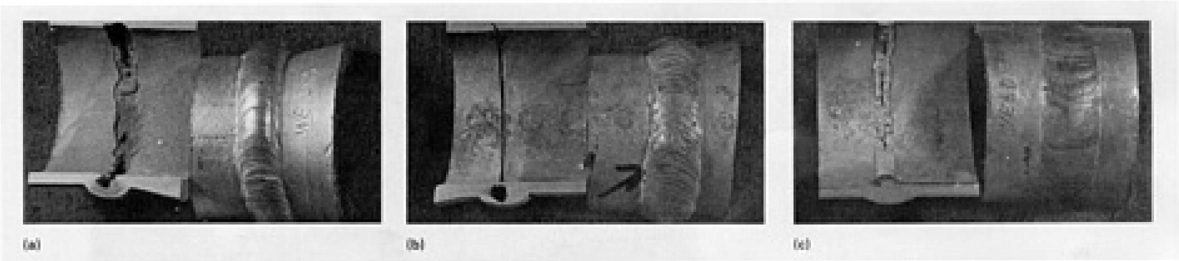

Fig. 4 Corrosion of three aluminum weldments in HNO_3 service. (a) and (b) GTA and oxyacetylene welds, respectively, showing crevice corrosion on the inside surface. (c) Standard GTA weld with full penetration is resistant to crevice corrosion.

Researchers have shown that aluminum alloys, both welded and unwelded, have good resistance to uninhibited HNO_3 (both red and white) up to 50 °C (120 °F). Above this temperature, most aluminum alloys exhibit knife-line attack (a very thin region of corrosion) adjacent to the welds. Above 50 °C (120 °F), the depth of knife-line attack increases markedly

with temperature. One exception was found in the case of a fusion-welded 1060 alloy in which no knife-line attack was observed even at temperatures as high as 70 °C (160 °F). In inhibited fuming HNO_3 containing at least 0.1% hydrofluoric acid (HF), no knife-line attack was observed for any commercial aluminum alloy or weldment even at 70 °C (160 °F).

More information on the welding of aluminum and aluminum alloys is available in the articles "Welding of Aluminum Alloys" and "Procedure Development and Practice Considerations for Resistance Welding" in *Welding, Brazing, and Soldering*, Volume 6 of the *ASM Handbook.* The corrosion of these materials is discussed in detail in the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume.

Corrosion of Tantalum and Tantalum Alloy Weldments

Examination of equipment fabricated from tantalum that has been used in a wide variety of service conditions and environments generally shows that the weld, HAZ, and base metal display equal resistance to corrosion. This same resistance has also been demonstrated in laboratory corrosion tests conducted in a number of different acids and other environments. However, in applications for tantalum-lined equipment, contamination of the tantalum with iron from underlying backing material, usually carbon steel, can severely impair the corrosion resistance of tantalum. About the only known reagents that rapidly attack tantalum are fluorine; HF and acidic solutions containing fluoride; fuming sulfuric acid (H_2SO_4) (oleum), which contains free sulfur trioxide (SO_3); and alkaline solutions.

An exception to the generalization that base metal and weldments in tantalum show the same corrosion resistance under aggressive media is discussed in the following example. Because tantalum is a reactive metal, the pickup of interstitial elements, such as oxygen, nitrogen, hydrogen, and carbon, during welding can have a damaging effect on a refractory metal such as tantalum.

Preferential Pitting of a Tantalum Alloy Weldment in H_2SO_4 Service. A 76-mm (3-in.) diameter tantalum alloy tee removed from the bottom of an H_2SO_4 absorber that visually showed areas of severe etching attack was examined. The absorber had operated over a period of several months, during which time about 11,400 kg (25,000 lb) of H_2SO_4 was handled. The absorber was operated at 60 °C (140 °F) with nominally 98% H_2SO_4. There was a possibility that some of the H_2SO_4 fed into the process stream may have been essentially anhydrous or even in the oleum range. Oleum is known to attack tantalum very rapidly at temperatures only slightly higher than 60 °C (140 °F). In addition, the H_2SO_4 effluent was found to contain up to 5 ppm of fluoride.

Investigation. The materials in both the flange and the corrugated portion of the tee were verified by x-ray fluorescence to be Tantaloy "63" (Ta-2.5W-0.15Nb). Corrosive attack was visible to the unaided eye on the radius of the flange, on the first corrugation of the part and in two bands--one on each side of the GTA weld about 13 mm (0.5 in.) from the weld centerline and running the full length of the piece. Other areas of the part, such as the lip weld joining the corrugated tube section to the flange, other areas of the base metal away from the weld, and even the weld metal itself (including the adjacent HAZ), appeared on a cursory visual basis to be free from significant attack.

Stereo microexamination showed that the corrosive attack took the form of pitting. The areas of most severe attack that were observed were parallel to the longitudinal weld, circumferentially around the first corrugation of the part, and on the radius of the flange. Corrosion was characterized by a large number of closely occurring pits. What appeared to be markings resembling lines or scratches during an examination with the unaided eye were actually found at magnifications up to 30× to be rows of corrosion pits aligned in the longitudinal direction and parallel to the weld. However, fewer somewhat shallower pits were found generally over the entire part.

In some locations, the pitting was extensive in the weld metal, in the HAZ, and even in the base metal 180° away from the weld. The extent of pitting appeared to be most severe on the inside diameter at sites that had been abraded by the tool used in forming the corrugations and in some areas containing scratches. There was no noticeable corrosion anywhere on the outside of the part.

Metallographic examination showed classical corrosion pits that were nearly spherical in shape. The maximum pit depth observed was 0.06 mm (2.5 mils). Pits did not appear to be typical of erosion or impingement-type attack, because the pits did not show the typical undercutting or undermining. Pitting did not follow the grain boundaries. No cracks were found propagating from the base of the pits in any of the samples; therefore, there was no evidence of corrosion fatigue or stress-corrosion cracking (SCC).

A transverse section taken from another area of severe attack 13 mm (0.5 in.) from the weld metal was bent in the transverse direction with the inside diameter of the sample in tension. The sample was fully ductile; it was cold flattened 180° on itself with a sharp bend radius.

Conclusions. The corrosion on the tee was pitting that occurred generally over the entire part. Pitting was more severely concentrated parallel to the weld metal at a distance of 13 mm (0.5 in.) from the centerline of the weld (which was well outside the HAZ of the weld), on the radius of the flange, and on the first corrugation at the inlet. There was no evidence that the attack was due to cavitation erosion, corrosion fatigue, or SCC. The attack did not reduce the ductility of the material. All areas of the part were fully ductile, as evidenced by the soft, ductile nature of the part during sawing and cutting and by bend tests in the area of most severe attack.

The specific corrosion agents responsible were believed to be H_2SO_4 in the oleum concentration range in the presence of some fluoride ion (F^-). Corrosion tests and years of industrial experience with equipment indicate that in the absence of F^- (or free fluorine) and in H_2SO_4 concentrations of 98% and below such pitting attack does not occur on tantalum or Tantaloy "63" metal at 60 °C (140 °F).

Related Laboratory Experiments. Some laboratory experiments were performed on weldments of tantalum and Tantaloy "63" that may relate to and suggest why preferential corrosion attack was observed parallel to the longitudinal weld of the tee in Example 1 at locations considerably beyond the weld HAZ.

Gas tungsten arc butt welds were made in specimens of Tantaloy "63" and tantalum in a copper welding fixture operated in open air with an argon-flooded torch and trailing shield and with an argon flood on the backside of the root of the weld. Both materials showed surface oxidation parallel to the weld at about the location of the hold-down clamps of the welding fixture. The presence of this oxide film or heat-tint was revealed by electrolytically anodizing the samples in a dilute phosphoric acid (H_3PO_4) solution at 325 V. This film has been arbitrarily designated as a heat-tint oxide. The zone of oxidation could have occurred either by air leaking past the hold-down clamps and reacting with the hot tantalum at this location or by oxygen that may have been present in the welding atmosphere at this location. Heat-tint oxides were not noted on the weld metal or the HAZ. This is perhaps because these regions of the weld reached a much higher temperature--sufficiently high to volatilize oxygen from the tantalum weld metal and HAZ as tantalum suboxide (TaO).

The heat-tint oxide layer was removed from the welded specimens by swabbing with a strong pickling solution of HNO_3, HF, and H_2SO_4 before the samples were anodized. The heat-tint oxide layer, as well as the clear base metal, was found to be unaffected by aqua regia (3 parts concentrated HCI and 1 part concentrated HNO_3 by volume) after 6 h of exposure at 80 °C (175 °F).

During pickling in the HNO_3-HF-H_2SO_4 mixture, it was noted that the heat-tint oxide was attacked more rapidly than the weld metal, the HAZ, or the base metal outside of the thermally oxidized region. Such heat-tint oxide was often barely visible on the as-welded samples, appearing only as a slight yellowish tinge on the surface in many cases. However, minimal immersion (a few seconds) in the acid pickle revealed the heat-tinted area as whitish or grayish, hazy or smoky bands parallel to the weld. After the oxide was completely removed by pickling, either by swab pickling or by completely immersing the sample in an HF-containing medium, all parts of the sample appeared to corrode at approximately the same rate.

Therefore, the pitting observed at certain regions parallel to the welds was believed to be associated with the initial removal of the heat-tint oxide. Once the heat-tint oxide was removed, this selective attack no longer occurred, and corrosion was uniform.

Oxygen Tolerance of Tantalum Weldments. Tantalum reacts with oxygen, nitrogen, and hydrogen at elevated temperatures. The absorption of these interstitial elements, often called a gettering reaction, produces a sharp reduction in ductility and can cause embrittlement. This impairment in ductility (and also in notch toughness, as manifested by an increase in ductile-to-brittle transition temperature) can be considered a form of corrosion. The other Group Va refractory metals (niobium and vanadium) and the Group IVa reactive metals (titanium, zirconium, and hafnium) can also suffer similar attack.

An investigation was conducted to determine the approximate tolerances of tantalum and Tantaloy "63" weldments for oxygen contamination that may be permitted during fabrication or subsequent service. Weldments of the materials were doped with various amounts of oxygen added either by anodizing or by oxidation in air. This was followed by vacuum annealing treatments to diffuse the oxygen through the sample cross section. The oxygen concentration was monitored

principally by hardness tests. Hardness is generally believed to be a better indicator of the extent of interstitial contamination than chemical analysis, which is subject to scatter and inaccuracy because of sampling difficulty. Bend tests (at room and liquid argon temperatures) and room-temperature Olsen cup formability tests were conducted to determine the hardness levels at which the materials embrittled.

The results showed that weldments of both materials remain ductile when hardened by interstitial contamination by oxygen up to a Rockwell 30T hardness in the low 80s. Above this hardness, embrittlement may be expected. The hardness level at which embrittlement occurs is substantially above the typical maximum allowable hardness of 65 HR30T specified for Tantaloy "63" or the 50 HR30T for tantalum flat mill products. Thus, if the extent of interstitial contamination by oxygen (and/or nitrogen) is controlled so that these maximum allowable hardness limits are not exceeded, embrittlement of weldments should not occur.

On the basis of chemical composition, the maximum oxygen tolerance for tantalum weldments appears to be about 400 to 550 ppm; for Tantaloy "63" weldments, it is about 350 to 500 ppm. Although commercially pure tantalum exhibits a somewhat higher tolerance for oxygen (and total interstitial contamination) than Tantaloy "63", the latter material appears to have somewhat better resistance to oxidation; this tends to offset the advantage tantalum has of a higher allowable oxygen pickup before embrittlement occurs. It should be further emphasized that the results are based on the assumption that oxygen was believed to be distributed relatively uniformly throughout the cross section in all parts of the weldment. A locally high concentration, such as a high surface contamination of oxygen or nitrogen, could result in a severe loss in ductility and could possibly even produce embrittlement. Therefore, all handling, cleaning, and fabrication practices on tantalum and its alloys should avoid producing such surface contamination as well as gross contamination. The article "Corrosion of Tantalum" in this Volume gives more detailed information on the corrosion of tantalum and tantalum alloys.

Corrosion of Austenitic Stainless Steel Weldments

The corrosion problems commonly associated with welding of austenitic stainless steels are related to precipitation effects and chemical segregation. These problems can be eliminated or minimized through control of base metal metallurgy, control of the welding practice, and selection of the proper filler metal.

Preferential Attack Associated With Weld Metal Precipitates. In austenitic stainless steels, the principal weld metal precipitates are δ-ferrite, σ phase, and $M_{23}C_6$ carbides. Small amounts of M_6C carbide may also be present. Sigma phase is often used to describe a range of chromium- and molybdenum-rich precipitates, including χ and laves (η) phases. These phases may precipitate directly from weld metal, but are most readily formed from weld metal δ-ferrite in molybdenum-containing austenitic stainless steels.

The δ-ferrite transforms into brittle intermetallic phases, such as σ and χ at temperatures ranging from 500 to 850 °C (930 to 1560 °F) for σ and 650 to 950 °C (1200 to 1740 °F) for χ. The precipitation rate for σ and χ phases increases with the chromium and molybdenum contents. Continuous intergranular networks of σ phase reduce the toughness, ductility, and corrosion resistance of austenitic stainless steels.

It is extremely difficult to discriminate between fine particles of σ and χ phases by using conventional optical metallographic techniques; hence the designation σ/χ phase. The use of more sophisticated analytical techniques to identify either phase conclusively is usually not justified when assessing corrosion properties, because the precipitation of either phase depletes the surrounding matrix of crucial alloying elements. Grain-boundary regions that are depleted in chromium and/or molybdenum are likely sites for attack in oxidizing and chlorine-bearing solutions. The damage caused by preferential corrosion of alloy-depleted regions ranges from the loss of entire grains (grain dropping) to shallow pitting at localized sites, depending on the distribution and morphology of the intermetallic precipitate particles at grain boundaries.

Because these precipitates are usually chromium- and molybdenum-rich, they are generally more corrosion resistant than the surrounding austenite. However, there are some exceptions to this rule.

Preferential attack associated with δ-ferrite and σ can be a problem when a weldment is being used close to the limit of corrosion resistance in environments represented by three types of acidic media:

- Mildly reducing (for example, HCl)
- Borderline active-passive (for example, H_2SO_4)

- Highly oxidizing (for example, HNO_3)

Acid cleaning of AISI type 304 and 316 stainless steel black liquor evaporators in the pulp and paper industry with poorly inhibited HCl can lead to weld metal δ-ferrite attack (Fig. 5 and 6). Attack is avoided by adequate inhibition (short cleaning times with sufficient inhibitor at low enough temperature) and by specifying full-finished welded tubing (in which the δ-ferrite networks within the weld metal structure are altered by cold work and a recrystallizing anneal). The latter condition can easily be verified with laboratory HCl testing, and such a test can be specified when ordering welded tubular products.

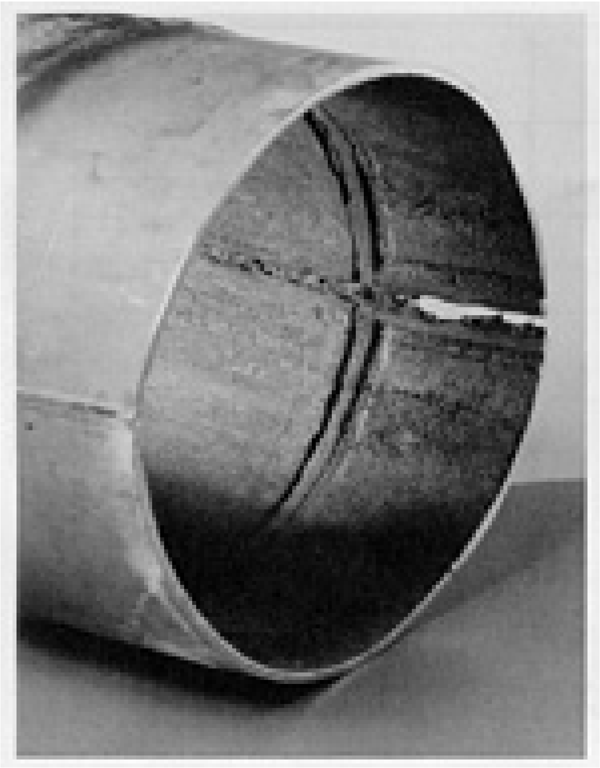

Fig. 5 Corroded type 316 stainless steel pipe from a black liquor evaporator. Two forms of attack are evident: preferential attack of the weld metal ferrite, suffered during HCl acid cleaning, and less severe attack in the sensitized HAZ (center). Source: Ref 8

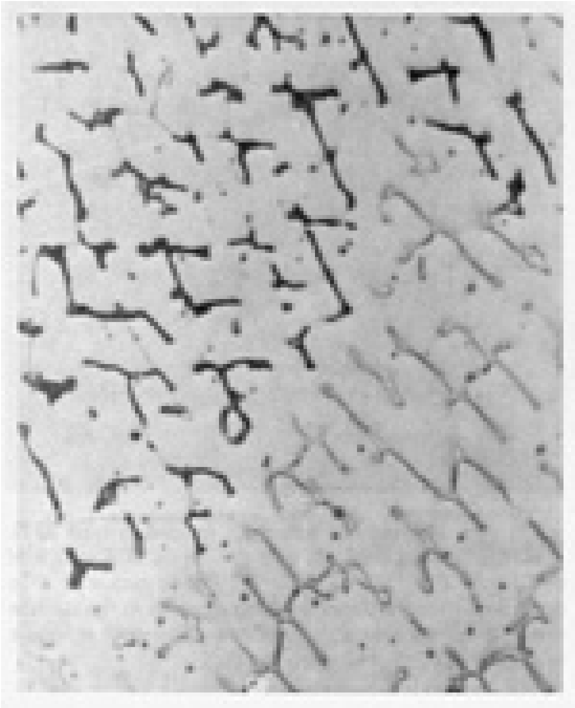

Fig. 6 Preferential corrosion of the vermicular ferrite phase in austenitic stainless steel weld metal. Discrete ferrite pools that are intact can be seen in the lower right; black areas in upper left are voids where ferrite has been attacked. Electrolytically etched with 10% ammonium persulfate. 500×. Source: Ref 9

Sulfuric acid attack of σ phase or of chromium- and molybdenum-depleted regions next to σ -phase precipitates is commonly reported, although it is difficult to predict because the strong influence of tramp oxidizing agents, such as ferric (Fe^{3+}) or cupric (Cu^{2+}) ions can inhibit preferential attack. Type 316L weld filler metal has been formulated with higher chromium and lower molybdenum to minimize σ-phase formation, and filler metals for alloys such as 904L are balanced to avoid δ-ferrite precipitation and thus minimize σ phase.

Highly oxidizing environments such as those found in bleach plants could conceivably attack δ-ferrite networks and σ phase. However, this mode of attack is not often a cause of failure, probably because free-corrosion potentials are generally lower (less oxidizing) than that required to initiate attack. Preferential attack of δ-ferrite in type 316L weld metal is most often reported after prolonged HNO_3 exposure, as in nuclear fuel reprocessing or urea production. For these applications, a low corrosion rate in the Huey test (ASTM A 262, practice C) is specified (Ref 10).

Pitting Corrosion. Under moderately oxidizing conditions, such as a bleach plant, weld metal austenite may suffer preferential pitting in alloy-depleted regions. This attack is independent of any weld metal precipitation and is a consequence of microsegregation or coring in weld metal dendrites. Preferential pitting is more likely in autogenous (no filler) GTA welds (Fig. 7), in 4 to 6% Mo alloys (Table 1), when the recommended filler metal has the same composition as the base metal (Fig. 8), and when higher heat input welding leaves a coarse microstructure with surface-lying dendrites (Fig. 9). Such a microstructure is avoided by use of a suitably alloyed filler metal (Fig. 8).

	Fox CN 20 25 M, IN-112, Avesta P12, Hastelloy alloy C-276
Avesta 254 SMO	**Avesta P12, IN-112, Hastelloy alloy C-276**

Even when suitable fillers are used, preferential pitting attack can still occur in an unmixed zone of weld metal. High heat input welding can leave bands of melted base metal close to the fusion line. The effect of these bands on corrosion resistance can be minimized by welding techniques that bury unmixed zones beneath the surface of the weldment.

When the wrong filler metal is used, pitting corrosion can readily occur in some environments. In the example shown in Fig. 10, the type 316L base metal was welded with a lower-alloy filler metal (type 308L). Tap water was the major environmental constituent contributing to crust formation on the weld joint. The type 316L base metal on either side of the joint was not affected.

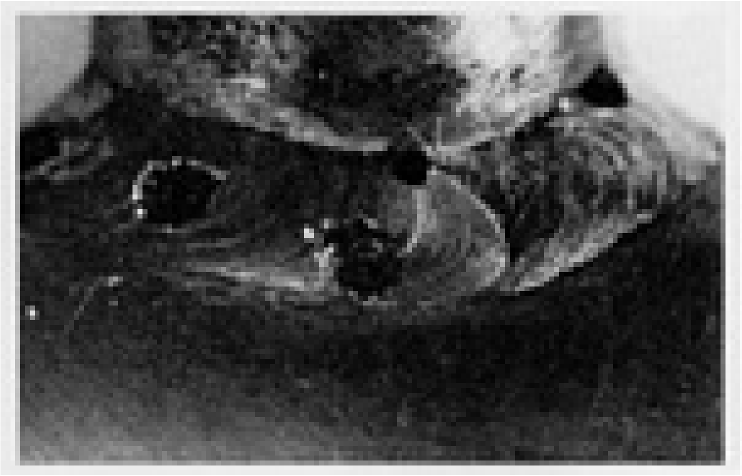

Fig. 10 Pitting of underalloyed (relative to base metal) type 308L weld metal. The type 316L stainless steel base metal is unaffected. About 2.5×

Crevice Corrosion. Defects such as residual welding flux and microfissures create weld metal crevices that are easily corroded, particularly in chloride-containing environments. Some flux formulations on coated shielded metal arc or stick electrodes produce easily detached slags, and other give slags that are difficult to remove completely even after gritblasting. Slags from rutile (titania-base) coatings are easily detached and give good bead shape. In contrast, slags from

the basic-coated electrodes for out-of-position welding can be difficult to remove; small particles of slag may remain on the surface, providing an easy initiation site for crevice attack (Fig. 11).

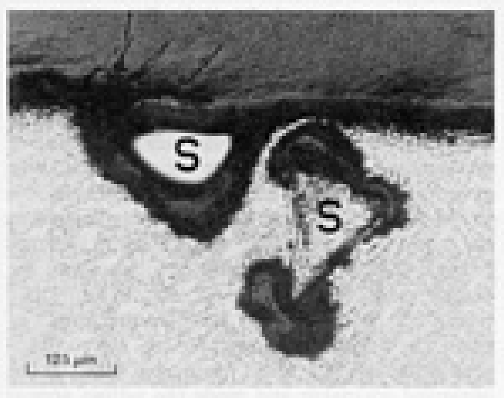

Fig. 11 Crevice corrosion under residual slag (S) in IN-135 weld metal after bleach plant exposure. Etched with glyceregia. Source: Ref 8

Microfissures or their larger counterparts, hot cracks, also provide easy initiation sites for crevice attack, which will drastically reduce the corrosion resistance of a weldment in the bleach plant. Microfissures are caused by thermal contraction stresses during weld solidification and are a problem that plagues austenitic stainless steel fabrications. These weld metal cracks are more likely to form when phosphorus and sulfur levels are higher (that is, more than 0.015% P and 0.015% S), with high heat input welding, and in austenitic weld metal in which the δ-ferrite content is low (<3%).

Small-scale microfissures are often invisible to the naked eye, and their existence can readily explain the unexpectedly poor pitting performance of one of a group of weldments made with filler metals of apparently similar general composition. The microfissure provides a crevice, which is easily corroded because stainless alloys are more susceptible to crevice corrosion than to pitting. However, microfissure-crevice corrosion is often mistakenly interpreted as self-initiated pitting (Fig. 12 and 13).

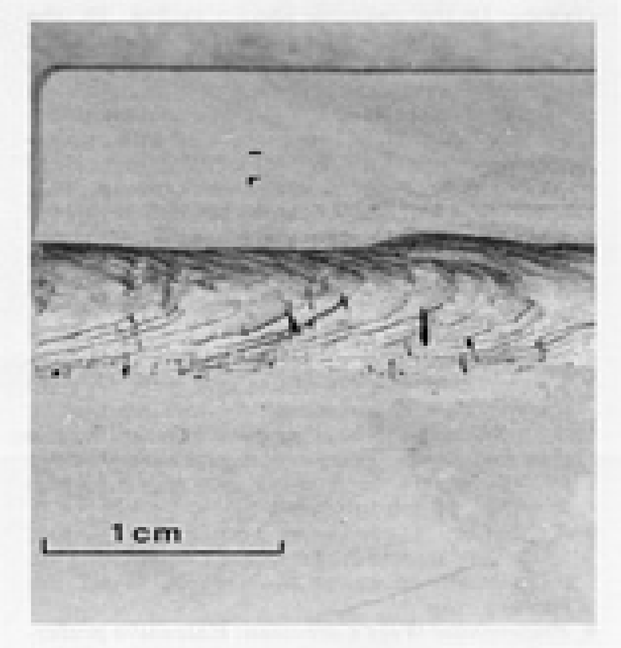

Fig. 12 Microfissure corrosion of IN-135 weld metal on an alloy 904L test coupon after bleach plant exposure.

See also Fig. 13. Source: Ref 8

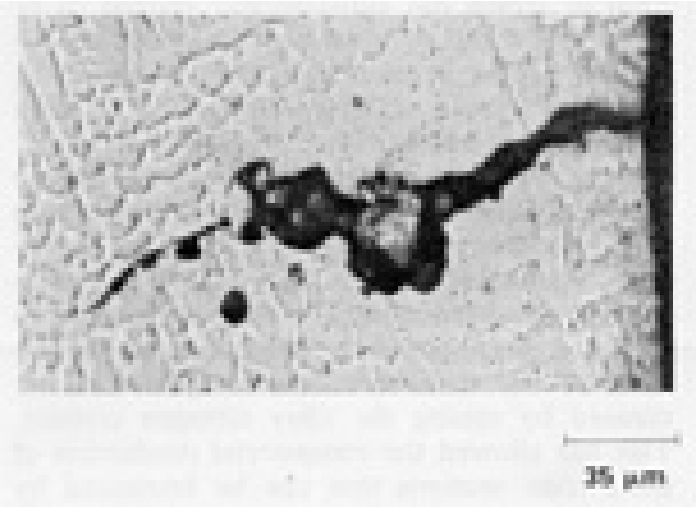

Fig. 13 Section from the bleach plant test coupon in Fig. 12 showing crevice corrosion that has almost obliterated evidence of a microfissure. This form of attack is often mistakenly interpreted as self-initiated pitting; more often, crevice corrosion originates at a microfissure. Etched with glyceregia. Source: Ref 8

Crevice corrosion sites can also occur at the beginning or end of the weld passes, between weld passes, or under weld spatter areas. Weld spatter is most troublesome when it is loose or poorly adherent. A good example of this type of crevice condition is the type 304 stainless system shown in Fig. 14.

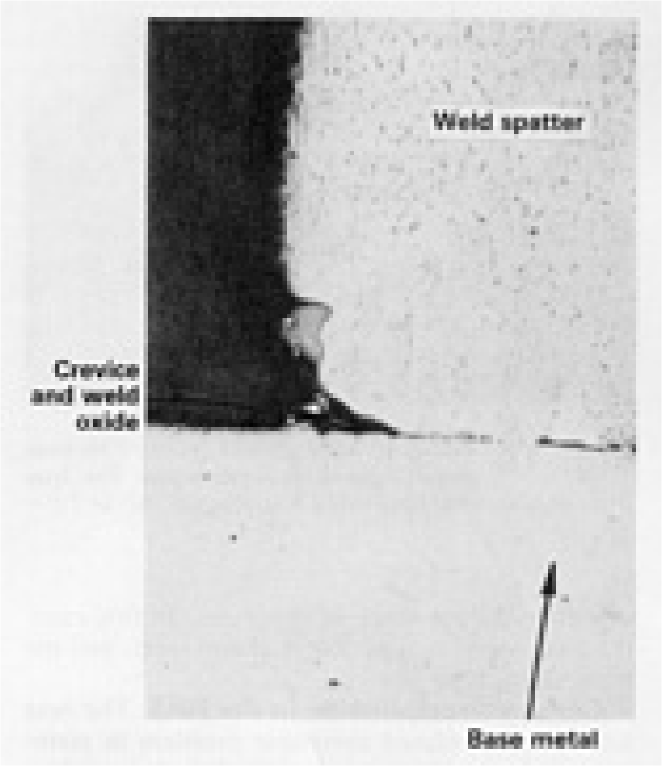

Fig. 14 Cross section of a weldment showing crevice corrosion under weld spatter. Oxides (light gray) have formed on the spatter and in the crevice between spatter and base metal

Microfissure corrosion in austenitic stainless steel weldments containing 4 to 6% Mo is best avoided with the nickel-base Inconel 625, Inconel 112, or Avesta P12 filler metals, which are very resistant to crevice attack. Some stainless electrodes are suitable for welding 4% Mo steels, but they should be selected with low phosphorus and sulfur to avoid microfissure problems.

Hot tap water is not thought to be particularly aggressive: however, Fig. 15 shows what can happen to a weld that contains a lack-of-fusion defect in the presence of chlorides. In this case, the base metal is type 304 stainless steel, and the weld metal type 308.

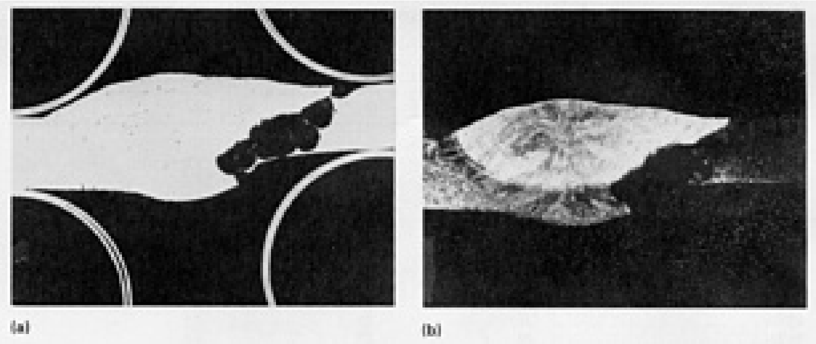

Fig. 15 Unetched (a) and etched (b) cross sections of a type 304 stainless steel weldment showing chloride pitting attack along a crevice created by a lack-of-fusion defect. Service environment: hot tap water

Carbide Precipitation in the HAZ. The best known weld-related corrosion problem in stainless steels is weld decay (sensitization) caused by carbide precipitation in the weld HAZ. Sensitization occurs in a zone subject to a critical thermal cycle in which chromium-rich carbides precipitate and in which chromium diffusion is much slower than that of carbon. The carbides are precipitated on grain boundaries that are consequently flanked by a thin chromium-depleted layer. This sensitized microstructure is much less corrosion resistant, because the chromium-depleted layer and the precipitate can be subject to preferential attack (Fig. 16). In North America, sensitization is avoided by the use of low-carbon grades such as type 316L (0.03% C max) in place of sensitization-susceptible type 316 (0.08% C max). In Europe, it is more common to use 0.05% C (max) steels, which are still reasonably resistant to sensitization, particularly if they contain molybdenum and nitrogen; these elements appear to raise the tolerable level of carbon and/or heat input. However, low-carbon stainless steels carry a small cost premium; therefore, they are not universally specified.

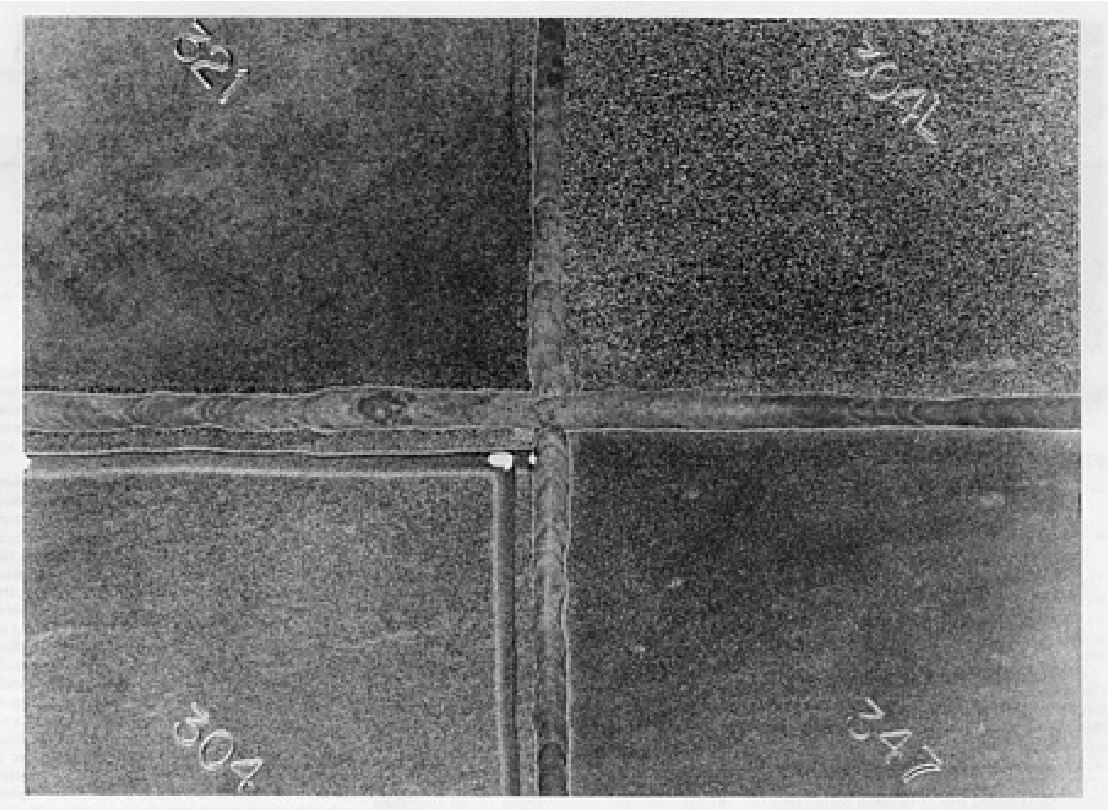

Fig. 16 Weld decay (sensitization) in austenitic stainless steel and methods for its prevention. Panels of four different AISI 300-series stainless steels were joined by welding and exposed to hot HNO_3 + HF solution. The weld decay evident in the type 304 panel was prevented in the other panels by reduction in carbon content (type 304L) or by addition of carbide-stabilizing elements (titanium in type 321, and niobium in type 347). Source: Ref 2

Thiosulfate ($S_2O_3^{2-}$) pitting corrosion will readily occur in sensitized HAZs of type 304 weldments in paper machine white-water service (Fig. 17). This form of attack can be controlled by limiting sources of $S_2O_3^{2-}$ contamination, the principal one of which is the brightening agent sodium hyposulfite ($Na_2S_2O_4$). However, nonsensitized type 304 will also be attacked, and type 316L is the preferred grade of stainless steel that should be specified for paper machine service.

Fig. 17 Thiosulfate pitting in the HAZ of a type 304 stainless steel welded pipe after paper machine white-water service. 2×. Source: Ref 8

At higher solution temperatures, sensitized type 304 and type 316 are particularly susceptible to SCC--whether caused by chlorides, sulfur compounds, or caustic. For example, type 304 or 316 kraft black liquor evaporators and white liquor tubing are subject to SCC in sensitized HAZs. In many cases cracking occurs after HCl acid cleaning. Although the initial crack path may be intergranular, subsequent propagation can have the characteristic branched appearance of transgranular chloride SCC. Intergranular SCC caused by sulfur compounds can also occur during the acid cleaning of sensitized stainless steels in kraft liquor systems.

Sigma Precipitation in HAZs. When the higher molybdenum alloys such as 904L, AL-6XN, and 254SMO were first developed, one of the anticipated corrosion problems was attack of single-phase precipitates in weld HAZs. This form of attack has subsequently proved to be either superficial or nonexistent in most applications, probably because the compositions of the alloys have been skillfully formulated to minimize σ phase-related hot-rolling problems.

More recently, nitrogen has been added to molybdenum-bearing austenitic stainless steels to retard the precipitation of chromium- and molybdenum-rich intermetallic compounds (σ or χ phases). The incubation time for intermetallic precipitation reactions in iron-chromium-nickel-molybdenum stainless alloys is significantly increased by raising the alloy nitrogen content. This has allowed the commercial production of thick plate sections that can be fabricated by multipass welding operations. In addition to suppressing the formation of deleterious phases, nitrogen, in cooperation with chromium and molybdenum, has a beneficial effect on localized corrosion resistance in oxidizing acid-chloride solutions.

Corrosion Associated With Postweld Cleaning. Postweld cleaning is often specified to remove the heat-tinted metal formed during welding. Resent work has shown that cleaning by stainless steel wire brushing can lower the corrosion resistance of a stainless steel weldment (Fig. 18). This is a particular problem in applications in which the base metal has marginal corrosion resistance. The effect may be caused by inadequate heat-tint removal, by the use of lower-alloy stainless steel brushes such as type 410 or 304, or by the redeposition of abraded metal or oxides.

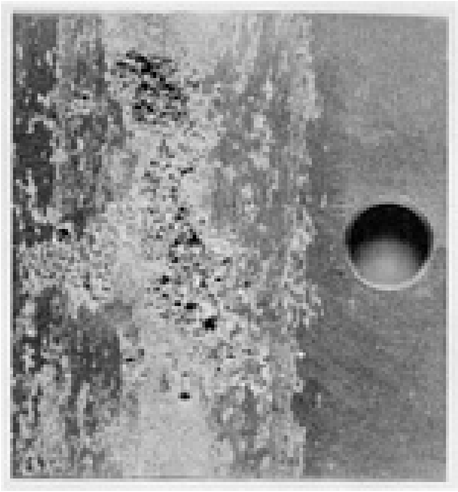

Fig. 18 Pitting corrosion associated with stainless steel wire brush cleaning on the back of a type 316L stainless steel test coupon after bleach plant exposure. Source: Ref 8

Any cleaning method may be impaired by contamination or by lack of control. Results of a study in bleach plants suggest that pickling and glass bead blasting can be more effective than stainless wire brushing and that brushing is more difficult to perform effectively in this case.

Corrosion Associated With Weld Backing Rings. Backing rings are sometimes used when welding pipe. In corrosion applications, it is important that the backing ring insert be consumed during the welding process to avoid a crevice. In the example shown in Fig. 19, the wrong type of backing ring was used, which left a crevice after welding. The sample was taken from a leaking brine cooling coil used in the production of nitroglycerin. The cooling contained calcium chloride ($CaCl_2$) brine inhibited with chromates. Coils were made by butt welding sections of seamless type 304L stainless steel tubing. This failure was unusual because several forms of corrosion had been observed.

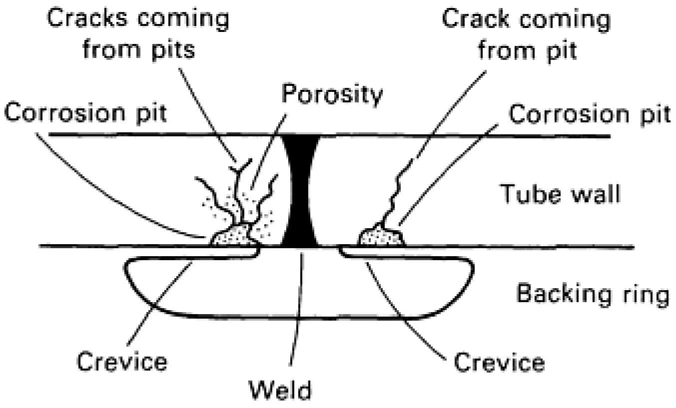

Fig. 19 Schematic of a stainless steel nitrator cooling coil weld joint. Failure was caused by improper design of the backing ring, which was not consumed during welding and left a crevice. Source: Ref 11

A metallographic examination of a small trepanned sample revealed the following:

- *Microstructure:* The base metal and weld metal microstructures appeared satisfactory
- *Pitting:* Irregular corrosion pits were seen on the inside tube surface at crevices formed by the tube and the backing ring adjacent to the tube butt weld. The deepest pits extended 0.1 to 0.2 mm (4 to 8 mils)

into the 1.65-mm (0.065-in.) thick tube wall

- *Cracking:* There were numerous brittle, branching transgranular cracks originating on the inside surface at the crevice under the backing ring
- *Preferential Weld Corrosion:* Extensive preferential corrosion of the ferrite phase (vermicular morphology) in the tube weld had occurred and penetrated almost completely through the tube wall. Corrosion originated on the outside surface of the tube

It was concluded that the preferential weld corrosion from the process side was the most probable cause of the actual leak in the nitrator coil. The preferential corrosion of ferrite in nitrating mixtures of HNO_3 and H_2SO_4 is well known. Whether this corrosion causes a serious problem depends on the amount of ferrite present in the weld. If the amount of ferrite is small and the particles are not interconnected, the overall corrosion rate is not much higher than that of a completely austenitic material. If the particles are interconnected, as in this case, there is a path for fairly rapid corrosion through the weld, causing failure to occur.

To minimize this problem, two possible solutions were considered. The first was to weld the coils with a filler metal that produces a fully austenitic deposit, and the second was to solution anneal at 1065 °C (1950 °F) after welding to dissolve most of the ferrite. It would also help to select stainless steel base metal by compositions (for example, high nickel, low chromium content) to minimize the production of ferrite during welding. Welding with a fully austenitic filler metal was considered to be the best approach.

Cracking on the brine side was caused by chloride SCC. Most probably, the cracking did not happen during operation at 15 °C (60 °F) or lower. It is thought that the cracking most likely occurred while the coil was being decontaminated at 205 to 260 °C (400 to 500 °F) in preparation for weld repairing of the leak. Brine that was trapped in the crevice between the tube wall and the backing ring was boiled to dryness. Under these conditions, SCC would occur in a short time.

There probably were stress cracks behind all of the backing rings. The future life of this coil was questionable. A new coil was recommended.

The pitting corrosion caused by the brine was not considered to be as serious as it first appeared. If this were the only corrosion (and the sample was representative of the coil), the coil would not have failed for considerable length of time. The decontamination process, which evaporated the trapped brine, produced some of the observed corrosion and made the pitting appear worse than it was before decontamination.

Chromates are anodic inhibitors and therefore can also greatly increase the corrosion (usually by pitting) in the system if insufficient quantities are used. This may also have occurred in the crevices in the nitrator coil butt welds, regardless of the bulk solution concentration. The best solution to this problem was to eliminate the crevices, that is, not to use backing rings.

Effects of GTA Weld Shielding Gas Composition. The chromium in a stainless steel has a strong chemical affinity for oxygen and carbon. Weld pools formed by electric arc processes must be shielded from the atmosphere to prevent slag formation and oxidation (Fig. 20), to maintain a stable arc, and to reduce contamination of the molten metal by the weld environment. Argon or argon plus helium gas mixtures are commonly used in GTA welding processes to create a barrier between the solidifying weld and the atmosphere. In other cases, nitrogen is commonly used as a backing gas to protect the backside of the root pass.

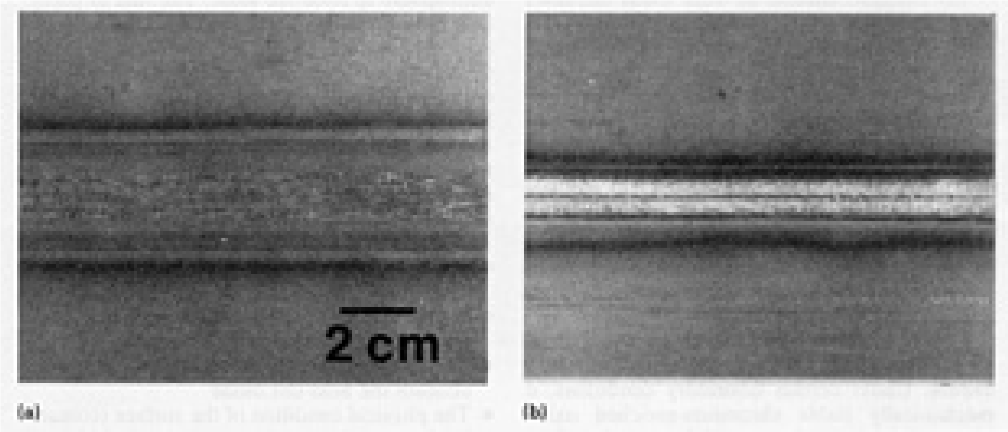

Fig. 20 Examples of properly shielded (a) and poorly shielded (b) autogenous GTA welds in type 304 stainless steel strip. Source: Ref 11

The composition of a shielding gas can be modified to improve the microstructure and properties of GTA welds in austenitic stainless steels. More specifically, the use of argon mixed with small volumes of nitrogen (10 vol% N_2 or less) in a GTA welding process enhances the corrosion resistance of iron-chromium-nickel-molybdenum-nitrogen stainless alloys in oxidizing acid chloride solutions (Fig. 21). In certain nonoxidizing solutions, argon-nitrogen shielding gas reduces the δ-ferrite content of weld metal, and influences weld metal solidification behavior.

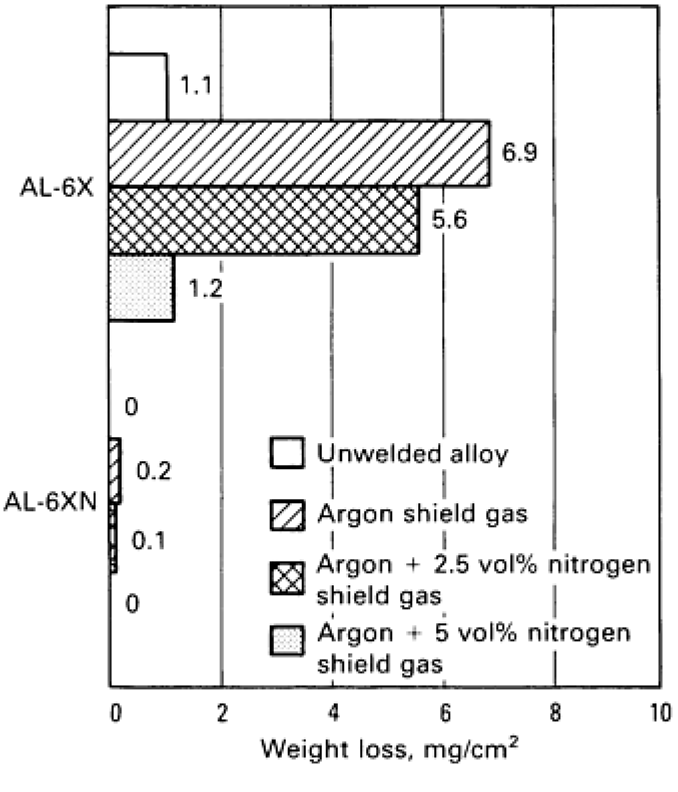

Fig. 21 Effect of GTA weld shielding gas composition on the corrosion resistance of two austenitic stainless steels. Welded strip samples were tested according to Ref 17; test temperature was 35 °C (95 °F). Source: Ref 11

The nitrogen content of weld metal increases with the partial pressure of nitrogen in the GTA weld shielding gas. The increase in weld metal nitrogen content is greater when nitrogen is mixed with an oxidizing gas, such as CO_2, than with

either a reducing (hydrogen) or a neutral (argon) gas. Porosity and concavity are observed in austenitic stainless steel weld metals when more than 10 vol% nitrogen is added to an argon shielding gas. Although solid-solution additions of nitrogen are not detrimental to the SCC resistance of unwelded molybdenum-containing austenitic stainless steels, an increased weld metal nitrogen content tends to increase susceptibility to SCC.

Effects of Heat-Tint Oxides on the Corrosion Resistance of Austenitic Stainless Steels. Under certain laboratory conditions, a mechanically stable chromium-enriched oxide layer can be formed on a stainless steel surface that enhances corrosion resistance. In contrast, the conditions created by arc-welding operations produce a scale composed of elements that have been selectively oxidized from the base metal. The region near the surface of an oxidized stainless steel is depleted in one or more of the elements that have reacted with the surrounding atmosphere to form the scale. The rate of oxidation for a stainless steel, and consequently the degree of depletion in the base metal, is independent of the alloy composition and is controlled by diffusion through the oxide. The oxidized, or heat-tinted, surface of a welded stainless steel consists of a heterogeneous oxide composed primarily of iron and chromium above a chromium-depleted layer of the base metal. The properties of such a surface depend on:

- The time and temperature of the thermal exposure
- The composition of the atmosphere in contact with the hot metal surface
- The chemical composition of the base metal beneath the heat-tint oxide
- The physical condition of the surface (contamination, roughness, thermomechanical history) prior to heat tinting
- The adherence of the heat-tint oxide to the base metal

The defects, internal stresses, and composition of the heat-tint oxide make it a poor barrier to any corrosive media that might initiate localized corrosion in the chromium-depleted layer of base metal.

The severity of localized corrosion at heat-tinted regions exposed to oxidizing chloride solutions is directly related to the temperature of the hot metal surface during welding. A heat-tint oxide on an austenitic stainless steel exposed in air first becomes obvious at approximately 400 °C (750 °F). As the surface temperature is increased, differently colored oxides develop that appear to be superimposed upon the oxides formed at lower temperatures (Table 2). Dark blue heat-tint oxides are the most susceptible to localized corrosion. It should be noted that gas-shielded surfaces do not form the same distinctly colored oxides as surfaces exposed to air during welding, but gas-shielded surfaces can also be susceptible to preferential corrosion.

Table 2 Welding conditions and corrosion resistance of heat-tinted UNS S31726 stainless steel plate

Welding conditions[(a)]				Corrosion test results[(b)]		
Heat input		**Welding current, A**	**Centerline heat-tint color**	**Maximum pit depth,**		Number of pits on heat-tinted surface

Source: Ref 12

(a) Single-pass autogenous bead-on-plate GTA welds were made to heat tint the root surface of 6.4-mm thick plate samples.

(b) Duplicate coupons, each with one 25- × 51-mm (1- × 2-in.) heat-tinted surface, were exposed to 10% $FeCl_3$ solutions at 50 °C (120 °F). The weld face and edges of each coupon were covered with a protective coating.

Whether a weld heat tint should be removed prior to service depends on the corrosion behavior of the given alloy when exposed to the particular environment in question. Preferential corrosion at heat-tinted regions is most likely to occur on an alloy that performs near the limit of its corrosion resistance in service, but certain solutions do not affect heat-tinted regions. Even when heat-tinted regions are suspected of being susceptible to accelerated corrosion in a particular environment, the following factors should be considered:

- The rate at which pits, once initiated in the chromium-depleted surface layer, will propagate through sound base metal
- The hazards associated with the penetration, due to localized corrosion, of a process unit
- The cost and effectiveness of an operation intended to repair a heat-tinted stainless steel surface

The corrosion resistance of heat-tinted regions can be restored in three stages. First, the heat-tint oxide and chromium-depleted layer are removed by grinding or wire brushing. Second, the abraded surface is cleaned with an acid solution or a pickling paste (a mixture of HNO_3 and HF suspended in an inert paste or gel) to remove any surface contamination and to promote the reformation of a passive film. Third, after a sufficient contact time, the acid cleaning solution or pickling paste is thoroughly rinsed with water, preferably demineralized or with a low chloride ion (Cl^-) content.

Grinding or wire brushing may not be sufficient to repair a heat-tinted region. Such abrading operations may only smear the heat-tint oxide and embed the residual scale into the surface, expose the chromium-depleted layer beneath the heat-tint oxide, and contaminate the surface with ferrous particles that were picked up by the grinding wheel or wire brush. A stainless steel surface should never be abraded with a wheel or brush that has been used on a carbon or low-alloy steel; wire brushes with bristles that are not made of a stainless steel of similar composition should also be avoided. Conversely, attempting to repair a heat-tinted region with only a pickling paste or acid solution may stain or even corrode the base metal if the solution is overly aggressive or is allowed to contact the surface for an extended time. If the acid is too weak, a chromium-depleted scale residue may remain on a surface. Even if the chromium-depleted layer were completely removed by a grinding operation, mechanically ground surfaces generally have inferior corrosion resistance compared to properly acid-pickled surfaces.

Unmixed Zones. All methods of welding stainless steel with a filler metal produce a weld fusion boundary consisting of base metal that has been melted but not mechanically mixed with filler metal and a partially melted zone in the base metal. The weld fusion boundary lies between a weld composite consisting of filler metal diluted by base metal and an HAZ in the base metal (Fig. 1). The width of the unmixed zone depends on the local thermal conditions along the weld fusion line. For a GTA welding process, the zone is most narrow at the weld face and is broadest near the middle of the weld thickness.

An unmixed zone has the composition of base metal but the microstructure of an autogenous weld. The microsegregation and precipitation phenomena characteristic of autogenous weldments decrease the corrosion resistance of an unmixed zone relative to the parent metal. Unmixed zones bordering welds made from overalloyed filler metals can be preferentially attacked when exposed on the weldment surface (Fig. 22). The potential for preferential attack of unmixed zones can be reduced by minimizing the heat input to the weld and/or by flowing molten filler metal over the surface of the unmixed zone to form a barrier to the service environment. Care must be taken in this latter operation to avoid cold laps and lack-of-fusion defects. In both cases, preferential attack is avoided as long as the surface of the unmixed zone lies beneath the exposed surface of the weldment.

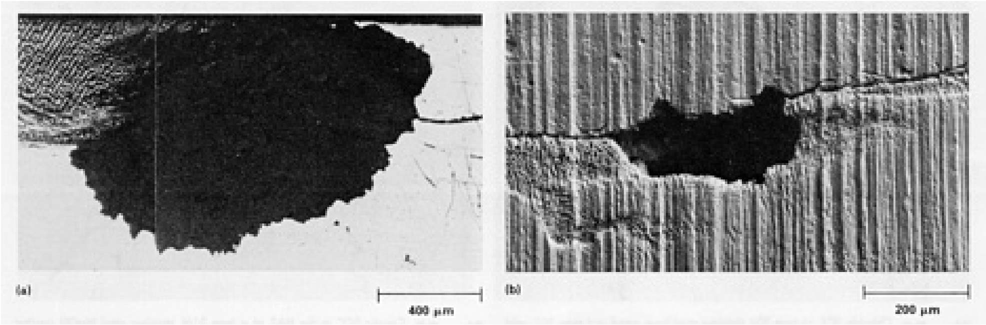

Fig. 22 Optical (a) and scanning electron (b) micrographs of pitting in the unmixed zone of iron-chromium-nickel-molybdenum stainless steel plates that were GTA welded with on overalloyed filler metal. The unmixed zones were preferentially attacked in an oxidizing acid chloride solution at elevated temperature.

Chloride SCC. Welds in the 300-series austenitic stainless steels, with the exception of types 310 and 310Mo, contain a small amount of δ-ferrite (usually less than 10%) to prevent hot cracking during weld solidification. In hot, aqueous chloride environments, these duplex weldments generally show a marked resistance to cracking, while their counterparts crack readily (Fig. 23). The generally accepted explanation for this behavior is that the ferrite phase is resistant to chloride SCC and impedes crack propagation through the austenite phase. Electrochemical effects may also play a part; however, under sufficient tensile stress, temperature, and chloride concentration, these duplex weldments will readily crack. An example is shown in Fig. 24.

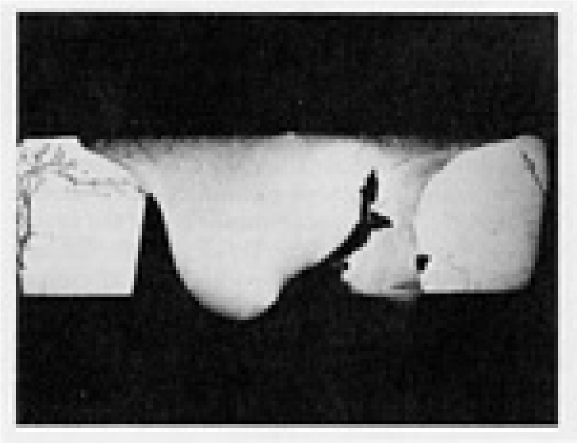

Fig. 23 Selective attack of a type 317L stainless steel weldment and chloride SCC of the adjacent 317L base metal. The environment was a bleaching solution (7 g/L Cl_2) at 70 °C (160 °F).

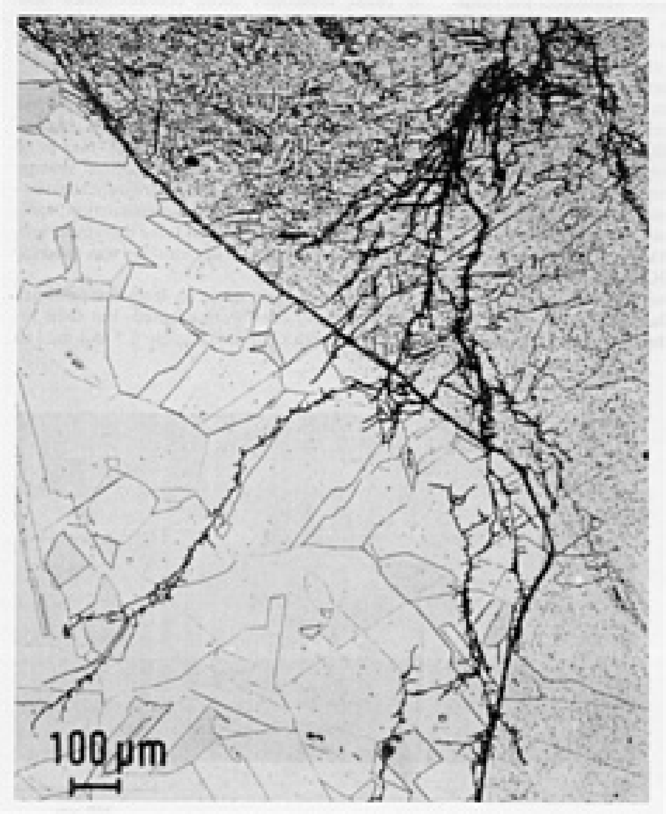

Fig. 24 Chloride SCC of type 304 stainless steel base metal and type 308 weld metal in an aqueous chloride environment at 95 °C (200 °F). Cracks are branching and transgranular.

Caustic Embrittlement (Caustic SCC). Susceptibility of austenitic stainless steels to this form of corrosion usually becomes a problem when the caustic concentration exceeds approximately 25% and temperatures are above 100 °C (212 °F). Because welding is involved in most fabrications, the weld joint becomes the focus of attention because of potential stress raiser effects and because of high residual shrinkage stresses. Cracking occurs most often in the weld HAZ.

In one case, a type 316L reactor vessel failed repeatedly by caustic SCC in which the process fluids contained 50% sodium hydroxide (NaOH) at 105 °C (220 °F). Failure was restricted to the weld HAZ adjacent to bracket attachment welds used to hold a steam coil. The stresses caused by the thermal expansion of the Nickel 200 steam coil at 1034 kPa (150 psig) aggravated the problem. Figure 25 shows the cracks in the weld HAZ to be branching and intergranular. Because it was not practical to reduce the operating temperature below the threshold temperature at which caustic SCC occurs, it was recommended that the vessel be weld overlayed with nickel or that the existing vessel be scrapped and a replacement fabricated from Nickel 200.

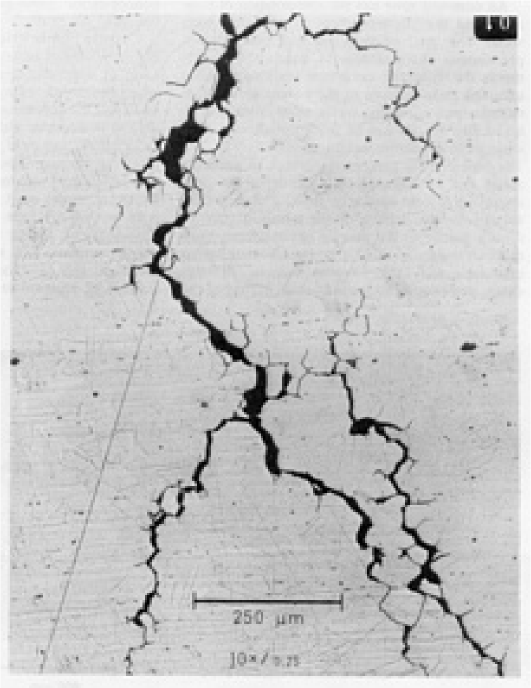

Fig. 25 Caustic SCC in the HAZ of a type 316L stainless steel NaOH reactor vessel. Cracks are branching and intergranular.

Microbiologically Induced Corrosion (MIC). Microbiological corrosion in the process industries is most often found in three areas: cooling water systems, aqueous waste treatment, and groundwater left in new equipment or piping systems after testing. Nearly all confirmed cases of MIC have been accompanied by characteristic deposits. These are usually discrete mounds. Deposit color can also be an indication of the types of microorganisms that are active in the system. For example, iron bacteria deposits on stainless steel, such as those produced by *Gallionella,* are often reddish.

Investigators have shown that in almost all cases the environment causing the damage was a natural, essentially untreated water containing one or more culprit species of microbiological organisms. In the case of austenitic stainless steel weldments, corrosion generated by bacteria takes a distinctive form, that is, subsurface cavities with only minute pinhole penetration at the surface. The following case history involving well water in Texas illustrates these characteristics (Ref 13).

New production facilities at one plant site required austenitic stainless steels, primarily types 304L and 316L, for resistance to HNO_3 and organic acids and for maintaining product purity. The piping was shop fabricated, field erected, and then hydrostatically tested. All of the large (>190,000 L, or 25,000 gal) flat-bottom storage tanks were field erected and hydrostatically tested. During the early stages of construction, sodium-softened plant well water (also used for drinking) containing 200 ppm of chlorides was used for testing.

No attempts were made to drain the pipelines after testing. Tanks were drained, but then refilled to a depth of approximately 0.5 to 1 m (2 to 3 ft) for ballast because of a hurricane threat. The water was left in the tanks to evaporate.

The problem became evident when water was found dripping from butt welds in type 304L and 316L piping (nominal wall thickness: 3.2 mm, or $\frac{1}{8}$ in.) approximately 1 and 4 months, respectively, after the hydrotest. Internal inspection showed pits in and adjacent to welds under reddish-brown deposits. Tank manways were uncovered, and similar conditions were found. As shown in Fig. 26, moundlike deposits were strung out along weld seams in the tank bottoms.

Fig. 26 Moundlike microbiological deposits along a weld seam in the bottom of a type 304L stainless steel tank after several months of exposure to well water at ambient temperature. Source: Ref 13

Figure 27 shows a closeup view of a typical deposit still wet with test water. The brilliantly colored deposit was slimy and gelatinous in appearance and to the touch, and it measured 76 to 102 mm (3 to 4 in.) in width. At one point during the investigation, a similar deposit on a weld that was covered with about 150 mm (6 in.) of water was thoroughly dispersed by hand. Twenty-four hours later, the deposit had returned in somewhat diminished form to exactly the same location.

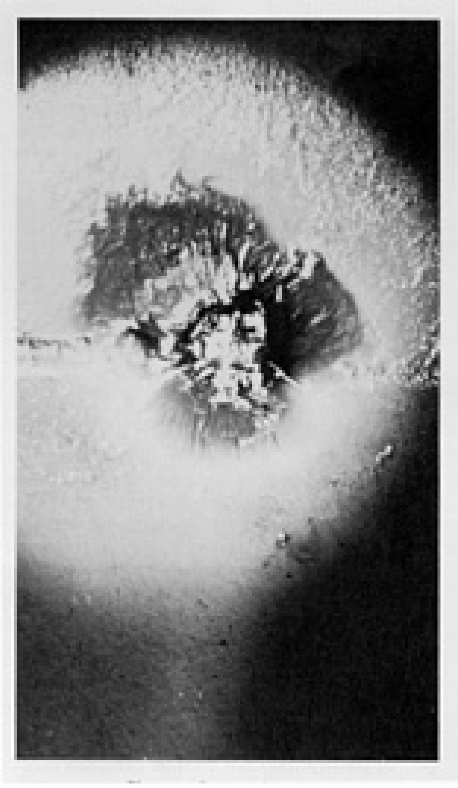

Fig. 27 Closeup of a wet deposit as shown in Fig. 26. Source: Ref 13

Figure 28 shows a nearly dry deposit. After wiping the deposit clean, a dark ring-shaped stain outlining the deposit over the weld was noted (Fig. 29). There was, however, no evidence of pitting or other corrosion, even after light sanding with emery. Finally, probing with an icepick revealed a large deep pit at the edge of the weld, as shown in Fig. 30. Figure 31, a radiograph of this weld seam, shows the large pit that nearly consumed the entire width of the weld bead, as well as several smaller pits. A cross section through a large pit in a 9.5-mm ($\frac{3}{8}$-in.) thick type 304L tank bottom is shown in Fig. 32.

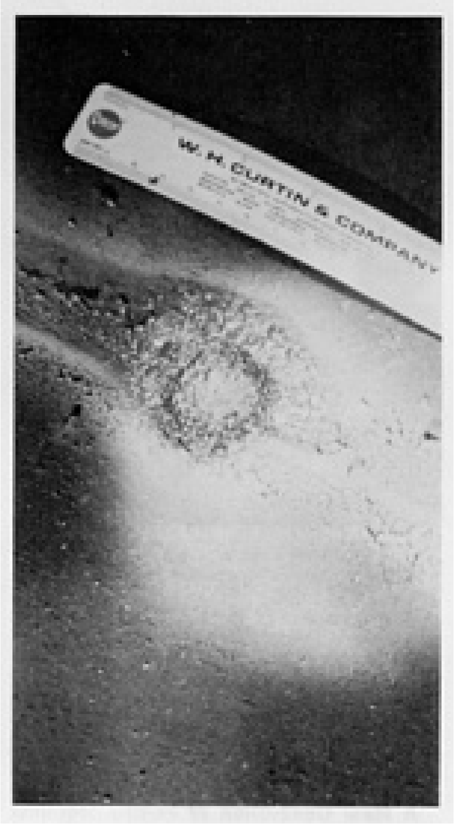

Fig. 28 Closeup of a dry deposit. See also Fig. 26 and 27. Source: Ref 13

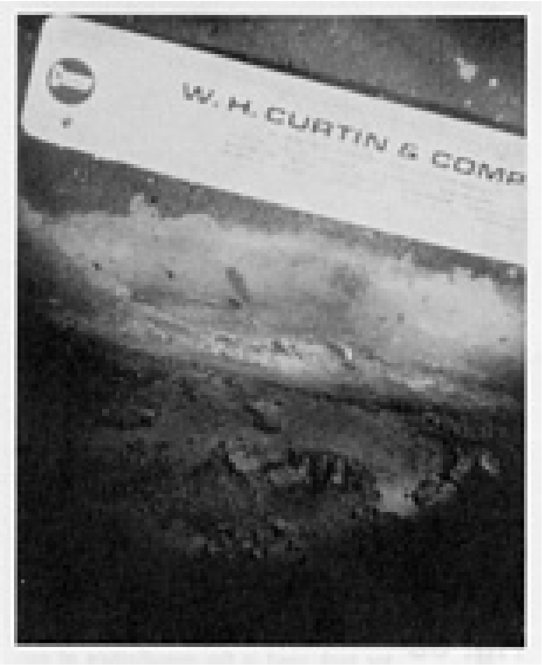

Fig. 29 Ring-shaped stain left around a weld after removal of the type of deposit shown in Fig. 26, 27, and 28. Source: Ref 13

Fig. 30 Large pit (center) at the edge of the weld shown in Fig. 29. The pit was revealed by probing with an icepick. Source: Ref 13

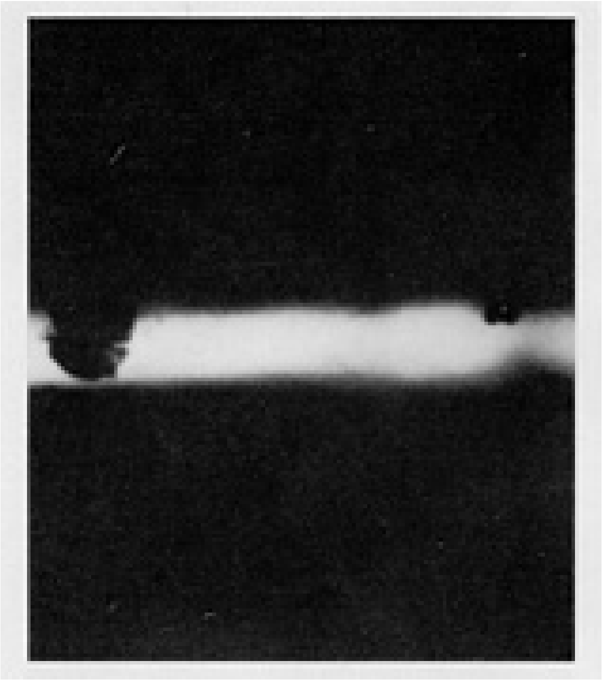

Fig. 31 Radiograph of a pitted weld seam in a type 304L stainless steel tank bottom. Source: Ref 13

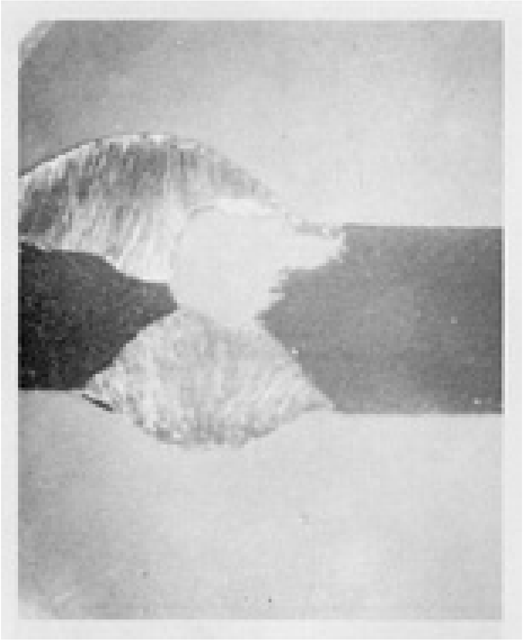

Fig. 32 Cross section through a pitted weld seam from a type 304L tank showing a typical subsurface cavity. Source: Ref 13

The characteristics of this mode of corrosion were a tiny mouth at the surface and a thin shell of metal covering a bottle-shaped pit that had consumed both weld and base metal. There was no evidence of intergranular or interdendritic attack of base or weld metal. However, pitted welds in a type 316L tank showed preferential attach of the -ferrite stringers (Fig. 33).

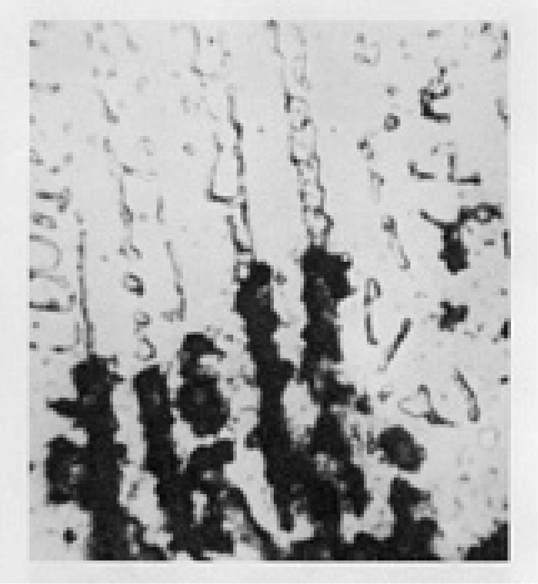

Fig. 33 Micrograph showing preferential attack of δ-ferrite stringers in type 316 stainless steel weld metal. 250×. Source: Ref 13

This type 316L tank was left full of hydrotest water for 1 month before draining. The bottom showed severe pitting under the typical reddish-brown deposits along welds. In addition, vertical rust-colored streaks (Fig. 34) were found above and below the sidewall horizontal welds, with deep pits at the edges of the welds associated with each streak (Fig. 35).

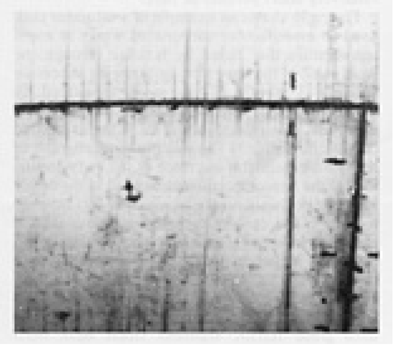

Fig. 34 Rust-colored streaks transverse to horizontal weld seams in the sidewall of a type 316L stainless steel tank. Source: Ref 13

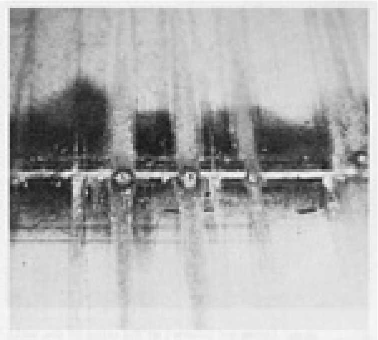

Fig. 35 Closeup of the rust-colored streaks shown in Fig. 24. Source: Ref 13

Analyses of the well water and the deposits showed high counts of iron bacteria (*Gallionella*) and iron/manganese bacteria (*Siderocapsa*). Both sulfate-reducing and sulfur-oxidizing bacteria were absent. The deposits also contained large amounts (thousands of parts per million) of iron, manganese, and chlorides.

As indicated, nearly all biodeposits and pits were found at the edges of, or very close to, weld seams. It is possible that the bacteria in stagnant well water were attracted by an electrochemical phenomenon or surface imperfections (oxide or slag inclusions, porosity, ripples, and so on) typically associated with welds. A sequence of events for the corrosion mechanism in this case might be the following:

- Attraction and colonization of iron and iron/manganese bacteria at welds
- Microbiological concentration of iron and manganese compounds, primarily chlorides, because Cl^- was the predominant anion in the well water
- Microbiological oxidation to the corresponding ferric and manganic chlorides, which either singly or in combination are severe pitting corrodents of austenitic stainless steel
- Penetration of the protective oxide films on the stainless steel surfaces that were already weakened by oxygen depletion under the biodeposits

All affected piping was replaced before the new facilities were placed in service. The tanks were repaired by sandblasting to uncover all pits, grinding out each pit to sound metal, and then welding with the appropriate stainless steel filler metal. Piping and tanks have been in corrosive service for about 19 years to date with very few leaks, indicating that the inspection, replacement, and repair program was effective.

Corrosion of Ferritic Stainless Steel Weldments

Conventional 400-series ferritic stainless steels such as AISI types 430, 434, and 446 are susceptible to intergranular corrosion and to embrittlement in the as-welded condition. Corrosion in the weld area generally encompasses both the weld metal and weld HAZ. Early attempts to avoid some of these problems involved the use of austenitic stainless steel filter metals; however, failure by corrosion of the HAZ usually occurred even when exposure was to rather mild media for relatively short periods of time.

Figure 36 shows an example of a saturator tank used to manufacture carbonated water at room temperature that failed by leakage through the weld HAZ of the base metal after being in service for only 2 months. This vessel, fabricated by welding with a type 308 stainless steel welding electrode, was placed in service in the as-welded condition. Figure 37 shows a photomicrograph of the weld/base metal interface at the outside surface of the vessel; corrosion initiated at the inside surface. Postweld annealing--at 785 °C (1450 °F) for 4 h in the case of type 430 stainless steel--restores weld area ductility and resistance to corrosion equal to that of the unwelded base metal.

Fig. 36 As-welded type 430 stainless steel saturator tank used in the manufacture of carbonated water that failed after 2 months of service. The tank was shielded metal arc welded using type 308 stainless steel filler metal. Source: Ref 14

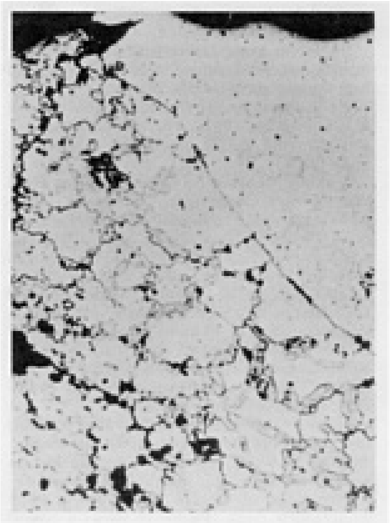

Fig. 37 Micrograph of the outside surface of the saturator tank in Fig. 36 showing intergranular corrosion at the fusion line. Source: Ref 14

To overcome some of these earlier difficulties and to improve weldability, several of the standard grade ferritic stainless steels have been modified. For example, type 405, containing nominally 11% Cr, is made with lower carbon and a small aluminum addition of 0.20% to restrict the formation of austenite at high temperature so that hardening is reduced during welding. For maximum ductility and corrosion resistance, however, postweld annealing is necessary. Recommendations for welding include either a 430- or a 309-type filler metal, the latter being used where increased weld ductility is desired.

A New Generation of Ferritic Stainless Steels. In the late 1960s and early 1970s, researchers recognized that the high chromium-molybdenum-iron ferritic stainless steels possessed a desirable combination of good mechanical properties and resistance to general corrosion, pitting, and SCC. These properties made them attractive alternatives to the austenitic stainless steels commonly plagued by chloride SCC.

It was reasoned that by controlling the interstitial element (carbon, oxygen, and nitrogen) content of these new ferritic alloys, either by ultrahigh purity or by stabilization, the formation of martensite (as well as the need for preheat and postweld heat treatment) could be eliminated, with the result that the welds would be corrosion resistant, tough, and ductile in the as-welded condition. To achieve these results, electron beam vacuum refining, vacuum and argon-oxygen decarburization, and vacuum induction melting processes were used. From this beginning, two basic ferritic alloy systems evolved:

- *Ultrahigh purity:* the (C + N) interstitial content is less than 150 ppm (Ref 15)
- *Intermediate purity:* the (C + N) interstitial content exceeds 150 ppm (Ref 15)

Although not usually mentioned in the alloy chemistry specifications, oxygen and hydrogen are also harmful, and these levels must be carefully restricted. Table 3 lists the compositions of some ultrahigh purity, intermediate purity, and standard-grade ferritic stainless steels.

Table 3 Typical compositions of some ferritic stainless steels

Alloy	Composition, %

The unique as-welded properties of the new ferritic stainless steels have been made possible by obtaining very low levels of impurities, including carbon, nitrogen, hydrogen, and oxygen, in the case of the alloys described as ultralow interstitials and by obtaining a careful balance of niobium and/or titanium to match the carbon content in the case of the alloys with intermediate levels of interstitials. For these reasons, every precaution must be taken, and welding procedures that optimize gas shielding and cleanliness must be selected to avoid pickup of carbon, nitrogen, hydrogen and oxygen.

To achieve maximum corrosion resistance, as well as maximum toughness and ductility, the GTA welding process with a matching filler metal is usually specified; however, dissimilar high-alloy weld metals have also been successfully used. In this case, the choice of dissimilar filler metal must ensure the integrity of the ferritic metal system. Regardless of which of the new generation of ferritic stainless steels is to be welded, the following precautions are considered essential.

First, the joint groove and adjacent surfaces must be thoroughly degreased with a solvent, such as acetone, that does not leave a residue. This will prevent pickup of impurities, especially carbon, before welding. The filler metal must also be handled carefully to prevent it from picking up impurities. Solvent cleaning is also recommended. *Caution:* Under certain conditions, when using solvents, a fire hazard or health hazard may exist.

Second, a welding torch with a large nozzle inside diameter, such as 19 mm ($\frac{3}{4}$ in.), and a gas lens (inert gas calming screen) is necessary. Pure, welding grade argon with a flow rate of 28 L/min (60 ft^3/h) is required for this size nozzle. In addition, the use of a trailing gas shield is beneficial, especially when welding heavy-gage materials. Use of these devices will drastically limit the pickup of nitrogen and oxygen during welding. Back gas shielding with argon is also essential. *Caution:* Procedures for welding austenitic stainless steels often recommend the use of nitrogen backing gas. Nitrogen must not be used when welding ferritic stainless steels. Standard GTA welding procedures used to weld stainless steels are inadequate and therefore must be avoided.

Third, overheating and embrittlement by excessive grain growth in the weld and HAZ should be avoided by minimizing heat input. In multipass welds, overheating and embrittlement should be avoided by keeping the interpass temperature below 95 °C (200 °F.)

Lastly, to avoid embrittlement further, preheating (except to remove moisture) or postweld heat treating should not be performed. Postweld heat treatment is used only with the conventional ferritic stainless alloys. The following example illustrates the results of not following proper procedures.

Leaking Welds in a Ferritic Stainless Steel Wastewater Vaporizer. A nozzle in a wastewater vaporizer began leaking after approximately 3 years of service with acetic and formic acid wastewaters at 105 °C (225 °F) and 414 kPa (60 psig).

Investigation. The shell of the vessel was weld fabricated in 1972 from 6.4-mm ($\frac{1}{4}$-in.) E-Brite stainless steel plate. The shell measured 1.5 m (58 in.) in diameter and 8.5 m (28 ft) in length. Nondestructive examination included 100% radiography, dye-penetrant inspection, and hydrostatic testing of all E-Brite welds.

An internal inspection of the vessel revealed that portions of the circumferential and longitudinal seam welds, in addition to the leaking nozzle weld, displayed intergranular corrosion. At the point of leakage, there was a small intergranular crack. Figure 38 shows a typical example of a corroded weld. A transverse cross section through this weld will characteristically display intergranular corrosion with grains dropping out (Fig. 39). It was also noted that the HAZ next to the weld fusion line also experienced intergranular corrosion a couple of grains deep as a result of sensitization (Fig. 40).

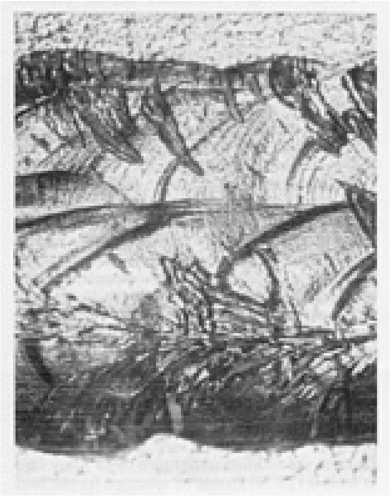

Fig. 38 Top view of a longitudinal weld in 6.4-mm ($\frac{1}{4}$-in.) E-Brite ferritic stainless steel plate showing intergranular corrosion. The weld was made with matching filler metal. About 4×

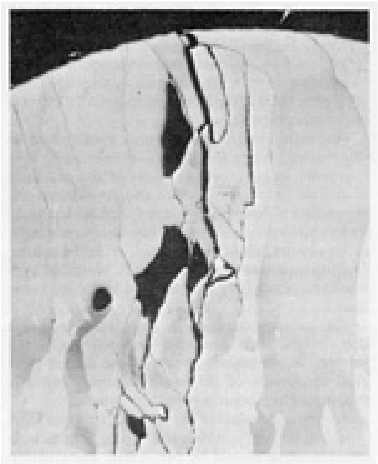

Fig. 39 Intergranular corrosion of a contaminated E-Brite ferritic stainless steel weld. Electrolytically etched with 10% oxalic acid. 200×

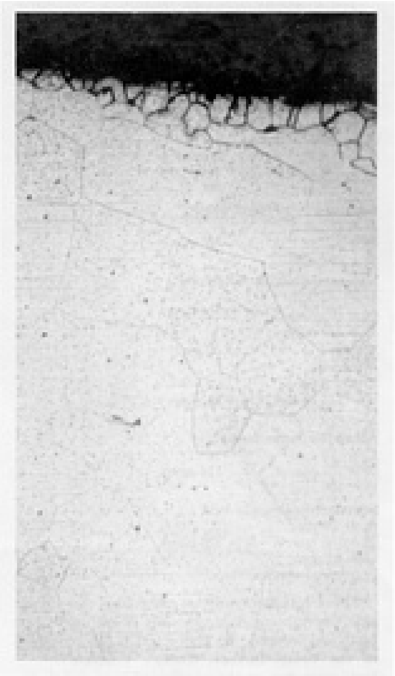

Fig. 40 Intergranular corrosion of the inside surface HAZ of E-Brite stainless steel adjacent to the weld fusion line. Electrolytically etched with 10% oxalic acid. 100×

The evidence indicated weldment contamination; therefore, effort was directed at finding the levels of carbon, nitrogen, and oxygen in the various components present before and after welding. The averaged results were as follows:

E-Brite
Base plate
C = 6 ppm
N = 108 ppm (C + N = 114 ppm)
O = 57 ppm
Corroded longitudinal weld
C = 133 ppm
N = 328 ppm (C + N = 461 ppm)
O = 262 ppm

Corroded circumferential weld
C = 34 ppm
N = 169 ppm (C + N = 203 ppm)
O = 225 ppm
E-Brite
Weld wire
C = 3 ppm
N = 53 ppm (C + N = 56 ppm)
O = 55 ppm
Sound longitudinal weld
C = 10 ppm
N = 124 ppm (C + N = 134 ppm)
O = 188 ppm
Sound circumferential weld
C = 20 ppm
N = 106 ppm (C + N = 126 ppm)
O = 85 ppm

These results confirmed suspicions that failure was due to excessive amounts of nitrogen, carbon, and oxygen. To characterize the condition of the vessel further, Charpy V-notch impact tests were run on the unaffected base metal, the HAZ, and the uncorroded (sound) weld metal. These tests showed the following ductile-to-brittle transition temperatures:

Specimen	Ductile-to-brittle transition temperature	
	°C	°F
Base metal	40 ± 3	105 ± 5
HAZ	85 ± 3	180 ± 5
Weld	5 ± 3	40 ± 5

Comparison of the interstitial levels of the corroded welds, sound welds, base metal, and filler wire suggested that insufficient joint preparation (carbon pickup) and faulty gas shielding were probably the main contributing factors that caused this weld corrosion failure. Discussions with the vendor uncovered two discrepancies. First, the welder was using a large, 19-mm ($\frac{3}{4}$-in.) inside diameter ceramic nozzle with a gas lens, but was flowing only 19 L/min (40 ft^3/h) of argon; this was the flow rate previously used with a 13-mm ($\frac{1}{2}$-in.) inside diameter gas lens nozzle. Second, a manifold system was used to distribute pure argon welding gas from a large liquid argon tank to various satellite welding stations in the welding shop. The exact cause for the carbon pickup was not determined.

Conclusions. Failure of the nozzle weld was the result of intergranular corrosion caused by the pickup of interstitial elements and subsequent precipitation of chromium carbides and nitrides. Carbon pickup was believed to have been caused by inadequate joint cleaning prior to welding. The increase in the weld nitrogen level was a direct result of inadequate argon gas shielding of the molten weld puddle. Two areas of inadequate shielding were identified:

- Improper gas flow rate for a 19-mm ($\frac{3}{4}$-in.) diam gas lens nozzle
- Contamination of the manifold gas system

In order to preserve the structural integrity and corrosion performance of the new generation of ferritic stainless steels, it is important to avoid the pickup of the interstitial elements carbon, nitrogen, oxygen, and hydrogen. In this particular case, the vendor used a flow rate intended for a smaller welding torch nozzle. The metal supplier recommended a flow rate of 23 to 28 L/min (50 to 60 ft^3/min) of argon for a 19-mm ($\frac{3}{4}$-in.) gas lens nozzle. The gas lens collect body is an important and necessary part of the torch used to weld these alloys. Failure to use a gas lens will result in a flow condition that is turbulent enough to aspirate air into the gas stream, thus contaminating the weld and destroying its mechanical and corrosion properties.

The manifold gas system also contributed to this failure. When this system is first used, it is necessary to purge the contents of the manifold of any air to avoid oxidation and contamination. When that is done, the system functions satisfactorily; however, when it is shut down overnight or for repairs, air infiltrates back in, and a source of contamination is reestablished. Manifold systems are never fully purged, and leaks are common.

The contaminated welds were removed, and the vessels were rewelded and put back into service. Some rework involved the use of covered electrodes of dissimilar composition. No problems have been reported to date.

Recommendations. First, to ensure proper joint cleaning, solvent washing and wiping with a clean lint-free cloth should be performed immediately before welding. The filler wire should be wiped with a clean cloth just prior to welding. Also, a word of caution: Solvents are generally flammable and can be toxic. Ventilation should be adequate. Cleaning should continue until cloths are free of any residues.

Second, when GTA welding, a 19-mm ($\frac{3}{4}$-in.) diameter ceramic nozzle with gas lens collect body is recommended. An argon gas flow rate of 28 L/min (60 ft^3/min) is optimum. Smaller nozzles are not recommended. Argon back gas shielding is mandatory at a slight positive pressure to avoid disrupting the flow of the welding torch.

Third, the tip of the filler wire should be kept within the torch shielding gas envelope to avoid contamination and pickup of nitrogen and oxygen (they embrittle the weld). If the tip becomes contaminated, welding should be stopped, the contaminated weld area ground out, and the tip of the filler wire that has been oxidized should be snipped off before proceeding with welding.

Fourth, a manifold gas system should not be used to supply shielding and backing gas. Individual argon gas cylinders have been found to provide optimum performance. A weld button spot test should be performed to confirm the integrity of the argon cylinder and all hose connections. In this test, the weld button sample should be absolutely bright and shiny. Any cloudiness is an indication of contamination. It is necessary to check for leaks or to replace the cylinder.

Fifth, it is important to remember that corrosion resistance is not the only criterion when evaluating these new ferritic stainless steels. Welds must also be tough and ductile, and these factors must be considered when fabricating welds.

Lastly, dissimilar weld filler metals can be successfully used. To avoid premature failure, the dissimilar combination should be corrosion tested to ensure suitability for the intended service.

Corrosion of Duplex Stainless Steel Weldments

In the wrought condition, duplex stainless steels have microstructures consisting of a fairly even balance of austenite and ferrite. The new generation of duplex alloys are now being produced with low carbon and a nitrogen addition. These alloys are useful because of their good resistance to chloride SCC, pitting corrosion, and intergranular corrosion in the as-welded condition. Nominal compositions of some duplex stainless steels are given in Table 4.

(a) Nominal unless otherwise indicated.

The distribution of austenite and ferrite in the weld and HAZ is known to affect the corrosion properties and the mechanical properties of duplex stainless steels. To achieve this balance in properties, it is essential that both base metal and weld metal be of the proper composition. For example, without nickel enrichment in the filler rod, welds can be produced with ferrite levels in excess of 80%. Such microstructures have very poor ductility and inferior corrosion resistance. For this reason, autogenous welding (without the addition of filler metal) is not recommended unless postweld solution annealing is performed, which is not always practical. To achieve a balanced weld microstructure, a low carbon content and the addition of nitrogen (with Alloy 2205 at least 0.12% N) should be specified for the base metal. Low carbon helps to minimize the effects of sensitization, and the nitrogen slows the precipitation kinetics associated with the segregation of chromium and molybdenum during the welding operation. Nitrogen also enhances the reformation of austenite in the HAZ and weld metal during cooling.

These duplex alloys have been used in Europe for many years; therefore, guidelines relating to austenite-ferrite phase distribution are available. It has been shown that to ensure resistance to chloride SCC welds should contain at least 25% ferrite. To maintain a good phase balance for corrosion resistance and mechanical properties (especially ductility and notch toughness) comparable to the base metal, the average ferrite content of the weld should not exceed 60%. This means using welding techniques that minimize weld dilution, especially in the root pass. Conditions that encourage mixing of the lower-nickel base metal with the weld metal reduce the overall nickel content. Weld metal with a lower nickel content will have a higher ferrite content, with reduced mechanical and corrosion properties. Once duplex base metal and welding consumables have been selected, it is then necessary to select joint designs and weld parameters that

will produce welding heat inputs and cooling rates so as to produce a favorable balance of austenite and ferrite in the weld and HAZ.

Researchers have shown that the high-ferrite microstructures that develop during welding in lean (low-nickel) base metal and weld metal compositions can be altered by adjusting welding heat input and cooling rate. In these cases, a higher heat input that produces a slower cooling rate can be used to advantage by allowing more time for ferrite to transform to austenite. There are, however, some practical aspects to consider before applying higher heat inputs indiscriminately. For example, as heat input is increased, base metal dilution increases. As the amount of lower-nickel base metal in the weld increases, the overall nickel content of the deposit decreases; this increases the potential for more ferrite, with a resultant loss in impact toughness, ductility, and corrosion resistance. This would be another case for using an enriched filler metal containing more nickel than the base metal. Grain growth and the formation of embrittling phases are two other negative effects of high heat inputs. When there is uncertainty regarding the effect that welding conditions will have on corrosion performance and mechanical properties, a corrosion test is advisable.

The influence of different welding conditions on various material properties of Alloy 2205 has been studied (Ref 16). Chemical compositions of test materials are given in Table 5, and the results of the investigation are detailed in the following sections.

Table 5 Chemical compositions of alloy 2205 specimens tested and filler metals used in Ref 16

Intergranular Corrosion. Despite the use of very high arc energies (0.5 to 6 kJ/mm, or 13 to 152 kJ/in.) in combination with multipass welding, the Strauss test (ASTM A 262, practice E) (Ref 10) failed to uncover any signs of sensitization after bending through 180°. The results of Huey tests (ASTM A 262, practice C) on submerged-arc welds showed that the corrosion rate increased slightly with arc energy in the studied range of 0.5 to 6.0 kJ/mm (13 to 152 kJ/in.). For comparison, the corrosion rate for parent metal typically varies between 0.15 and 1.0 mm/yr (6 and 40 mils/yr), depending on surface finish and heat treatment cycle.

Similar results were obtained in Huey tests of specimens from bead-on-tube welds produced by GTA welding. In this case, the corrosion rate had a tendency to increase slightly with arc energy up to 3 kJ/mm (76 kJ/in.).

Pitting tests were conducted in 10% ferric chloride ($FeCl_3$) at 25 and 30 °C (75 and 85 °F) in accordance with ASTM G 48 (Ref 17). Results of tests on submerged-arc test welds did not indicate any significant change in pitting resistance when the arc energy was increased from 1.5 to 6 kJ/mm (38 to 152 kJ/in.). Pitting occurred along the boundary between two adjacent weld beads. Attack was caused by slag entrapment in the weld; therefore, removal of slag is important.

Gas tungsten arc weld test specimens (arc energies from 0.5 to 3 kJ/mm, or 13 to 76 kJ/in.) showed a marked improvement in pitting resistance with increasing arc energy. In order for duplicate specimens to pass the $FeCl_3$ test at 30 °C (85 °F), 3 kJ/mm (76 kJ/in.) of arc energy was required. At 25 °C (75 °F), at least 2 kJ/mm (51 kJ/in.) was required to achieve immunity. Welds made autogenously (no nickel enrichment) were somewhat inferior, but improvements were achieved by using higher arc energies.

For comparison with a different alloy. Fig. 41 shows the effect of heat input on the corrosion resistance of Ferralium alloy 255 welds made autogenously and tested in $FeCl_3$ at 15 °C (60 °F). Preferential corrosion of the ferrite phase is shown in Fig. 42. In a different test, Ferralium alloy 255 was welded autogenously and tested in a neutral chloride solution according to ASTM D 1141 (Ref 19) at 60 to 100 °C (140 to 212 °F). In this case, preferential attack of the austenite phase was observed. An example is shown in Fig. 43. Similar results would be expected for alloy 2205.

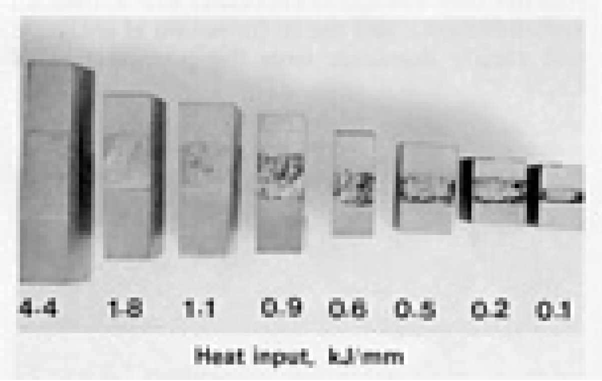

Fig. 41 Effect of welding heat input on the corrosion resistance of autogenous GTA welds in Ferralium alloy 255 in 10% $FeCl_3$ at 10 °C (40 °F). The base metal was 25.4 mm (1 in.) thick. Source: Ref 18

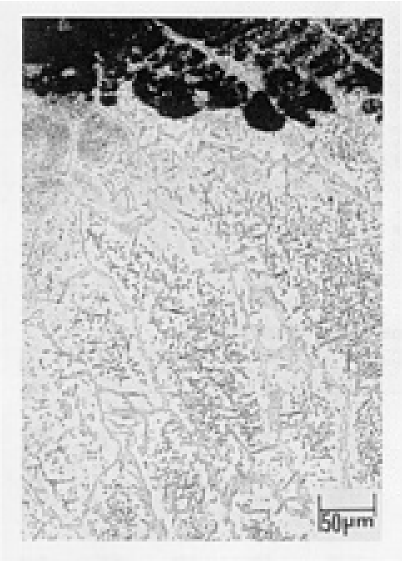

Fig. 42 Preferential corrosion of the ferrite phase in the weld metal of Ferralium alloy 255 GTA welds in 10% $FeCl_3$ at room temperature. Base metal was 3.2 mm ($\frac{1}{8}$ in.) thick.

Fig. 43 Preferential attack of the continuous austenite phase in an autogenous GTA weld in Ferralium alloy 255. Crevice corrosion test was performed in synthetic seawater according to ASTM D 1141 (Ref 19) at 100 °C (212 °F). Etched with 50% HNO_3. 100×

A study of the alloy 2205 weld microstructures (Ref 16) revealed why high arc energies were found to be beneficial to pitting resistance. Many investigations have indicated that the presence of chromium nitrides in the ferrite phase lowers the resistance to pitting of the weld metal and the HAZ in duplex stainless steels. In this study, both weld metal and HAZ produced by low arc energies contained an appreciable amount of chromium nitride (Cr_2N) (Fig. 44). The nitride precipitation vanished when an arc energy of 3 kJ/mm (76 kJ/in.) was used (Fig. 45).

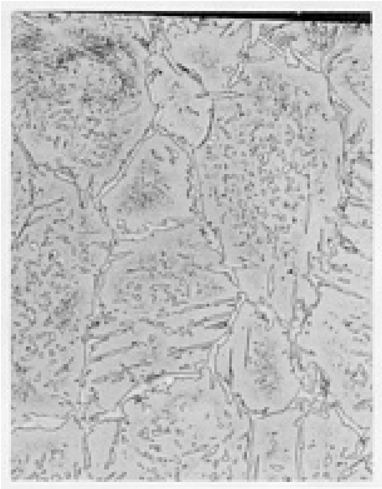

Fig. 44 Microstructure of bead-on-tube weld made by autogenous GTA welding with an arc energy of 0.5 kJ/mm (13 kJ/in.). Note the abundance of chromium nitrides in the ferrite phase. See also Fig. 45. 200×. Source: Ref 16

Fig. 45 Microstructure of bead-on-tube weld made by autogenous GTA welding with an arc energy of 3 kJ/mm (76 kJ/in.). Virtually no chromium nitrides are present, which results in adequate pitting resistance. 200×. Source: Ref 16

The results of $FeCl_3$ tests on submerged-arc welds showed that all top weld surfaces passed the test at 30 °C (85 °F) without pitting attack, irrespective of arc energy in the range of 2 to 6 ky/mm (51 to 152 kJ/in.). Surprisingly, the weld metal on the root side, which was the first to be deposited, did not pass the same test temperature.

The deteriorating effect of high arc energies on the pitting resistance of the weld metal on the root side was unexpected. Potentiostatic tests carried out in 3% NaCl at 400 mV versus SCE confirmed these findings. Microexamination of the entire joint disclosed the presence of extremely fine austenite precipitates, particularly in the second weld bead (Fig. 46) but also in the first or root side bead. The higher the arc energy, the more austenite of this kind was present in the first two weld beads. Thus, nitrides give rise to negative effects on the pitting resistance, as do fine austenite precipitates that were presumably reformed at as low a temperature as approximately 800 °C (1470 °F).

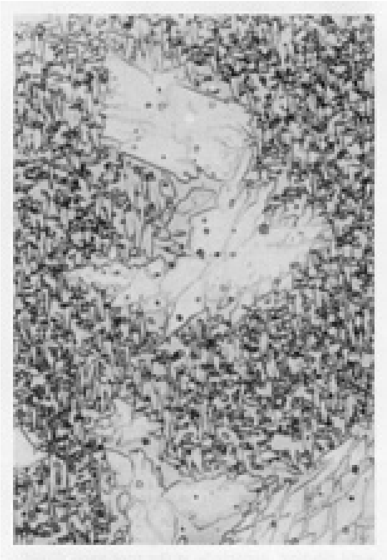

Fig. 46 Microstructure of the second weld bead of a submerged-arc weld joint in 20-mm ($\frac{3}{4}$-in.) duplex stainless steel plate. The extremely fine austenite precipitate was formed as a result of reheating from the subsequent weld pass, which used an arc energy of 6 kJ/mm (152 kJ/in.). 1000×. Source: Ref 16

Therefore, the resistance of alloy 2205 to pitting corrosion is dependent on several factors. First, Cr_2N precipitation in the coarse ferrite grains upon rapid cooling from temperatures above about 1200 °C (2190 °F) causes the most severe impairment to pitting resistance. This statement is supported by a great number of $FeCl_3$ tests as well as by potentiostatic pitting tests. Generally, it seems difficult to avoid Cr_2N precipitation in welded joints completely, particularly in the HAZ, the structure of which can be controlled only by the weld thermal cycle. From this point of view, it appears advisable to employ as high an arc energy as practical in each weld pass. In this way, the cooling rate will be slower (but not slow enough to encounter 475 °C (885 °F) embrittlement), and the re-formation of austenite will clearly dominate over the precipitation of Cr_2N.

In addition, if there were no restriction on maximum interpass temperature, the heat produced by previous weld passes could be used to decrease the cooling rate further in the critical temperature range above about 1000 °C (1830 °F). Preliminary tests with preheated workpieces have shown the significance of temperature in suppressing Cr_2N precipitation. Currently, the maximum recommended interpass temperature for alloy 2205 is 150 °C (300 °F). This temperature limit does not appear to be critical, and it is suggested that this limit could be increased to 300 °C (570 °F). The maximum recommended interpass temperature for Ferralium alloy 255 is 200 °C (390 °F). Excessive grain growth as a result of too much heat input must also be considered to avoid loss of ductility and impact toughness.

Second, the fine austenite precipitates found in the reheated ferrite when high arc energies and multipass welding were combined are commonly referred to as γ_2 in the literature. The harmful influence of γ_2 on the pitting resistance has been noted with isothermally aged specimens, but as far as is known, it has never been observed in connection with welding. It is felt, however, that γ_2 is less detrimental to pitting than Cr_2N. Moreover, γ_2 formation is believed to be beneficial to mechanical properties, such as impact strength and ductility.

A third factor that lowers pitting resistance is oxide scale. Where possible, all surface oxides should be removed by mechanical means or, preferably, by pickling. Root surfaces (in pipe), however, are generally inaccessible, and pitting resistance must rely on the protection from the backing gas during GTA welding. It is therefore advisable to follow the current recommendation for stainless steels, which is a maximum of 25 ppm oxygen in the root backing gas.

Stress-Corrosion Cracking. The SCC resistance of alloy 2205 in aerated, concentrated chloride solutions is very good. The effect of welding on the SCC resistance is negligible from a practical point of view. The threshold stress for various welds, as well as for unwelded parent metal in the $CaCl_2$ test, is as high as 90% of the tensile strength at the testing temperature. This is far above all conceivable design limits.

Also, in environments containing both hydrogen sulfide (H_2S) and chlorides, the resistance of welds is almost as high as for the parent metal. In this type of environment, however, it is important to avoid too high a ferrite content in weld metal and HAZ. For normal welding of joints, the resulting ferrite contents should not cause any problems. For weld repair situations, however, care should be taken so that extremely high ferrite contents (>75%) are avoided. To preserve the high degree of resistance to SCC, the ferrite content should not be less than 25% (Ref 20).

Another reason to avoid coarse weld microstructures (generated by excessive welding heat) is the resultant nonuniform plastic flow, which can locally increase stresses and induce preferential corrosion and cracking effects.

Use of High-Alloy Filler Metals. In critical pitting or crevice corrosion applications, the pitting resistance of the weld metal can be enhanced by the use of high nickel-chromium-molybdenum alloy filler metals. The corrosion resistance of such weldments in Ferralium alloy 255 is shown in Table 6. For the same weld technique, it can be seen that using high-alloy fillers does improve corrosion resistance. If high-alloy fillers are used, the weld metal with have better corrosion resistance than the HAZ and the fusion line. Therefore, again, proper selection of welding technique can improve the corrosion resistance of the weldments.

(b) HAZ plus weld metal

Corrosion of Nickel and High-Nickel Alloy Weldments

The corrosion resistance of weldments is related to the microstructural and microchemical changes resulting from thermal cycling. The effects of welding on the corrosion resistance of nickel-base alloys are similar to the effects on the corrosion resistance of austenitic stainless steels. For example, sensitization due to carbide precipitation in the HAZ is a potential problem in both classes of alloys. However, in the case of nickel-base alloys, the high content of such alloying elements as chromium, molybdenum, tungsten, and niobium can result in the precipitation of other intermetallic phases, such as μ, σ, and η.

Therefore, this section is concerned with the characteristics of the various nickel-base alloys and the evolution of these alloys. The corrosion resistance of weldments is dictated not only by the HAZ but also by the weld metal itself. The effect

of elemental segregation on weld metal corrosion must also be examined. The nickel-base alloys discussed in this section are the solid-solution alloys.

The nickel-molybdenum alloys, represented by Hastelloy alloys B and B-2, have been primarily used for their resistance to corrosion in nonoxidizing environments such as HCl. Hastelloy alloy B has been used since about 1929 and has suffered from one significant limitation: weld decay. The welded structure has shown high susceptibility to knife-line attack adjacent to the weld-metal and to HAZ attack at some distance from the weld. The former has been attributed to the precipitation of molybdenum carbide (Mo_2C); the latter, to the formation of M_6C-type carbides. This necessitated postweld annealing, a serious shortcoming when large structures are involved. The knife-line attack on an alloy B weldment is shown in Fig. 47. Many approaches to this problem were attempted, including the addition of carbide-stabilizing elements, such as vanadium, titanium, zirconium, and tantalum, as well as the lowering of carbon.

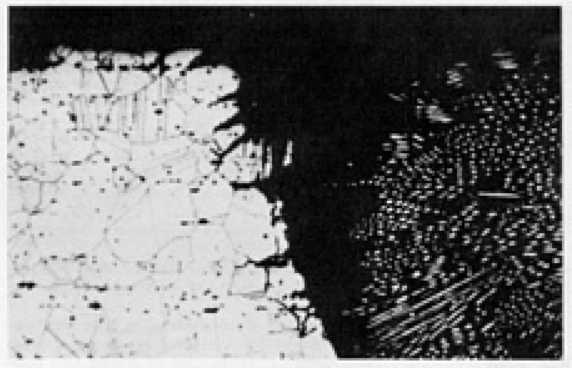

Fig. 47 Cross section of a Hastelloy alloy B weldment corroded after 16 days of exposure in boiling 20% HCl. 80×. Source: Ref 21

The addition of 1% V to an alloy B-type composition was first patented in 1959. The resultant commercial alloys--Corronel 220 and Hastelloy alloy B-282--were found to be superior to alloy B in resisting knife-line attack but were not immune to it. In fact, it was demonstrated that the addition of 2% V decreased the corrosion resistance of the base metal in HCl solutions. During this time, improvements in melting techniques led to the development of a low-carbon low-iron version of alloy B called alloy B-2. This alloy did not exhibit any propensity to knife-line attack (Fig. 48).

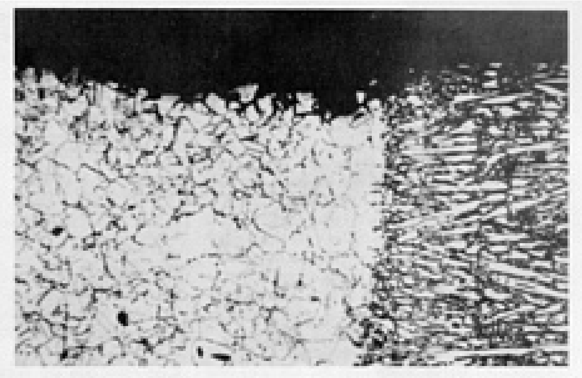

Fig. 48 Cross section of a Hastelloy alloy B-2 weldment after 16 days of exposure to boiling 20% HCl. 80×. Source: Ref 21

Segregation of molybdenum in weld metal can be detrimental to corrosion resistance in some environments. In the case of boiling HCl solutions, the weld metal does not corrode preferentially. However, in H_2SO_4 + HCl and H_2SO_4 + H_3PO_4 acid mixtures, preferential corrosion of as-welded alloy B-2 has been observed (Fig. 49). No knife-line or HAZ attack was noted in these tests. During solidification, the initial solid is poorer in molybdenum and therefore can corrode

preferentially. This is shown in Fig. 49 for an autogenous GTA weld in alloy B-2. In such cases, postweld annealing at 1120 °C (2050 °F) will be beneficial.

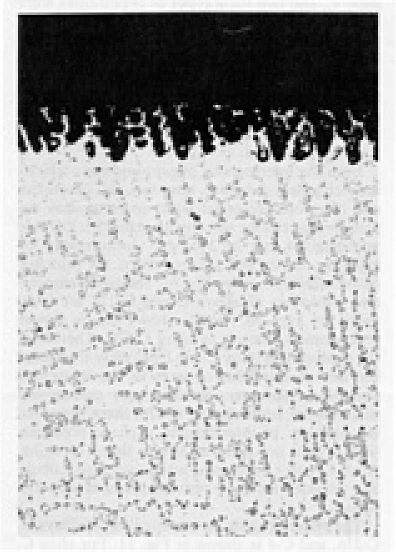

Fig. 49 Preferential corrosion of autogenous GTA weld in Hastelloy alloy B-2 exposed to boiling 60% H_2SO_4 + 8% HCl

The nickel-chromium-molybdenum alloys represented by the Hastelloy C family of alloys and by Inconel 625 have also undergone evolution because of the need to improve the corrosion resistance of weldments. Hastelloy alloy C (UNS N10002) containing nominally 16% Cr, 16% Mo, 4% W, 0.04% C, and 0.5% Si had been in use for some time but had required the use of postweld annealing to prevent preferential weld and HAZ attack. Many investigations were carried out on the nature of precipitates formed in alloy C, and two main types of precipitates were identified. The first is a Ni_7Mo_6 intermetallic phase called μ, and the second consists of carbides of the Mo_6C type. Other carbides of the $M_{23}C_6$ and M_2C were also reported. Another type, an ordered Ni_2Cr-type precipitate, occurs mainly at lower temperatures and after a long aging time; it is not of great concern from a welding viewpoint.

Both the intermetallic phases and the carbides are rich in molybdenum, tungsten, and chromium and therefore create adjacent areas of alloy depletion that can be selectively attacked. Carbide precipitation can be retarded considerably by lowering carbon and silicon; this is the principle behind Hastelloy alloy C-276. The time-temperature behaviors of alloys C and C-276 are compared in Fig. 50, which shows much slower precipitation kinetics in alloy C-276. Therefore, the evolution of alloy C-276 from alloy C enabled the use of this alloy system in the as-welded condition. However, because only carbon and silicon were controlled in C-276, there remained the problem of intermetallic μ-phase precipitation, which occurred at longer times of aging. Alloy C-4 was developed with lower iron, cobalt, and tungsten levels to prevent precipitation of μ phases.

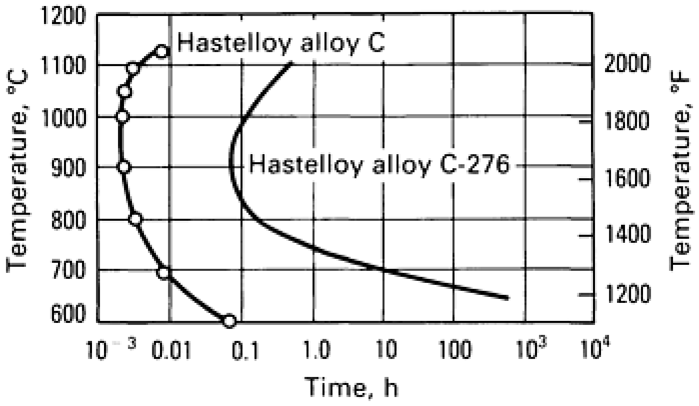

Fig. 50 Time-temperature transformation curves for Hastelloy alloys C and C-276. Intermetallics and carbide phases precipitate in the regions to the right of the curves. Source: Ref 22

The effect of aging on sensitization of alloys C, C-276, and C-4 is shown in Fig. 51. For alloy C, sensitization occurs in two temperature ranges (700 to 800 °C, or 1290 to 1470 °F, and 900 to 1100 °C, or 1650 to 2010 °F) corresponding to carbide and μ-phase precipitation, respectively. For alloy C-276, sensitization occurs essentially in the higher temperature region because of μ-phase precipitation. Also, the μ-phase precipitation kinetics in alloy C-276 are slow enough not to cause sensitization problems in many high heat input weldments; however, precipitation can occur in the HAZ of alloy C-276 welds (Fig. 52). Because C-4 has lower tungsten than C-276, it has lower pitting and crevice corrosion resistance, for which tungsten is beneficial. Therefore, an alternate solution to alloy C-4 was needed in which both corrosion resistance and thermal stability are preserved. Hastelloy alloy C-22 has demonstrated improved corrosion resistance and thermal stability.

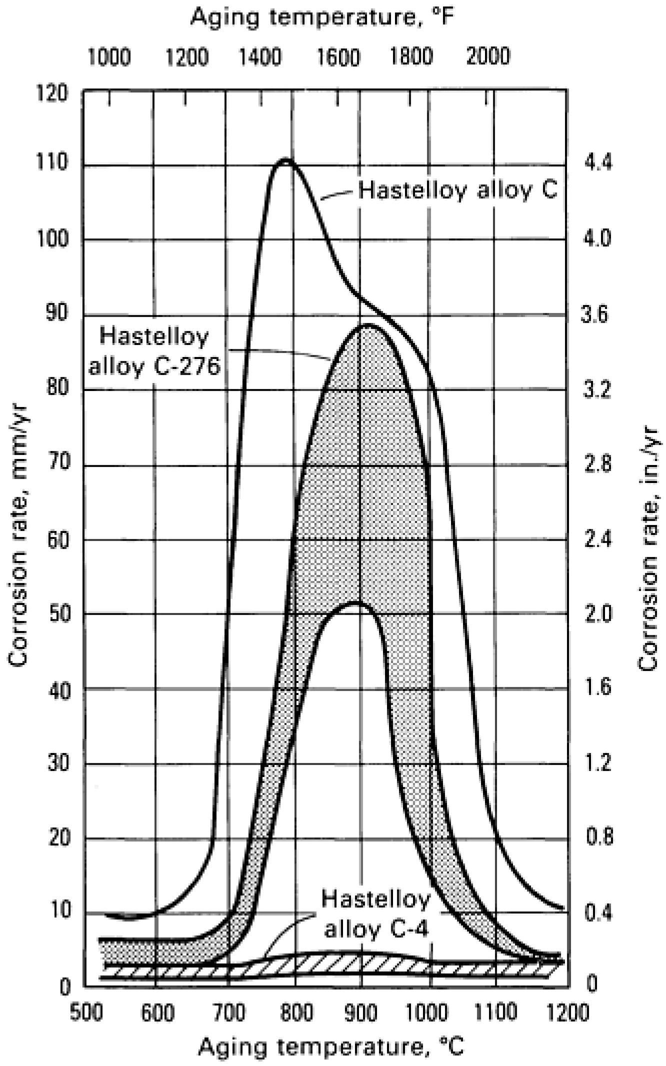

Fig. 51 Effect of 1-h aging treatment on corrosion resistance of three Hastelloy alloys in 50% H_2SO_4 + 42 g/L $Fe_2(SO_4)_3$. Source: Ref 23

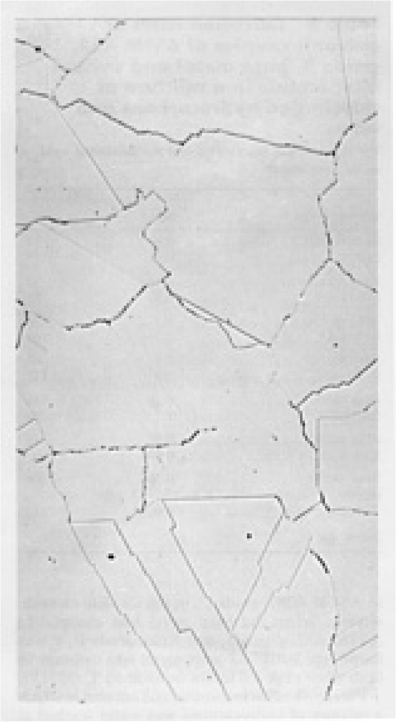

Fig. 52 Typical microstructure of the HAZ of a multipass submerged-arc weld in Hastelloy alloy C-276. Source: Ref 24

Because of the low carbon content of alloy C-22, the precipitation kinetics of carbides were slowed. Because alloy C-22 has lower molybdenum and tungsten levels than alloy C-276, μ-phase precipitation was also retarded.

From a weld HAZ point of view, this difference is reflected in lower grain-boundary precipitation even in a high heat input weld (Fig. 53). The HAZ microstructure of alloy C-4 was similar to this. This difference in the sensitization of the HAZ is also illustrated in Fig. 54, which shows that the HAZ and weld metal of alloy C-276 are attacked to a considerable extent in an oxidizing mixture of H_2SO_4, ferric sulfate ($Fe_2(SO_4)_3$), and other chemicals.

Corrosion of Carbon Steel Weldments

The corrosion behavior of carbon steel weldments is dependent on a number of factors. Consideration must be given to the compositional effects of the base metal and welding consumable and to the different welding processes used. Because carbon steels undergo metallurgical transformations across the weld and HAZ, microstructures and morphologies become important. A wide range of microstructures can be developed based on cooling rates, and these microstructures are dependent on energy input, preheat, metal thickness (heat sink effects), weld bead size, and reheating effects due to multipass welding. As a result of their different chemical compositions and weld inclusions (oxides and sulfides), weld metal microstructures are usually significantly different from those of the HAZ and base metal. Similarly, corrosion behavior can also vary.

In addition, hardness levels will be lowest for high heat inputs, such as those produced by submerged-arc weldments, and will be highest for low-energy weldments (with faster cooling rates) made by the shielded metal arc processes. Depending on the welding conditions, weld metal microstructures generally tend to be fine grained with basic flux and somewhat coarser with acid or rutile (TiO_2) flux compositions.

During welding, the base metal, HAZ, and underlying weld passes experience stresses due to thermal expansion and contraction. Upon solidification, rather high levels of residual stress remain as a result of weld shrinkage. Stress concentration effects as a result of geometrical discontinuities, such as weld reinforcement and lack of full weld penetration (dangerous because of the likelihood of crevice corrosion and the possibility of fatigue cracking), are also important because of the possibility of SCC. Achieving full weld penetration, minimizing excessive weld reinforcement through control of the welding process or technique, and grinding (a costly method) can be effective in minimizing these geometric effects. A stress-relieving heat treatment is effective in reducing internal weld shrinkage stress and metal hardness to safe levels in most cases.

Preferential HAZ Corrosion. An example of preferential weld corrosion in the HAZ of a carbon steel weldment is shown in Fig. 55. This phenomenon has been observed in a wide range of aqueous environments, the common link being that the environments are fairly high in conductivity, while attack has usually, but not invariably, occurred at pH values below about 7 to 8.

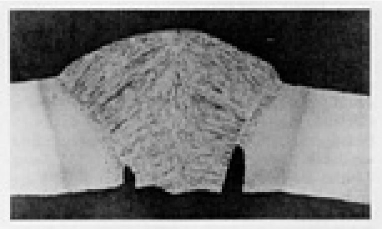

Fig. 55 Preferential corrosion in the HAZ of a carbon steel weldment after service in an aqueous environment. 5×. Source: Ref 25

The reasons for localized weldment attack have not been fully defined. There is clearly a microstructural dependence, and studies on HAZs show corrosion to be appreciably more severe when the material composition and welding are such that hardened structures are formed. It has been known for many years that hardened steel may corrode more rapidly in acid conditions than fully tempered material, apparently because local microcathodes on the metal surface stimulate the cathodic hydrogen evolution reaction. On this basis, water treatments ensuring alkaline conditions should be less likely to induce HAZ corrosion, but even at pHs near 8, hydrogen ion (H^+) reduction can account for about 20% of the total corrosion current; pH values substantially above this level would be needed to suppress the effect completely.

Preferential Weld Corrosion. It is probable that similar microstructural considerations also apply to the preferential corrosion of weld metal, but in this case, the situation is further complicated by the presence of deoxidation products, their type and number depending largely on the flux system employed. Consumable type plays a major role in determining weld metal corrosion rate, and the highest rates of metal loss are normally associated with shielded metal arc electrodes using a basic coating. In seawater, for example, the corrosion rate for a weld made using a basic-coated consumable may be three times as high as for weld metal from a rutile-coated consumable. Fewer data are available for submerged-arc weld metals, but it would appear than they are intermediate between basic and rutile shielded metal arc electrodes and that a corrosion rate above that of the base steel can be expected.

Galvanic-corrosion effects have also been observed and have caused unexpected failure of piping tankage and pressure vessels where the welds are anodic to the base metal (Ref 26). The following examples illustrate the point.

In one case, premature weld failures were experienced in a 102-mm (4-in.) ASTM A 53 pipe that was used to transfer a mixture of chlorinated hydrocarbons and water. During construction, the pipeline was fabricated with E7010-Al welding electrodes (see Table 7 for the composition limits for all materials discussed in these examples). Initial weld failures and subsequent tests showed the following welding electrodes to be anodic to the A53 grade B base metal: E7010-Al, E6010, E6013, E7010-G, and E8018-C2. Two nickel-base electrodes--Inco-Weld A (AWS A5.11, class ENiCrFe-2) and Incoloy welding electrode 135--were tested; they were found to be cathodic to the base metal and to prevent rapid weld corrosion. The corrosion rates of these various galvanic couples are listed in Table 8.

Table 7 Compositions of carbon steel base metals and some filler metals subject to galvanic corrosion

See Table 8 and 9 for corrosion rates of galvanic couples.

Another example is the failure of low-carbon steel welds in seawater service at 25 °C (75 °F). Fabrications involving ASTM A285, grade C, plate welded with E6013 electrodes usually start to fail in the weld after 6 to 18 months in seawater service at this temperature. Welds made with E7010 electrodes do not fail. Tests were conducted in seawater at 50 °C (120 °F) using A285, grade C, plate welded with E6010, E7010-Al, and E7010-G. It was determined that E7010-Al was the best electrode to use in seawater and that E6010 and E7010-G were not acceptable (although they were much better than E6013), because they were both anodic to the base metal. A zero resistance ammeter was used to determine whether the electrodes were anodic or cathodic in behavior.

In another case, welds made from E7010-Al electrodes to join ASTM A285, grade C, base metal were found to be anodic to the base metal when exposed to raw brine, an alkaline-chloride (pH > 14) stream, and raw river water at 50 °C (120 °F). When E7010-G was exposed to the same environment, it was anodic to the base metal in raw brine and raw river water and was cathodic to ASTM A285, grade C, in the alkaline-chloride stream. When the base metal was changed to ASTM A53, grade B, and A 106, grade B, it was found that E7010-Al weld metal was cathodic to both when exposed to raw brine at 50 °C (120 °F).

Finally, routine inspection of a column in which a mixture of hydrocarbons was water washed at 90 °C (195 °F) revealed that E7016 welds used in the original fabrication were corroding more rapidly than the ASTM A285, grade C, base metal. Corroded welds were ground to sound metal, and E7010-Al was used to replace the metal that was removed. About 3 years later, during another routine inspection, it was discovered that the E7010-Al welds were being selectively attacked. Tests were conducted that showed E7010-Al and E7016 weld metals to be anodic to A285, grade C, while E7018 and E8018-C2 would be cathodic. Corrosion rates of these various galvanic couples are given in Table 9.

Table 9 Corrosion rates of galvanic couples of ASTM A285, grade C, base metal and various filler metals at 90 °C (195 °F) in water used to wash a hydrocarbon stream

E8018-C2	**1.04**	**41**

Source: Ref 26

These examples demonstrate the necessity for testing each galvanic couple in the environment for which it is intended. Higher-alloy filler metals can sometimes be used to advantage to prevent rapid preferential weld corrosion.

Stress-Corrosion Cracking. There is no doubt that residual welding stresses can cause SCC in environments in which such failure represents a hazard. This is the case for failure by both active path and hydrogen embrittlement mechanisms, and in the latter case, failure may be especially likely at low heat input welds because of the enhanced susceptibility of the hardened structures inevitably formed. Most SCC studies of welds in carbon and carbon-manganese steels have evaluated resistance to hydrogen-induced SCC, especially under sour (H_2S) conditions prevalent to the oil and gas industry. Although full definition of the effect of specific microstructural types has not been obtained, an overriding influence of hardness is evident (Fig. 56). The situation regarding active path cracking is less clear, but there are few, if any, cases in

which SCC resistance increases at higher strength levels. On this basis, it is probable that soft, transformed microstructures around welds are preferable.

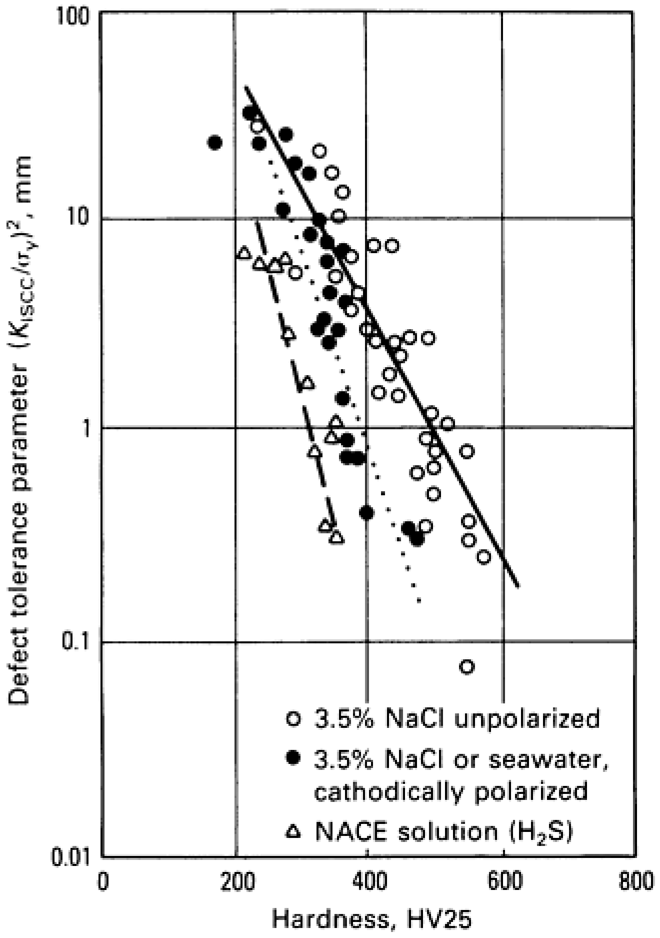

Fig. 56 SCC defect tolerance parameter versus hardness for carbon steel weldments in three environments. Data are derived from published tests on precracked specimens of various types of carbon steel base metals, HAZs, and weld metals. SCC defect tolerance parameter is dependent on crack length; details are available in Ref 25. Source: Ref 25

Carbon and low-alloy steels are also known to fail by SCC when exposed to solutions containing nitrates (NO_3^-). Refrigeration systems using a 30% magnesium nitrate ($Mg(NO_3)_2$) brine solution, for example, are commonly contained in carbon steel. In this case, pH adjustment is important, as is temperature. Failures in the HAZ due to SCC have been reported when brine temperatures have exceeded 30 °C (90 °F) during shutdown periods. To avoid these failures, carbon steel is being replaced with type 304L stainless. Others have stress relieved welded carbon steel systems and have operated successfully, although elevated-temperature excursions are discouraged.

More recently, it has been shown that cracking can occur under certain conditions in carbon dioxide (CO_2) containing environments, sometimes with spectacular and catastrophic results. Processes in the oil, gas, and chemical industries require removal of CO_2 from process streams by a variety of absorbants. In most cases, process equipment is fabricated from plain carbon steel.

SCC in Oil Refineries. Monoethanolamine (MEA) is an absorbant used to remove acid gases containing H_2S and CO_2 in oil refining operations. Recent failures in several refineries have shown that cracks can be parallel or normal to welds, depending on the orientation of principal tensile stresses. Cracking has been reported to be both transgranular and intergranular.

Before 1978, postweld stress relief of carbon steel weldments in MEA systems was performed only when the metal temperature of the equipment was expected to exceed 65 °C (150 °F) and the acid gas contained more than 80% CO_2 or when temperatures were expected to exceed 95 °C (200 °F) in any acid gas concentration.

Currently, any equipment containing MEA at any temperature and at any acid gas concentration is being postweld stress relieved. This is the result of surveys conducted by several refineries to define the extent of the SCC problem in this environment. These inspection programs showed that leaks were widespread and were found in vessels that ranged in age from 2 to 25 years. However, there were no reports of cracking in vessels that had been postweld stress relieved. In addition, it was found that all concentrations of MEA were involved and that MEA solutions were usually at relatively low temperatures (below 55 °C, or 130 °F). Equipment found to suffer from cracking included tanks, absorbers, carbon treater drums, skimming drums, and piping. The following example of a metallurgical investigation conducted by one oil refinery illustrates the problem of SCC of carbon steel in amine service (Ref 27).

Leaking Carbon Steel Weldments in a Sulfur Recovery Unit. In December 1983, two leaks were discovered at a sulfur recovery unit. More specifically, the leaks were at pipe-to-elbow welds in a 152-mm (6-in.) diam line operating in lean amine service at 50 °C (120 °F) and 2.9 MPa (425 psig). Thickness measurements indicated negligible loss of metal in the affected areas, and the leaks were clamped. In March 1984, 15 additional leaks were discovered, again at pipe-to-elbow welds of lean amine lines leading to two major refining units. The piping had been in service for about 8 years.

Investigation. Metallurgical examination of several of the welds revealed that leaking occurred at what appeared to be stress-corrosion cracks originating from the inside surface. Cracks were present in weld metal and base metal approximately 5 mm (0.2 in.) away from the weld, and they passed through the HAZ, as shown in Fig. 57. In other cases, stress-corrosion cracks also originated in the HAZ. The cracks typically ran parallel to the weld (Fig. 58).

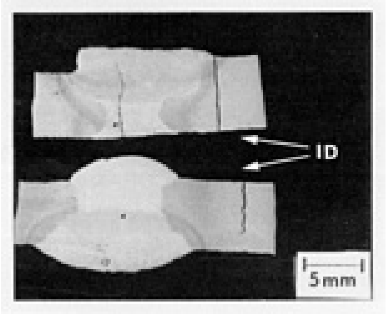

Fig. 57 Cross sections of pipe-to-elbow welds showing stress-corrosion cracks originating from the inside surface of the weld metal and the base metal. Source: Ref 27

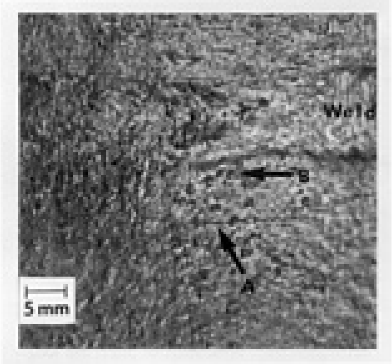

Fig. 58 Photograph of inside surface of a pipe showing 38-mm (1.5-in.) stress-corrosion crack (A) next to and parallel to a circumferential weld. Also shown are shallow corrosion pits (B). Source: Ref 27

Brinell hardness values, obtained by conversion of Knoop microhardness readings, were 133 to 160 (pipe base metal), 160 to 230 (weld metal), 182 to 227 (HAZs), and 117 to 198 (elbow base metal). The pipe base metal had an equiaxed fine-grain microstructure typical of low-carbon steel, and the elbow base metal had a nonequiaxed microstructure typical of hot-finished fittings. Carbon contents ranged from 0.25 to 0.30% by weight. Cracking was intergranular, as shown in Fig. 59 and 60.

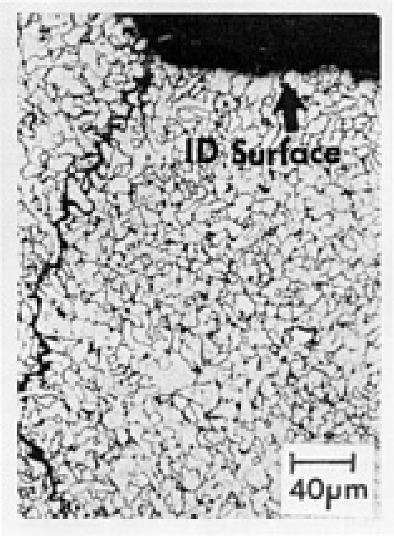

Fig. 59 Micrograph showing tight intergranular SCC originating at the inside surface of a pipe. Source: Ref 27

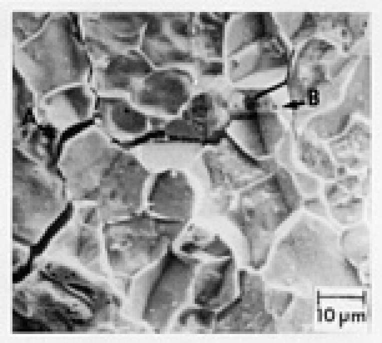

Fig. 60 SEM micrograph showing intergranular SCC (A) and initiation sites for pitting (B) on the inside surface of a pipe. Source: Ref 27

The refinery operators immediately embarked on a program of visual inspection of all amine lines. As of June 1985, a total of 35 leaks in lean amine piping had been discovered. All leaks were at cracks in or around pipe-to-elbow welds, except for two leaks at welds that connected a tee and reducer, respectively. Piping size ranged from 76 to 305 mm (3 to 12 in.). Service temperature ranged from 40 to 60 °C (100 to 140 °F), with most leaks having occurred in lines carrying lean amine at 55 °C (130 °F). Pressures ranged from atmospheric to 2.9 MPa (425 psig), with most leaks having occurred between 2.8 and 2.9 MPa (400 and 425 psig). All piping had been in service for about 8 years, except two leaks at piping welds that had been in service for only 4 years.

As had been generally accepted industry practice, the specifications called for stress relieving or postweld heat treatment of piping and vessels in amine service at temperatures above 95 °C (200 °F). Therefore it was highly unlikely that any of the leaking welds had received postweld heat treatment. Further metallurgical examination of leaking welds from various lines conclusively confirmed that the leaking originated at stress-corrosion cracks. No leaks were found in rich amine piping. The characteristics of the mode of fracture suggested that the failure mechanism was a form of caustic SCC.

It is interesting to note that other researchers also have metallographically examined numerous samples of similar cracks; their results can be summarized as follows:

- Cracks were essentially intergranular and were filled with gray oxide scale.
- Hardness of welds and HAZ's was less than 200 HB
- Cause of fracture was believed to be a form of caustic SCC
- Cracking occurs whether or not MEA solutions contain corrosion inhibitors

Preventive Measures. As a result of this particular investigation and others, all welds in equipment in MEA service are being inspected. Wet fluorescent magnetic-particle inspection after sandblasting to remove oxides and scale appears to be the most effective technique. Shear-wave ultrasonic (SWU) inspection has also been used for piping, but it does not always distinguish SCC and other defect indications, such as shrinkage cracks, slag inclusions, lack of fusion, or fatigue cracks. Nevertheless, SWU is considered helpful, because these other types of defects also can pose a threat to the structural integrity of the system in question. Inspection frequency is dependent on the critical nature of the particular equipment in question, and most important, all welds in these systems are now being postweld stress relieved.

Corrosion of Welds in Carbon Steel Deaerator Tanks. Deaerator tanks, the vessels that control free oxygen and other dissolved gases to acceptable levels in boiler feedwater, are subject to a great deal of corrosion and cracking. Several years ago, there were numerous incidences of deaerator tank failures that resulted in injury to personnel and property damage losses. Since that time, organizations such as the National Board of Boiler and Pressure Vessel Inspectors and the Technical Association of the Pulp and Paper Industry have issued warnings to plant operators, and these warnings have resulted in the formation of inspection programs for evaluating the integrity of deaerator tanks. As a result, many operators have discovered serious cracking problems. The following example illustrates the problem (Ref 28).

Weld Cracking in Oil Refinery Deaerator Vessels. Two deaerator vessels with associated boiler feedwater storage tanks operated in similar service at a refinery. The vertical deaerator vessels were constructed of carbon steel (shell and dished heads), with trays, spray nozzles, and other internal components fabricated of type 410 stainless steel. Boiler feedwater was treated by sand filtration using pressure filters, followed by ion-exchange water softening. Hardness was controlled at less than 0.5 ppm calcium carbonate ($CaCO_3$). A strong cationic primary coagulant (amine) was used to aid the filtering of colloidal material. Treated water was blended with condensate containing 5 ppm of a filming amine corrosion inhibitor. Final chemistry of the feedwater was controlled to the limits given in Table 10. Oxygen scavenging was ensured by the addition of catalyzed sodium bisulfite ($NaHSO_3$) to the storage tanks. Treated water entered the top of the tray section of the deaerators through five or six spray nozzles and was stored in the horizontal tanks below the deaerators.

Table 10 Chemistry limits on deaerator feedwater

Control parameter	Limit
Total hardness	**<0.5 ppm as $CaCO_3$**
Phenolphthalein alkalinity	**Trace (max)**
Methyl orange alkalinity	**14-18 ppm as $CaCO_3$**
Chloride	**7.6-8.8 ppm**
Total dissolved solids	**70-125 ppm**

Source: Ref 28

Inspection Results. Deaerator vessel and storage tank A were inspected. All tray sections were removed from the deaerator. With the exception of the top head to shell weld in the deaerator, all internal welds were ground smooth and magnetic particle inspected. No cracks were found. Corrosion damage was limited to minor pitting of the bottom head in the deaerator vessel.

Inspection of deaerator vessel B revealed cracking at one weld. Tray sections were removed from the deaerator vessel, and shell welds were gritblasted. Except for the top head to shell weld in the deaerator, all internal welds in both B units were then ground smooth and magnetic particle inspected. Three transverse cracks were found at the bottom circumferential weld in the deaerator vessel. These were removed by grinding to a depth of 1.5 mm (0.06 in.).

Inspection of storage tank B revealed numerous cracks transverse to welds. With the shell constructed from three rings of plate, the longitudinal ring welds were located just below the water level. These longitudinal welds exhibited no detectable cracking. One circumferential crack was found above the working water level in the vessel. The remaining cracks were located at circumferential welds below the working water level. Numerous cracks transverse to circumferential welds were detected, but only one longitudinal crack was detected. All cracks were removed by grinding to a depth of 2 mm (0.08 in.).

Unlike deaerator vessel A, it was noted that none of the spray nozzles in deaerator vessel B was operational at the time of inspection. In addition, two valves had fallen to the bottom of the deaerator vessel. The bottom section of trays in deaerator vessel B had fallen to the bottom of the storage vessel. Corrosion damage in deaerator vessel B was limited to underdeposit pitting attack at circumferential welds in the bottom.

Metallurgical Analysis. A section was cut from a circumferential weld region in storage tank B. As shown in Fig. 61, the cracking was predominantly transverse to the weld. Chemical analysis was performed on samples cut from weld metal and base metal; the results are given in Table 11. The results show that the steel plate was not aluminum- or silicon-killed, but was most likely a rimmed grade. Cross sections were cut perpendicular to both transverse and longitudinal cracks and were examined metallographically.

Source: Ref 28

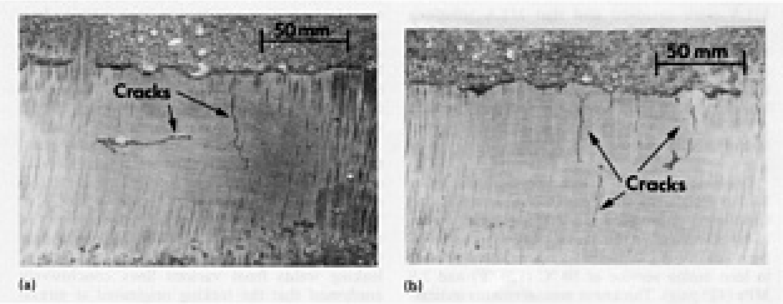

Fig. 61 Transverse and longitudinal cracks on as-ground weld areas on the inside surface of storage vessel B. (a) Transverse and longitudinal cracks. (b) Transverse cracks. Source: Ref 28

As shown in Fig. 62, metallographic examination of the base metal structures revealed ferrite and lamellar pearlite phases with a nearly equiaxed grain structure. The approximate grain size was ASTM 6 to 7. Figure 63 shows a longitudinal crack in a weld HAZ, with associated grain refinement. Cracking initiated from the bottom of a pit. The oxide associated with the major crack was extensive and contained numerous secondary cracks. Analysis of the oxide deposit within the crack by wavelength-dispersive spectroscopy revealed slightly less oxygen than an Fe_2O_3 standard. Therefore, it was assumed that the oxide deposit was a mixture of Fe_3O_4 and Fe_2O_3.

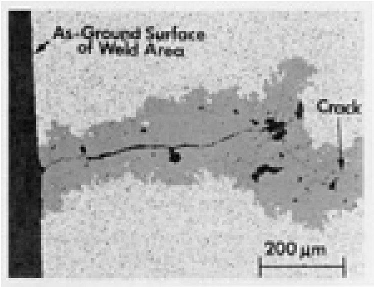

Fig. 63 Micrograph of a longitudinal crack in the HAZ of a weld from storage vessel B. Etched with nital. Source: Ref 28

Figure 64 shows a crack extending into base metal, transverse to the weld, with secondary cracking to the periphery of the oxidized region. It was clear that the oxide exhibited extensive internal cracking. Figure 64 also shows the entrainment of lamellar pearlite phase (dark) within the oxide corrosion product. In addition, the crack tips are blunt.

(c) Microcracks and entrained pearlite phase in the oxide corrosion product. (b) and (c) Etched with nital. Source: Ref 28

Discussion. The cracks described in this example are very similar to those found in many other investigations, despite a variety of deaerator vessel designs and operating conditions. Cracks typically display the following characteristics:

- Cracks occur most often in welds and HAZs, but can also occur in the based metal
- Cracks are generally transverse to the weld HAZ, and occur both parallel and perpendicular to the hoop stress direction
- The worst cracks appear to be located in circumferential and head-to-shell welds in horizontal vessel designs
- Cracks are concentrated at, but not solely located within, the working water level in the vessel
- Cracks are perpendicular to the vessel plate surface
- Cracks are predominantly transgranular with minor amounts of branching
- Cracks are filled with iron oxide. Cracking of the oxide corrosion product is followed by progressive corrosion. The ferrite phase is selectively attacked, with retention of the pearlite phase within the oxide corrosion product
- Cracks initiate from corrosion pits. Weld defects, however, can also become active sites for crack initiation
- Crack tips are blunt

Conclusions. These findings suggest that the failure mechanism is a combination of low-cycle corrosion fatigue and stress-induced corrosion. Extensive oxide formation relative to the depth of cracking is a key feature. The formation of oxide was associated with corrosion attack of the ferrite phase. The lamellar pearlite phase remained relatively intact and was contained within the oxide product. The oxide itself exhibited numerous cracks, allowing aqueous corrosion of fresh metal to occur at the oxide/metal interface. Mechanical or thermal stresses are most likely responsible for this network of cracks within the oxide product. The mechanism appears to be stress-assisted localized corrosion. Sharp, tight cracks were not found in fresh metal beyond the periphery of the oxide corrosion product. It therefore appears reasonable that cracking could have occurred subsequent to corrosion and within the brittle oxide.

Cracking at welds and HAZs suggests that residual weld shrinkage stresses play a major role. Welds in deaerator vessels typically have not been postweld stress relieved. It is not unusual to find residual welding stresses of yield strength magnitude. This problem can be aggravated by vessel design (high localized bending stresses around saddle supports that fluctuate with water level and are accelerated by operational upsets).

No fault was found with the steel plate chemical composition or with welding consumables. There was no evidence of embrittlement or caustic SCC (that is, no branched intergranular cracks).

Recommendations. All welds in deaerator vessels should be postweld stress relieved. Operational upsets should be avoided, and water chemistry must be maintained with acceptable limits. This is especially true with regard to water oxygen levels, which should be kept low to minimize pitting corrosion.

Corrosion Economic Calculations

Ellis D. Verink, Jr., Department of Materials Science and Engineering, University of Florida

Introduction

ENGINEERING ECONOMY is a discipline that can be used to assist engineers and engineering managers in measuring the economic impact of their decisions on the financial goals of a business. Basically, engineering economy is concerned with money as a resource and as the price of other resources. Business success requires the prudent and efficient use of all resources, including money. The principles of engineering economy permit direct comparisons of potential alternatives in monetary terms. In this way, they encourage efficient use of resources.

Corrosion is basically an economic problem. Thus, the corrosion behavior of materials is an important consideration in the economic evaluation of any project. It is not always wise to select the material with the lowest initial cost, because the initial cost is not necessarily the last cost. Overall costs include maintenance, downtime, time value of money, tax aspects, and obsolescence.

This article will discuss the principles and terminology of engineering economy and their application to a number of generic corrosion-related problems. Several of these problems appeared in NACE Standard RP-02-72 (Ref 1).

Money and Time

Consider the effects of time and earning power on $20. If $20 is placed in the bank and earns interest at a rate of 5% per year, it grows to $21 when the interest, $1, is paid at the end of the year. Thus, $20 today at 5% is equivalent to $21 a year from now. Stated another way, in order to have $21 one year from now, only $20 need be deposited today if the interest rate is 5%. The $20 is termed the discounted present value of the $21 needed 1 year from now. The initial deposit as well as the earned interest left in the account have earning power because the interest is compounded, which means that it is computed on both the principal and the accrued interest.

Suppose the $20 were used to pay four equal, annual installments of $5 each. Without interest, the $20 would be exhausted after making the last payment. If the $20 is deposited in the bank at 5% interest, it will be worth $21 at the end of the first year. Paying out $5 would leave $16 to be held at interest the second year. The $16 invested at 5% will earn $0.80 in 1 year. Subtracting $5 from $16.80 leaves $11.80 to be held at 5% interest for the third year. A sum of $11.80 will earn $0.59 by the end of the third year at 5%. Another annual payment of $5 leaves $7.39 to earn interest during the fourth year. Adding the $0.37 interest earned during the fourth year and subtracting the final $5 annual payment leaves a balance of accrued interest of $2.76.

The earning power of money permits another strategy. If the initial deposit were reduced to $17.73 at 5% interest, $5 can be paid out each year for 4 years, leaving nothing. This example illustrates the distinction between the terms equivalent and equal. Twenty dollars is equal to four payments of $5 each. It would also be equivalent to four $5 annual payments

(only) if the interest rate were 0. The $17.73 is not equal to the sum of four payments of $5 each. However, when $17.73 is invested at 5%, it is equivalent to four annual payments of $5.

The term equivalent implies that the concept of the time value of money is applied at some specific interest rate. Therefore, for an amount of money to have a precise meaning, it must be fixed both in time and amount. Mathematical formulas and tables are available to translate an amount of money at any particular time into an equivalent amount at another date.

Many kinds of translations are possible. For example, a single amount of money can be translated into an equivalent amount at either a later or an earlier date. This is accomplished by calculating the present worth (PW) or the future worth (FW) as of the present date. Single amounts of money can be translated into equivalent annuities, *A,* involving a series of uniform amounts occurring each year. Conversely, annuities can be translated into equivalent single amounts at an earlier or later date. The present worth of an annuity, *P/A,* is the single amount of money equivalent to a future annuity. The single amount equivalent to a past annuity is referred to as the future worth of an annuity, *F/A.*

It also is possible to calculate the amount of money that would be equivalent to a nonuniform series of cash flows. Two types of nonlinear series that find application are an arithmetic progression, in which the series changes by a constant amount, and a geometric progression, in which the series changes by a constant rate. The arithmetic progression is considered to be representative of variable costs, such as maintenance costs, which may increase as equipment ages. The geometric progression is used to represent the effects of inflation or deflation.

Money and Time

Consider the effects of time and earning power on $20. If $20 is placed in the bank and earns interest at a rate of 5% per year, it grows to $21 when the interest, $1, is paid at the end of the year. Thus, $20 today at 5% is equivalent to $21 a year from now. Stated another way, in order to have $21 one year from now, only $20 need be deposited today if the interest rate is 5%. The $20 is termed the discounted present value of the $21 needed 1 year from now. The initial deposit as well as the earned interest left in the account have earning power because the interest is compounded, which means that it is computed on both the principal and the accrued interest.

Suppose the $20 were used to pay four equal, annual installments of $5 each. Without interest, the $20 would be exhausted after making the last payment. If the $20 is deposited in the bank at 5% interest, it will be worth $21 at the end of the first year. Paying out $5 would leave $16 to be held at interest the second year. The $16 invested at 5% will earn $0.80 in 1 year. Subtracting $5 from $16.80 leaves $11.80 to be held at 5% interest for the third year. A sum of $11.80 will earn $0.59 by the end of the third year at 5%. Another annual payment of $5 leaves $7.39 to earn interest during the fourth year. Adding the $0.37 interest earned during the fourth year and subtracting the final $5 annual payment leaves a balance of accrued interest of $2.76.

The earning power of money permits another strategy. If the initial deposit were reduced to $17.73 at 5% interest, $5 can be paid out each year for 4 years, leaving nothing. This example illustrates the distinction between the terms equivalent and equal. Twenty dollars is equal to four payments of $5 each. It would also be equivalent to four $5 annual payments (only) if the interest rate were 0. The $17.73 is not equal to the sum of four payments of $5 each. However, when $17.73 is invested at 5%, it is equivalent to four annual payments of $5.

The term equivalent implies that the concept of the time value of money is applied at some specific interest rate. Therefore, for an amount of money to have a precise meaning, it must be fixed both in time and amount. Mathematical formulas and tables are available to translate an amount of money at any particular time into an equivalent amount at another date.

Many kinds of translations are possible. For example, a single amount of money can be translated into an equivalent amount at either a later or an earlier date. This is accomplished by calculating the present worth (PW) or the future worth (FW) as of the present date. Single amounts of money can be translated into equivalent annuities, *A,* involving a series of uniform amounts occurring each year. Conversely, annuities can be translated into equivalent single amounts at an earlier or later date. The present worth of an annuity, *P/A,* is the single amount of money equivalent to a future annuity. The single amount equivalent to a past annuity is referred to as the future worth of an annuity, *F/A.*

It also is possible to calculate the amount of money that would be equivalent to a nonuniform series of cash flows. Two types of nonlinear series that find application are an arithmetic progression, in which the series changes by a constant

amount, and a geometric progression, in which the series changes by a constant rate. The arithmetic progression is considered to be representative of variable costs, such as maintenance costs, which may increase as equipment ages. The geometric progression is used to represent the effects of inflation or deflation.

Notation and Terminology

American National Standards Institute (ANSI) standard Z94.5 (Ref 2), a compilation of the symbology and terminology of the field, offers to practitioners the improved communication benefits of standardization. With the development and publication of this standard and its adoption by the Institute of Industrial Engineers and the Engineering Economy Division of the American Society of Engineering Education, it is expected that future books and articles requiring symbols common to engineering economy will use these, because they represent the consensus choice of the prominent authors and educators in this field. This should eliminate one of the significant deterrents to the use of these methods in the past.

Table 1 lists the definitions and symbols used for parameters. Table 2 lists functional forms of compound interest factors. 3 is an explanatory supplement to Table 2, and it represents diagrams, algebraic forms, and uses for compound interest factors.

Table 1 Suggested standard definitions and symbols used for parameters

Definition of parameter	Symbol
Effective interest rate per interest period (discount rate)	i
Nominal interest rate per year	r
Number of compounding periods	n
Number of compounding periods per year	m
Present sum of money. The letter *P* implies present (or equivalent present value)	P
Future sum of money. The letter *F* implies future (or equivalent future value)	F
End-of-period cash flows (or equivalent end-of-period values) in a uniform series continuing for a specified number of periods. The letter *A* implies annual or annuity	A
Uniform period-by-period increase or decrease in cash flows (or equivalent values); the arithmetic gradient	G
Amount of money (or equivalent value) flowing continuously and uniformly during a given period	$\bar{P}$ **or** $\bar{F}$
Amount of money (or equivalent value) flowing continuously and uniformly during each and every period continuing for a specific number of periods	$\bar{A}$

Table 2 Functional forms of compound interest factors

See Table 3 for further explanation.

Factor number	**Factor name**	Functional format
Group I: all cash flows discrete: end-of-period compounding		
1	Compound amount factor (single payment)	**(*F/P*, *i*%, *n*)**
2	Present worth factor (single payment)	**(*P/F*, *i*%, *n*)**
3	Sinking fund factor	**(*A/F*, *i*%, *n*)**
4	Capital recovery factor	**(*A/P*, *i*%, *n*)**
5	Compound amount factor (uniform series)	**(*F/A*, *i*%, *n*)**
6	Present worth factor (uniform series)	**(*P/A*, *i*%, *n*)**
7	Arithmetic gradient conversion factor (to uniform series)	**(*A/G*, *i*%, *n*)**
8	Arithmetic gradient conversion factor (to present value)	**(*P/G*, *i*%, *n*)**
Group II: all cash flows discrete: continuous compounding		
9	Continuous compounding compound amount factor (single payment)	**(*F/P*, *r*%, *n*)**
10	Continuous compounding present worth factor (single payment)	**(*P/F*, *r*%, *n*)**
11	Continuous compounding sinking fund factor	**(*A/F*, *r*%, *n*)**
12	Continuous compounding capital recovery factor	**(*A/P*, *r*%, *n*)**
13	Continuous compounding compound amount factor (uniform series)	**(*F/A*, *r*%, *n*)**
14	Continuous compounding present worth factor (uniform series)	**(*P/A*, *r*%, *n*)**
Group III: continuous, uniform cash flows: continuous compounding (payments during one period only)		
15	Continuous compounding present worth factors (single, continuous payment)	$(P/\bar{F}, i\%, n)$

16	Continuous compounding compound amount factor (single, continuous payment)	**($F/\overline{P}$, i%, n)**
Group IV: continuous, uniform cash flows: continuous compounding (payments during a continuous series of periods)		
17	Continuous compounding sinking fund factor (continuous, uniform payments)	**($\overline{A}/F$, i%, n)**
18	Continuous compounding capital recovery factor (continuous, uniform payments)	**($\overline{A}/P$, i%, n)**
19	Continuous compounding compound amount factor (continuous, uniform payments)	**($F/\overline{A}$, i%, n)**
20	**Continuous compounding present worth factor (continuous, uniform, payments)**	**($P/\overline{A}$, i%, n)**

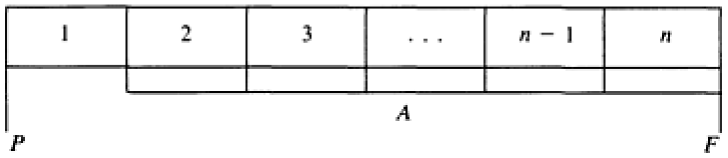
Table 3 Diagrams, algebraic forms, and uses for compound interest factors

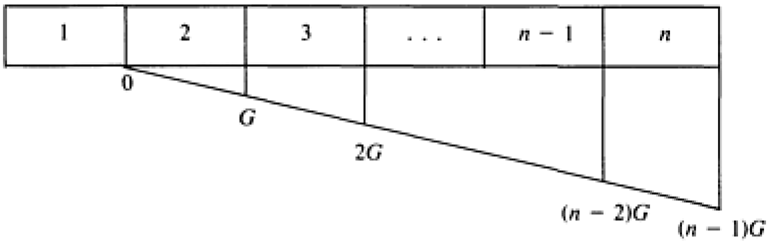
Factor number	Factor name	Algebraic form	Use when:
Group I: all cash flows discrete: end-of-period compounding			

Cash flow diagram for factors 1–6 (and 9–14):



Factor number	Factor name	Algebraic form	Use when:
1.	Compound amount factor (single payment)	$(1+i)^n$	Given P, to find F
2.	Present worth factor (single payment)	$(1+i)^{-n}$	Given F, to find P
3.	Sinking fund factor	$\dfrac{i}{(1+i)^n-1}$	Given F, to find A
4.	Capital recovery factor	$\dfrac{i(1+i)^n}{(1+i)^n-1}$	Given P, to find A
5.	Compound amount factor (uniform series)	$\dfrac{(1+i)^n-1}{i}$	Given A, to find F
6.	Present worth factor (uniform series)	$\dfrac{(1+i)^n-1}{i(1+i)^n}$	Given A, to find P

Cash flow diagram for factors 7 and 8:

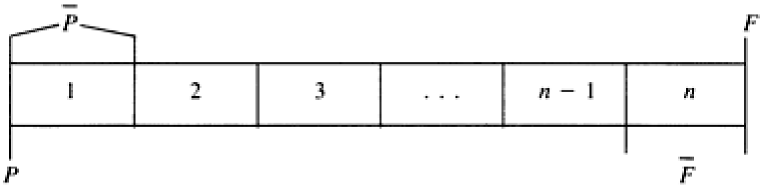


Factor number	Factor name	Algebraic form	Use when:
7.	Arithmetic gradient conversion factor (to uniform series)	$\left[\dfrac{1}{i}-\dfrac{n}{(1+i)^n-1}\right]$	Given G, to find A
8.	Arithmetic gradient conversion factor (to present value)	$\left[\dfrac{1}{i}-\dfrac{n}{(1+i)^n-1}\right]\left[\dfrac{(1+i)^n-1}{i(1+i)^n}\right]$	Given G, to find P
Group II: all cash flows discrete: continuous compounding			
9.	Continuous compounding compound amount factor (single payment)	e^{rn}	Given P, to find F
10.	Continuous compounding present worth factor (single payment)	e^{-rn}	Given F, to find P
11.	Continuous compounding sinking fund factor	$\dfrac{e^r-1}{e^{rn}-1}$	Given F, to find A
12.	Continuous compounding capital recovery factor	$\dfrac{e^{rn}(e^r-1)}{e^{rn}-1}$	Given P, to find A
13.	Continuous compounding compound amount factor (uniform series)	$\dfrac{e^{rn}-1}{e^r-1}$	Given A, to find F
14.	Continuous compounding present worth factor (uniform series)	$\dfrac{e^{rn}-1}{e^{rn}(e^r-1)}$	Given A, to find P

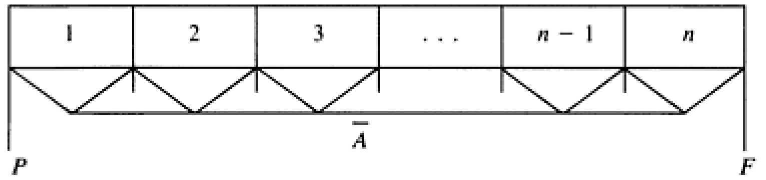
(continued)

Factor number	Factor name	Algebraic form	Use when:
Group III: continuous, uniform cash flows: continuous compounding (payments during one period only)			
Cash flow diagram for factors 15 and 16:			
15.	Continuous compounding present worth factor (single continuous payment)	$\frac{e^r - 1}{re^{rn}} = \frac{i(1+i)^{-n}}{\ln(1+i)}$	Given *F*, to find *P*
16.	Continuous compounding compound amount factor (single continuous payment)	$\frac{e^{rn}(e^r - 1)}{re^r} = \frac{i(1+i)^{n-1}}{\ln(1+i)}$	Given *P*, to find *F*
Group IV: continuous, uniform cash flows (payments during a continuous series of periods)			
Cash flow diagram for factors 17–20:			
17.	Continuous compounding sinking fund factor (continuous, uniform payments)	$\frac{r}{e^{rn} - 1} = \frac{\ln(1+i)}{(1+i)^n - 1}$	Given *F*, to find *A*
18.	Continuous compounding capital recovery factor (continuous, uniform payments)	$\frac{re^{rn}}{e^{rn} - 1} = \frac{(1+i)^n \ln(1+i)}{(1+i)^n - 1}$	Given *P*, to find *A*
19.	Continuous compounding compound amount factor (continuous, uniform payments)	$\frac{e^{rn} - 1}{r} = \frac{(1+i)^n - 1}{\ln(1+i)}$	Given *A*, to find *F*
20.	Continuous compounding present worth factor (continuous, uniform payments)	$\frac{e^{rn} - 1}{re^{rn}} = \frac{(1+i)^n - 1}{(1+i)^n \ln(1+i)}$	Given *A*, to find *P*

Cash flow diagram for factors 15 and 16:



Cash flow diagram for factors 17–20:



The basic form of the notation used for all time value factors consists of a ratio of two letters representing two amounts of money--for example, *P/A* or *F/P*--plus an interest rate, *i*%, and a number of periods, *n*. These are customarily written as (*P/A*, *i*%, *n*) or (*F/P*, *i*%, *n*). The present worth, *P*, of a known annuity, *A*, can also be expressed as:

$$P = A\left(\frac{P}{A}\right) \qquad \textbf{(Eq 1)}$$

Or the future worth, *F*, of a known present amount *P*, as:

$$F = P\left(\frac{F}{P}\right) \qquad \textbf{(Eq 2)}$$

Other forms are also common, such as PW( ) or FW( ), which are called operators because they represent some computational operation, such as the present worth or future worth of whatever is inside the parentheses.

It should be evident that (*F/P*) is the reciprocal of (*P/F*) and that (*F/A*) and (*A/F*) are also reciprocals. This observation is useful because it means that only three time factors need to be tabulated in order to conduct six operations. Another algebraic relationship shows that if two time value factors are multiplied, the product is a third time value factor. For example:

$$\left(\frac{A}{F}\right)\left(\frac{P}{A}\right)=\left(\frac{P}{F}\right) \qquad \textbf{(Eq 3)}$$

Methods of Economic Analysis

Economic analysis methods that concern the entire service life are sometimes called life-cycle-cost methods. Those methods that lead to single measure numbers include:

- Internal rate of return (IROR)
- Discounted payback (DPB)
- Present worth (PW), also referred to as net present value (NPV)
- Present worth of future revenue requirements (PWRR)
- Benefit-cost ratios (BCR)

All five methods use the concept of present worth. Although each method has certain advantages, the individual methods vary considerably with regard to their application and complexity.

The IROR method compares the initial capital investment with the present worth of a series of net revenues or savings over the anticipated service life. Expenses include operation, maintenance, taxes, insurance, and overheads, but do not include return on (or of) the invested capital. From an economic standpoint, IROR consists essentially of the interest cost on borrowed capital plus any existing (positive or negative) profit margin. The disadvantage of this measure of economy is that it ignores benefits extending beyond the assumed life of the equipment and thus may omit a substantial part of the actual service life. This may lead to unnecessarily pessimistic measures of long-range economy.

The PWRR method is particularly applicable to regulated public utilities, for which the rates of return are more or less fixed by regulation. It is also applicable where it has already been determined by IROR analysis that a project is economically viable; the engineer must determine which is the most economic alternative under circumstances in which several alternatives produce the same revenue, with some creating less expense (requirement for revenue) than others and consequently a greater profit margin (or lower losses). The principally objection to the PWRR method is that it is inadequate where alternatives are competing for a limited amount of capital, because it does not identify the alternative that produces the greatest return on invested capital.

The DPB and BCR methods are somewhat more complicated than the PWRR method. The BCR method is similar to the IROR method in that both require that alternatives be examined not only for economic measures compared to a "do nothing" scenario but also for incremental measures associated with incremental capital investments.

The PW method, also referred to as the net present value method, is considered the easiest and most direct of the five methods and has the broadest application to engineering economy problems. Many industries refer to this method as the discounted cash flow method of analysis. This method is often used to test the results of other methods of analysis. Therefore, because this method is often preferred, it will be given primary attention in this article.

Annual Versus Continuous Compounding

For completeness, Table 1, 2, and 3 contain formulas involving annual and continuous compounding. Because actual cash flow (both inward and outward) is continuous, continuous compounding might seem to be the more accurate assumption for engineering economy studies. In reality, although the overall cash flows tend to be continuous, the cash flow data are seldom precise enough in economy studies to take full advantage of continuous compounding. It is also true that the normal purpose of the economy study is to analyze some specific event that will occur at a specific time; therefore, a procedure that is readily associated with a specific time seems appropriate. For these reasons, and because it is conceptually easier to understand and apply, annual compounding will be used in this article.

The present worth method is a form of discounted cash flow in which cash flow data (which must include dates of receipts and disbursements) are discounted to present worth. Before applying these methods, a management decision must be made regarding the desired life (usually expressed as a number of years, *n*) and the minimum acceptable rate of return on invested capital for a project (expressed in terms of the effective interest rate, *i*, or the nominal rate or return, *r*). Rates of return (before taxes) vary among industries, ranging from 10 to 15% where obsolescence is not high to 25 to 40% (or perhaps higher) for more dynamic industries. It would be convenient if the minimum acceptable rate of return were known in advance of making engineering economy analyses; however, it is not always easy to learn what rate of return is considered to be acceptable. Under such circumstances, it is helpful to prepare a series of economic alternatives in which the rate of return is varied in order to provide management with options.

Applying the Present Worth Method. To illustrate the features of this method, it will be determined whether an expenditure of $15,000 should be made to reduce labor and maintenance from $8200 to $5100 per year. Money is worth 10%, and the life of the project is 10 years. The effects of taxes and depreciation have been omitted for simplicity.

Table 4 shows the projected pattern of cash flow for Plan A (the present method, which consists of paying $8200 per year for labor and maintenance) and for Plan B (the proposed method, which consists of an initial expenditure of $15,000 plus $5100 per year for labor and maintenance over the life of the project). A minus sign means that money leaves the bank; a plus sign means that the bank balance increases in size. The net cash flow for each year appears in the right hand column under the heading "B - A."

Table 4 Tabulation of cash flow

Period, years	**Plan A (the present method)**	**Plan B (the proposed method)**	B - A, dollars
0	. . .	-15,000	**-15,000**
1	-8200	-5100	**+3100**
2	-8200	-5100	**+3100**
3	-8200	-5100	**+3100**
4	-8200	-5100	**+3100**
5	-8200	-5100	**+3100**
6	-8200	-5100	**+3100**
7	-8200	-5100	**+3100**
8	-8200	-5100	**+3100**
9	-8200	-5100	**+3100**
10	-8200	-5100	**+3100**

Totals	-$82,000	-$66,000	+$16,000

Selection of Plan B will result in a net positive cash flow, that is, the net amount of money in the bank is increased over the life of the project when Plan B is selected. Before concluding that Plan B should be implemented, it is necessary to reduce these cash flows to a common basis for comparison and to determine whether the objective of a 10% rate of return has been achieved. The present worth (or present value) of these cash flows provides such a basis. The rate of return for Plan B is calculated by iteration, using interest tables and interpolating between values.

First Iteration. Assume a rate of return of 10% and refer to Table 5:

$$PW = -15000 + 3100\left(\frac{P}{A}10\%,\ 10\,years\right) = -15000 + 3100(6.145) = +\$4047.95 \qquad \textbf{(Eq 4)}$$

The rate of return for which the discounted cash flow is equal to 0 (that is, the first term on the right in Eq 4 is balanced by the second term) is the actual rate of return. From the first iteration, it is already evident that Plan B returns in excess of 10% because the net cash flow is positive. Thus, Plan B is preferred. The numerical value of the actual rate of return can be determined by additional iterations. Such an exercise will reveal that the rate of return in this case is 16.1%.

In this example, Plans A and B could represent alternative materials of construction having different corrosion rates, with the annual dollar difference being related to the consequences of corrosion on maintenance costs. This presupposes the availability of corrosion data that can be used to estimate expected life, maintenance costs, and so on. Other examples will illustrate how to account for the effects of salvage value, taxes, and depreciation.

Depreciation

Depreciation has been defined as the lessening in value of an asset with the passage of time. All physical assets (except land) depreciate with time. There are several types of depreciation. Two of the more common types are physical depreciation and functional depreciation. Accidents can also cause loss of value, but this cause is often accommodated in other ways, such as insurance and reserves, and therefore will not be considered in this article.

Physical depreciation includes such phenomena as deterioration resulting from corrosion, rotting of wood, bacterial action, chemical decomposition, and wear and tear, which can reduce the ability of an asset to render its intended service. Functional depreciation does not result from the inability of an asset to serve its intended purpose but rather from the fact that some other asset is available that can perform the desired function more economically. Thus, obsolescence, inadequacy, and/or the inability to meet the demands placed on the asset lead to functional depreciation. Technological advances produce improvements that often result in the obsolescence of existing assets.

The manner in which depreciation can be accounted for is largely a tax question. The tax laws specify the procedures that are permissible. Because tax laws change occasionally, procedures that are attractive under a given set of circumstances may become unattractive (or even forbidden) under other circumstances. Some of the more common methods of depreciation include:

- Straight line
- Declining balance
- Declining balance switching to straight line
- Sum of the year's digits
- Accelerated cost recovery system

The straight-line depreciation method assumes that the value of an asset declines at a constant rate. If the original cost *P* of the asset was $6000 and the asset had a salvage value *S* of $1000 after a service life of 5 years, the annual depreciation would be ($6000 - 1000)/5 -- $1000 per year. Annual depreciation *D* can be expressed as:

$$D = \frac{(P - S)}{n} \qquad \textbf{(Eq 5)}$$

The book value of the asset would decrease at the end of each year by the amount of the annual depreciation until, at the end of the fifth year, the book value would be the same as the salvage value.

The declining-balance method assumes that the asset depreciates more rapidly during the early years of its service life than in the later years. A certain percent depreciation is applied each year to the remaining book value of the asset. Under these circumstances, the size of the depreciation declines with each successive year until the asset is fully depreciated. When the declining-balance method is used, the maximum rate that has been permissible for tax purposes is double the straight-line rate. This accounts for the term double-declining balance. In addition, before 1981, businesses were allowed to depreciate an asset by using declining-balance depreciation for the early years, followed by straight-line depreciation when the allowable depreciation (using declining balance) fell below the amount permissible under straight-line depreciation.

The sum of the year's digits method assumes that the value of an asset decreases at a decreasing rate. Assume that an asset has a 5-year life. The sum of the year's digits equals 1 + 2 + 3 + 4 + 5 = 15. For the $6000 asset mentioned above, which has a salvage value after 5 years of $1000, depreciation for the first year would be ($6000 - 1000) (5/15) = $1666.67. Depreciation for the second year would be ($6000 - 1000) (4/15) = $1333.33, and so on, until the asset is fully depreciated.

Most of the property acquired before 1981 is still being depreciated by one of the methods mentioned above. Each of these (pre-1981) methods requires the taxpayer to estimate a useful life based on experience or on an Internal Revenue Service (IRS) Guideline. The guidelines are presented as ranges of values in the class life asset depreciation range (ADR) system. The midpoint of the range is referred to as the ADR life.

Other Methods. For property placed in service after 1981, the accelerated cost recovery system (ACRS), which is a part of the Economy Recovery Act of 1981, prescribed a different method for recovering the cost of depreciable property. The accelerated cost recovery system provides that eligible depreciable assets be assigned to one of only four classes of property based on expected useful life:

- *Three-year property* includes automobiles, light-duty trucks, research and experimental equipment, and other equipment having an ADR life of 4 years or less
- *Five-year property* includes all personal property as well as most production equipment and public utility property with an ADR life between 5 and 18 years
- *Ten-year property* includes public utility property with an ADR life between 18 and 25 years as well as real property with an ADR life less than or equal to $12\frac{1}{2}$ years
- *Fifteen-year property* includes depreciable real property with an ADR life greater than $12\frac{1}{2}$ years as well as public utility property with an ADR life greater than 25 years

Table 6 lists depreciation percentages for the ACRS classes. After property has been assigned to the proper ACRS class, the depreciation rate is prescribed by the IRS and is based on the declining-balance method and a depreciation rate of (150%/*n*). The method switches to straight-line depreciation when the declining-balance depreciation falls below the straight-line depreciation. For 15-year property, the rate for the first year is one-half that of the second year on the assumption that the property will be used for only one-half of the first year (Table 6).

Table 6 Depreciation percentages for ACRS classes

Recovery years is	Classes of property			
	3-year	**5-year**	**10-year**	15-year public utility
1	25	15	8	**5**
2	38	22	14	**10**
3	37	21	12	**9**
4	. . .	21	10	**8**
5	. . .	21	10	**7**
6	. . .	. . .	10	**7**
7	. . .	. . .	9	**6**
8	. . .	. . .	9	**6**
9	. . .	. . .	9	**6**

10	. . .	. . .	9	**6**
11	. . .	. . .	. . .	**6**
12	. . .	. . .	. . .	**6**
13	. . .	. . .	. . .	**6**
14	. . .	. . .	. . .	**6**
15	**. . .**	**. . .**	**. . .**	**6**

The percentages listed in Table 6 are applied to the original cost of the asset with no consideration for future salvage value. If there is an actual salvage value at the time the asset is retired, the tax liability is determined after taking into account the actual salvage amount and the (then) book value. Table 7 gives an example of ACRS depreciation.

Table 7 An example of ACRS depreciation

End of year	**Depreciation charges during year**	Book value at end of year, dollars
0	. . .	**6000**
1	(0.15)($6000) = $ 900	**5100**
2	(0.22)($6000) = 1320	**3780**
3	(0.21)($6000) = 1260	**2520**
4	(0.21)($6000) = 1260	**1260**
5	**(0.21)($6000) = 1260**	**0**

The only other option under ACRS is straight-line depreciation using the recovery periods shown in Table 8. The taxpayer may select one of the three optional recovery periods appropriate for the applicable ACRS property class. Salvage values are ignored.

Table 8 Straight-line recovery periods for ACRS

Class of property	Optional recovery periods, years
3-year	**3, 5, or 12**
5-year	**5, 12, or 25**
10-year	**10, 25, or 35**
15-year	**15, 35, or 45**

Generalized Equations

It is possible to prepare generalized equations that will simplify the solution of a large percentage of engineering economy problems. These equations take into account the influence of taxes, depreciation, operating expenses, and salvage value in the calculation of present worth and annual cost. Using these equations, a problem can be solved merely by entering data into the equations with the assistance of the compound interest tables and solving for the unknown value. The tax rate *t* is expressed as a decimal. Operating expense is represented by *X.* The letter *S* represents salvage value. The other symbols are explained in Tables 1, 2, and 3.

For straight-line depreciation:

$$PW = -P + \left\{ \frac{t(P-S)}{n} \right\} \left(\frac{P}{A,} i\%, n \right)$$

$$-(1-t)(X)\left(\frac{P}{A,} i\%, n \right) + S\left(\frac{P}{F,} i\%, n \right) \qquad \textbf{(Eq 6)}$$

where *P,* the first term, is the cost at time zero of the initial investment. The value at time zero is a definition of present worth (at time zero). Therefore, it is not necessary to translate this amount to another date, because the evaluation will be made as of time zero. The investment involves flow of money out of the bank; therefore, the sign of this term is minus.

The second term in Eq 6 concerns depreciation. The depreciation method will influence the mathematical formation of this term. The portion enclosed in braces expresses the annual amount of tax credit permitted by this method of depreciation--in this case, straight-line depreciation. The portion in parentheses translates these equal annual amounts back to time zero by converting them to present worth. The ACRS depreciation methods allow specific straight-line depreciation options. When one of these options is chose, the formulation of this term remains the same as shown above, with the exception that salvage is ignored. If the straight-line option is not chosen, this term in the generalized formula becomes a series of terms, each having the tax rate multiplied by the appropriate depreciation percentage of the initial cost (in accordance with Table 6) multiplied by the appropriate single-payment present worth factor, *P/F,* for the applicable year and interest rate. The sum of these terms will represent the effect of depreciation on present worth.

The third term in Eq 6 actually consists of two terms. One is [(*X*) (*P/A*, *i*%, *n*)], which represents the cost of items properly chargeable as expense, such as the cost of maintenance or insurance and the cost of inhibitors. Because this term involves expenditure of money from the bank, it carries a minus sign. The term [*t*(*X*) (*P/A*, *i*%, *n*)] accounts for the tax credit for this business expense. Because it represents a savings, the sign is plus.

The fourth term translates the anticipated (future) value of salvage to present value. This is a one-time event rather than a uniform series and therefore involves the single-payment present worth factor. As noted above, the ACRS depreciation method ignores the salvage value of an asset; therefore, when using the ACRS method, the fourth term is 0.

Present worth can be converted to equivalent annual cost *A* by:

$$A = (PW)\left(\frac{A}{P,}i\%, n\right) \quad \textbf{(Eq 7)}$$

Alternative materials with the same life can be compared from an engineering economy standpoint merely by comparing the magnitude of their present values. However, if the candidate materials have different life expectancies, it is necessary to convert present worth to equivalent annual cost *A* to compare the materials from an engineering economy standpoint. The material with the lowest annual cost is the material of choice.

Examples and Applications

Example 1. A new heat exchanger is required in conjunction with a rearrangement of existing facilities. Because of corrosion, the expected life of a carbon steel exchanger is 5 years. The installed cost is $9500. An alternative to the carbon steel heat exchanger is a unit fabricated of AISI type 316 stainless steel with an installed cost of $26,500 and an estimated life of 15 years to be written off in 11 years. The minimum acceptable rate of return is 10%, the tax rate is 48%, and the depreciation method is straight line. It is necessary to determine which unit would be more economical based on annual costs.

Because the lives of the two heat exchangers are unequal, the economic choice cannot be based merely on the discounted cash flow over a single life of each alternative. Instead, comparison must be made on the basis of equivalent uniform annual costs, commonly referred to as annual cost, as mentioned above. In this example, data are given for only the first two terms of Eq 6. The third term, which involves maintenance expense, and the fourth term involving salvage value are both assumed to be 0.

The first step is to compute the discounted cash flow over one life span for each alternative. This involves calculation of the present worth for each material:

$$PW_{steel} = -\$9500 + \left\{0.48\frac{(9500-0)}{5}\right\}(3.791) = -\$6043 \quad \textbf{(Eq 8)}$$

$$PW_{316} = -\$26500 + \left\{0.48\frac{(26500-0)}{11}\right\}(6.495) = -\$18989 \quad \textbf{(Eq 9)}$$

To compare the two alternatives, both discounted cash flows (the present worths) must be converted to annual costs:

$$A_{\text{steel}} = -\$6043(0.2638) = -\$1594 \quad \textbf{(Eq 10)}$$

$$A_{316} = -\$18{,}989(0.15396) = -\$2924 \quad \textbf{(Eq 11)}$$

Therefore, the carbon steel heat exchanger, which has the lower annual cost, is the more economical alternative under these conditions.

Example 2. In this case, the carbon steel heat exchanger in Example 1 will require $3000 in yearly maintenance (painting, use of inhibitors, cathodic protection, and so on). It will be determined whether carbon steel would remain the preferred alternative under these conditions.

Maintenance costs are treated as expense items with a 1-year life (end-of-year costs). This example involves the third term in Eq 6. In Example 1, the annual cost without the yearly maintenance cost was calculated; therefore, in this example, the annual cost including maintenance ($3000 per year) can be obtained simply by subtracting the after-tax maintenance costs from the result given in Example 1:

$$A_{\text{steel}} = -\$1594 - (1 - 0.48)(\$3000) = -\$3154 \quad \textbf{(Eq 12)}$$

Because this is an after-tax cash flow, the quantity [(1 - 0.48)($3000)] is the after-tax maintenance cost; 0.48 is the tax rate expressed as a decimal. The $3000 is the present value of the maintenance for the first year; therefore, no further discounting is necessary in this case. Comparing this result with the annual cost of AISI type 316 stainless steel in Example 1, it is evident that if $3000 is required each year to keep the carbon steel unit operative, the stainless steel unit would be more economical.

Example 3. Given the conditions described in Example 1, this example will determine the service life at which the carbon steel heat exchanger is economically equivalent to the type 316 stainless steel unit if it is not certain that a 5-year life will be attained for unprotected carbon steel.

The carbon steel heat exchanger will be economically equivalent to the type 316 stainless steel heat exchanger when their annual costs are equal. Therefore, the problem can be solved by determining how many years of life for steel will be equivalent to an annual cost of $2924. Trial and error methods are useful for such problems. Trying $n = 3$ years gives:

$$PW_{steel} = -\$9500 + 0.48\left\{\frac{(9500-0)}{3}\right\}(2.487) = -\$5719 \quad \textbf{(Eq 13)}$$

$$A_{\text{steel}} = -\$5719(0.40211) = -\$2300 \quad \textbf{(Eq 14)}$$

Trying $n = 2$ years yields:

$$PW_{steel} = -\$9500 + 0.48\left\{\frac{(9500-0)}{2}\right\}(1.736) \quad \textbf{(Eq 15)}$$

$$A_{\text{steel}} = -\$5542(0.57619) = -\$3193 \quad \textbf{(Eq 16)}$$

Thus, a carbon steel heat exchanger must last more than 2 years, but will be economically favored in less than 3 years under the conditions given.

Example 4. Under the conditions described in Example 3, it will be determined how much product loss X could be tolerated after 2 of the 5 years of anticipated life, for example, from roll leaks or a few tube failures, before the selection of type 316 stainless steel could have been justified. Equating:

$$A_{316} = A_{\text{steel}} + A_{\text{product loss}}$$
$$-\$2924 = -\$1594 + [(1 - 0.48)(X)(0.8264)][0.2638] \quad \textbf{(Eq 17)}$$

Solving for X:

$$-\$1330 = 0.1134(X)$$
$$X = -\$11{,}728 \quad \textbf{(Eq 18)}$$

The term (1 - 0.48) will be recognized from the third term of Eq 6 as (1 - t) where t is the tax rate. The quantity 0.8264 is the single-payment present worth factor, (*P/F*, 10%, 2 years) and translates the product loss X to its present worth at time zero. The quantity [0.2638] is the uniform series capital recovery factor, (*A/P*, 10%, 5 years) and translates the present worth of the product loss to annual cost so that it can be added to the annual cost of steel for comparison with the annual cost of AISI type 316 stainless steel. If production losses exceed $11,728 in year two (no losses in other years), the AISI type 316 heat exchanger could be justified.

Fundamentals of Corrosion Protection in Aqueous Solutions

Henry Leidheiser, Jr., Lehigh University

Introduction

THE IMPORTANT METALS in structures--aluminum, copper, iron, zinc, and so on--are inherently unstable. Their ionic solutions and their carbonates, hydroxides, oxides, sulfides, sulfates, and many other salts are more stable than the free metal under the many conditions to which these metals are exposed. The free energy change for the conversion of these metals to a compound is a large negative value, and the thermodynamic driving force to convert the elemental metal to an oxide or salt is great. Thus, to retain a required physical property of the metal, such as strength, thermal conductivity, magnetic nature, or electrical conductivity, it is essential to protect the metal from the environments to which it is expected to be exposed. This article will describe the various methods that can be used to protect a metallic system against corrosion. These methods can be divided into the following: thermodynamic protection, kinetic protection, barrier protection, structural design, environmental control, and metallurgical design.

The objective of most protective systems is to reduce the rate of corrosion to a value that is tolerable or that will allow the material to attain its normal or desired lifetime. Only in a limited number of cases must corrosion protection be designed to eliminate corrosion completely.

Protection on a Thermodynamic Basis

This type of protection is based on the requirement that the metal have a high positive value for the free energy change for conversion of the metal to the corrosion products that can form in the environment to which the metal is exposed. For example, the free energy change for the conversion of gold to its oxide is 163,000 J/mol (39,000 cal/mol), and for the conversion of silver to its ion at standard state in an aqueous phase, the free energy change is 77,000 J/mol (18,430 cal/mol). These two metals could *a priori* be expected to resist corrosion when exposed to oxygenated pure water, because the tendency in these systems is for the metal to be more stable than its aquated ion or its oxide. As a general rule, a metal M whose thermodynamic potential in contact with its ions is a high positive value for the reaction $M - ne^- \rightarrow M^{n+}$ is stable in aqueous solutions at room temperature. No blanket statement can be made without full knowledge of the composition of the aqueous phase because some ions and other complexing agents may form complexes that are more thermodynamically stable than the free metal.

Another form of thermodynamic protection is obtained when an external potential is applied such that the metal is stable with respect to the metal ion concentration in the aqueous phase with which it is in contact. For example, if nickel immersed in an aqueous solution of pH 4 is polarized externally to a potential of -0.5 V, elemental nickel is stable with respect to its ions, and nickel will be protected from corrosion. However, this potential is more negative than the potential for the generation of hydrogen, and hydrogen formation may occur. These facts are illustrated in the Pourbaix (potential versus pH) diagram for nickel shown in Fig. 1. The dashed line labeled A represents the phase boundary for the equilibrium, $H_2 \rightarrow 2H^+ + 2e^-$, with hydrogen at unit fugacity being stable below this line and the hydrogen ion (H^+) at unit activity stable above this line. More detailed information about Fig. 1 can be found in Ref 1. This type of diagram is very useful for appraising the relative thermodynamic stabilities of the metal with respect to its ions and its hydrous and anhydrous oxides. Stability diagrams for metals in contact with water are given in Ref 1.

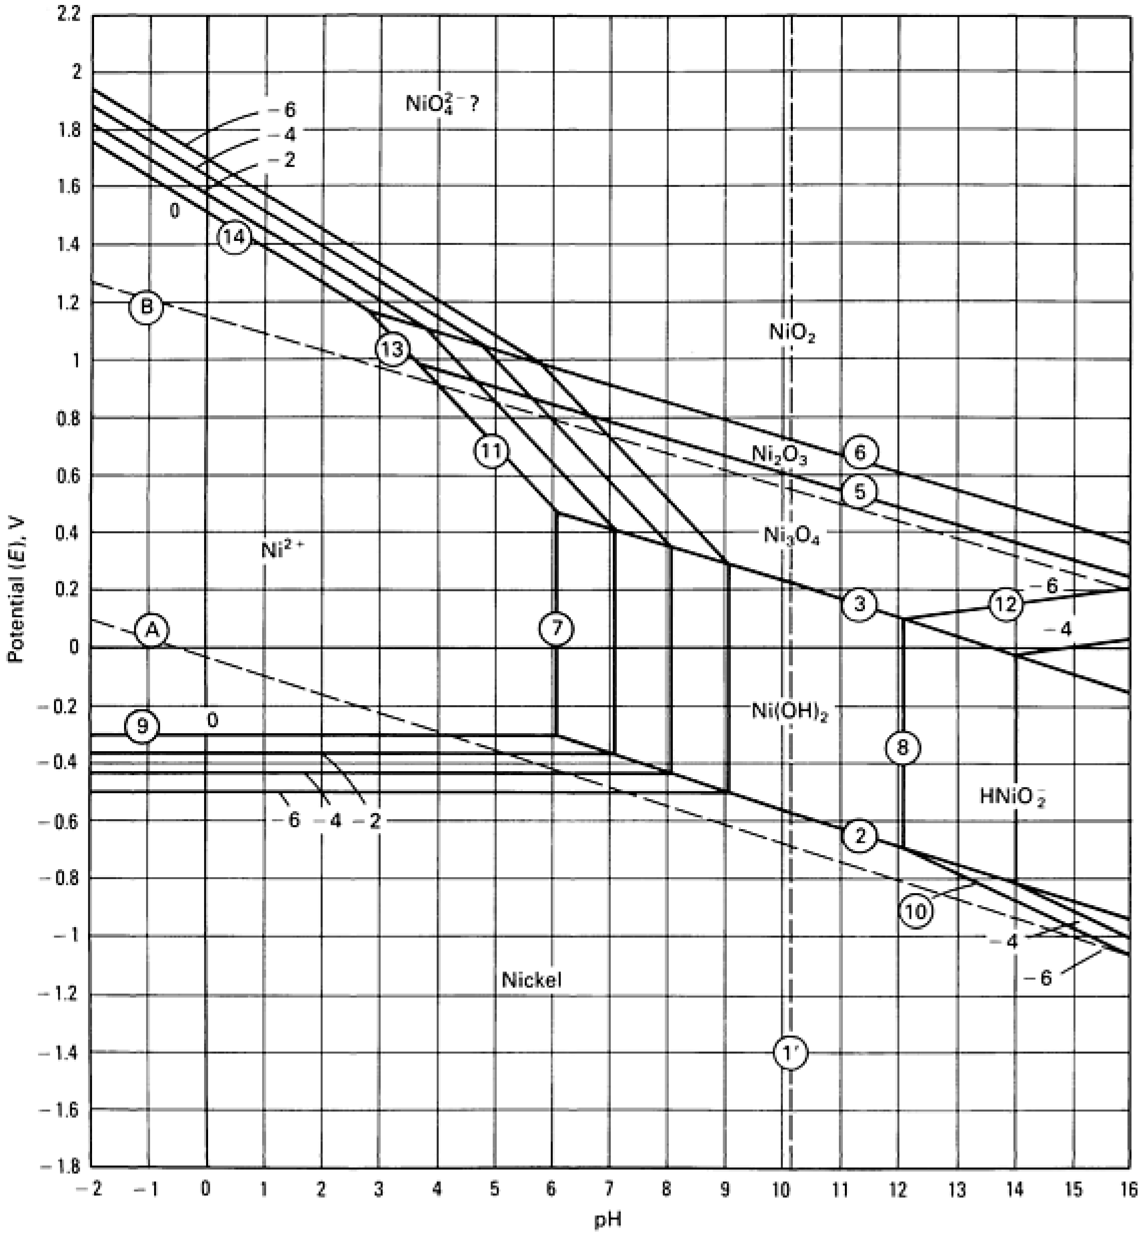

Fig. 1 The Pourbaix diagram for the nickel-water system at 25 °C (75 °F). See Ref 1 for details. Source: Ref 1

Protection on a Kinetic Basis

The corrosion rate of an actively corroding metal is determined by the intersection of the kinetic curves that characterize the anodic and cathodic halves of the corrosion reaction. If the rates of either of these reactions can be changed such that the intersection point is at a lower current density, the corrosion rate is reduced.

A widely used method for taking advantage of the corrosion kinetics is known as cathodic protection. In some cases, the applied potential is not sufficient to polarize the metal into its thermodynamic stability region, such as in the case of nickel described previously. In the kinetics case, a small potential is applied between an inert electrode and the metal to be protected. The potential of the metal is made more negative, and the rate of the anodic reaction is reduced. Figure 2 shows a diagram illustrating the phenomenon of cathodic protection. If a metal exhibiting the anodic and cathodic polarization curves shown in Fig. 2 is polarized to the potential denoted by A--B, the cathodic current density is that shown as A. The extrapolated anodic polarization curve allows calculation of the corrosion rate B. This type of diagram

enables calculation of the corrosion rate under any specific applied cathodic potential. More detailed descriptions of the principles and practice of cathodic protection are given in the article "Cathodic Protection" in this Volume.

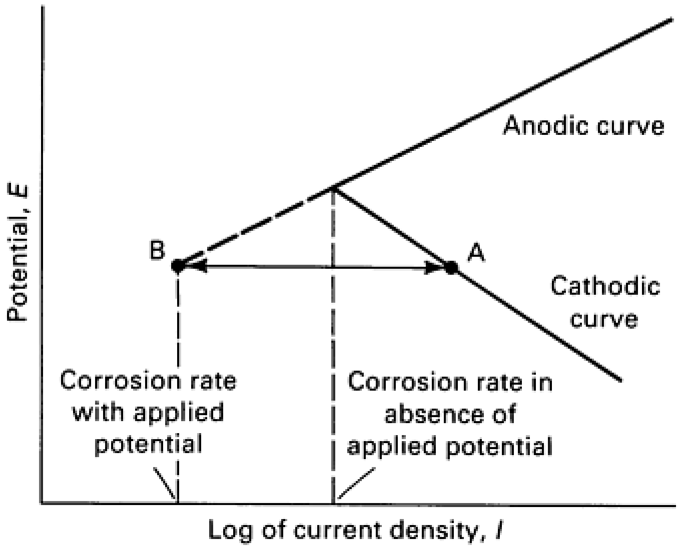

Fig. 2 Diagram showing how the corrosion rate can be calculated when a cathodic potential is applied. The situation shown is schematic in nature, and other factors must be considered when cathodic protection is applied in practice.

As stated above, the rate of the overall corrosion reaction is limited by the rate at which the slower of the anodic or cathodic reactions occurs. One of the two reactions is rate controlling. A knowledge of the rate-controlling reaction can often be applied to reducing the corrosion rate. An example is the use of inhibitors that selectively reduce the cathodic hydrogen evolution reaction in the acid pickling of steel. The pickling solution effectively attacks the oxide, with little attack on the base steel, because the anodic corrosion reaction is limited by the low rate of the cathodic hydrogen evolution reaction.

A second example is the corrosion of zinc in neutral chloride solution. As shown in Fig. 3, the anodic reaction occurs at the metal/oxide interface, and the cathodic oxygen reduction reaction occurs at the oxide/solution interface. The electrons formed by the anodic reaction must pass through the oxide to be available for the cathodic reaction on the oxide surface. A reduction in the electron conductivity of the oxide causes a reduction in the rate of electron transfer and a consequent reduction in the corrosion rate. The conductivity of the oxide can be reduced by doping the oxide with cobalt by using a zinc-cobalt alloy or by introducing cobalt into the oxide on the surface by immersion in a solution of cobalt ions (Ref 2).

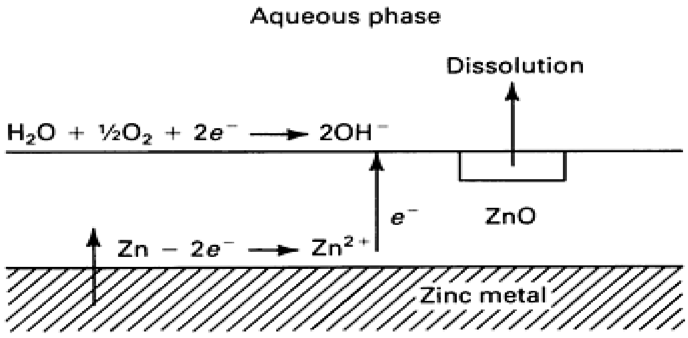

Fig. 3 The mechanism by which zinc corrodes in a neutral chloride solution. Source: Ref 2

Barrier Protection

The concept of barrier protection is very simple: The metal is protected from the environment by coating it with a barrier that resists penetration by aggressive environmental constituents. Five types of barrier coatings will be discussed: anodic oxides, ceramic and inorganic coatings, inhibitors, organic coatings, and phosphate and other conversion coatings.

Anodic oxides are widely used to protect aluminum from corrosion. The metal and many of its alloys are anodized in such acids as boric ($B_2O_3 \cdot 3H_2O$), oxalic, phosphoric (H_3PO_4), and sulfuric (H_2SO_4) under conditions in which an oxide is formed on the surface. The oxides formed in $B_2O_3 \cdot 3H_2O$ are relatively thin and nonporous in nature, but they are not suitable for protecting aluminum against corrosion in aggressive environments. The oxides formed in H_3PO_4 or H_2SO_4 are many microns thick and are very porous. The porosity is reduced in a second step in which the oxide is sealed in steam, boiling water, or aqueous solutions containing nickel acetate ($Ni(C_2H_3O_2)_2$) or other salts.

The anodizing of aluminum is widely utilized to protect aluminum components on automobiles, buildings, storm doors, and windows (see the article "Aluminum Anodizing" in this Volume). Other metals are protected to a limited extent by anodization before the component is placed in service. Stainless steels and other iron alloys that form passive oxides in aggressive environments are also protected from corrosion by applying an anodic potential while the part is in service. This potential is sufficient to maintain a barrier oxide on the surface. This method, known as anodic protection, is discussed in detail in the article "Anodic Protection" in this Volume.

Ceramic coatings based on special cements are used to protect steel from corrosion. They serve as a barrier and also maintain an alkaline environment at the steel/ceramic interface in which the corrosion rate is low. Inorganic coatings, such as silica, are used to protect stainless steel from tarnishing, and silicon nitride coatings are used to protect some types of components in electronic devices. Many other ceramic and inorganic coatings are used industrially to protect vital components against corrosion. More information on the use of ceramic coatings for corrosion protection is available in the articles "Porcelain Enamels" and "Chemical-Setting Ceramic Linings" in this Volume.

Corrosion Inhibitors. In many cases, the role of inhibitors is to form a surface coating one or several molecular layers thick that serves as a barrier. Many effective organic inhibitors have a reactive group attached to a hydrocarbon. The reactive group interacts with the metal surface, and the hydrocarbon portion of the molecule is in contact with the environment. Cinnamates (salts or esters of cinnamic acid) are used to protect steel surfaces against corrosion in neutral or slightly alkaline media by this mechanism.

The behavior of the corrosion potential can be used to determine which of the half reactions is most affected by the inhibitor. Figure 4 illustrates three cases. In Fig. 4(a), the corrosion inhibitor affects the anodic and cathodic curves equally. The corrosion rate is reduced to the value I_{inhib}, but the corrosion potential is unaffected. In Fig. 4(b), the cathodic reaction is affected to a greater extent, and the corrosion potential moves to a more negative value. In Fig. 4(c), the anodic reaction is affected to a greater extent, and the corrosion potential moves to a more positive value. The change in corrosion potential in the presence of an inhibitor can thus be used to estimate the kinetics of the inhibition. Generally, additional information is needed to draw firm conclusions. More information on the use of inhibitors is available in the articles "Corrosion Inhibitors for Oil and Gas Production," "Corrosion Inhibitors for Crude Oil Refineries," and "Control of Environmental Variables in Water Recirculating Systems" in this Volume.

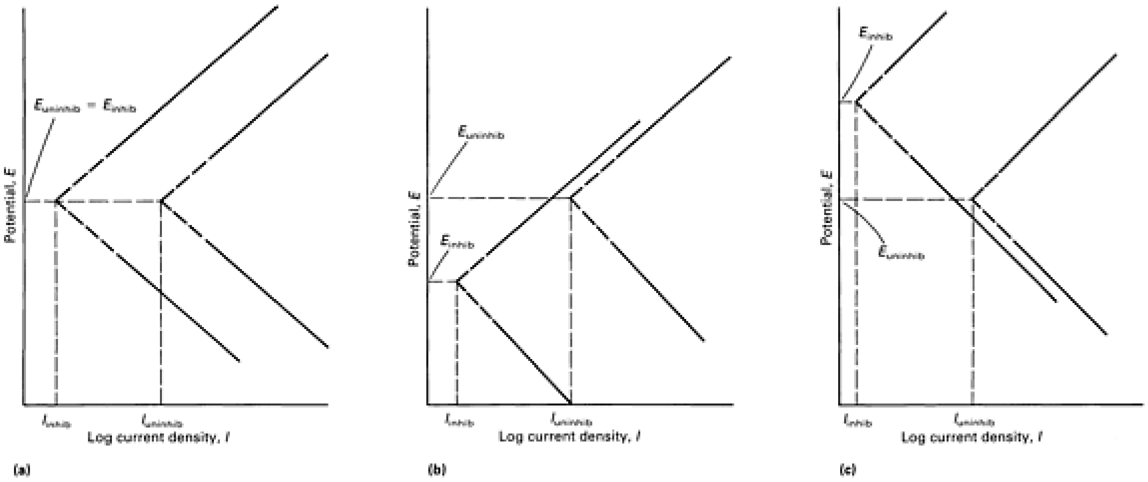

Fig. 4 Examples of three extreme cases in which corrosion inhibitors affect corrosion kinetics. (a) The inhibitor affects the anodic and cathodic curves to an equal extent. The corrosion rate is reduced, but the corrosion potential remains the same. (b) The corrosion inhibitor affects the cathodic curve extensively, and the potential in the presence of the inhibitor becomes more negative. (c) The corrosion inhibitor affects the anodic curve extensively, and the potential in the presence of the inhibitor becomes more negative.

Organic coatings are the most widely used barrier coating for protecting aluminum, steel, and zinc against atmospheric corrosion. The main function of the coating is to serve as a barrier to water, oxygen, and ions and thus prevent the cathodic reaction $H_2O + \frac{1}{2}O_2 + 2e^- \rightarrow 2OH^-$ from occurring beneath the coating. The protective barrier properties may be lost by the collection of water at the interface in the form of a thin layer or as blisters. Once water is present as an aqueous phase at the interface, the electrochemical corrosion reaction is possible by charge transfer laterally between neighboring anodic and cathodic areas or by charge transfer through the coating. Therefore, it is important to have coatings that are good barriers for water. In practice, a second line of defense is used to provide protection if the barrier properties of the organic coating are inadequate. A corrosion inhibitor, such as lead chromate ($PbCrO_4$), is incorporated into the primer. As a water phase develops, some of the chromate is solubilized and is available for inactivating the portions of the surface that are in contact with the aqueous phase. For additional information, see the article "Organic Coatings and Linings" in this Volume.

Conversion Coatings. Organic coatings are effective only if they protect the entire metal surface. Because many uses for organic coatings are on automobiles and appliances that may be damaged during service, the damaged area must not lead to total loss of the protective property near the damaged region. Certain conversion coatings provide resistance to lateral loss of corrosion protection. Phosphate coatings, chromate coatings, and mixed-oxide coatings are applied before the organic coating. These coatings, intermediate between the metal and the organic coating, are known as conversion coatings because they convert some of the base metal to a coating in which ions of the base metal are a component. Additional information on conversion coatings is available in the articles "Phosphate Conversion Coatings" and "Chromate Conversion Coatings" in this Volume.

Protection by Structural Design

Inappropriate design is often the source of severe corrosion. Crevices provide locations where an occluded corrosion cell may develop. Liquid is retained in a crevice long after the atmosphere has a low moisture level; the chemical nature of the ions formed by the corrosion process is acidic, and the corrosion rate is accelerated. The corrosion product occupies a larger volume than the metal from which it is formed, and the expansion forces are often sufficient to break a clamping bolt or cause serious deformation.

Designs that have recesses where rainwater can collect result in longer periods of time during which the metal can support an electrochemical reaction and consequently a higher corrosion rate. Erosive conditions, when combined with a corrosive medium, can lead to rapid corrosion rates. Drain water containing a sediment should not be allowed to drip or run over metal.

Structures should be designed, installed, and used such that the length of time they are wet with water is minimized. The corrosion reaction will only occur when liquid water is present on the metal. Liquid water can occur at relative humidities below 100% when deliquescent salts are present on the surface; therefore, it is useful to remove contaminants at regular intervals. Erosive agents dispersed in flowing liquids should also be avoided. An excellent summary of designing to minimize corrosion is given in Ref 3, and more information on this subject is available in the article "Design Details to Minimize Corrosion" in this Volume.

Protection by Environmental Control

This method of protection is limited to closed systems in which changes in the composition of the corrosion medium can be tolerated. The method depends on removing a constituent of the corrosion reaction from the medium or, in some cases, adding a component to the medium. Constituents that can be removed from the corrosion medium include oxygen; living materials, such as bacteria; erosive components in flowing systems; solid matter that may provide crevicelike situations at the bottom of pipes or tanks; and specific ions, such as chloride (Cl^-), that accelerate corrosion processes. Additives that may reduce corrosion in closed systems include agents that control pH, oxidizing agents that destroy organic matter, surface-active agents that maintain sediment in suspension, inhibitors, agents that reduce dissolved oxygen concentration, and materials that remove scale from the surface. Environmental control is a complicated subject, and specialists in cooling water treatment, boiler water treatment, and waste treatment should be consulted.

Protection by Metallurgical Design

The most obvious aspect of metallurgical design is the use of the proper alloy for the environment against which protection is sought. Economic and lifetime considerations are important factors in the choice of the alloy, and each situation must be considered individually (see the article "Materials Selection" in this Volume). Metallurgical considerations are also necessary once the alloy has been selected. Variables that influence the corrosion rate or sensitivity to fatigue or corrosion cracking include grain size, preferred orientation, presence of inclusions, method of fabrication, surface preparation method, and heat treatment.

Cleaning for Surface Conversion

William D. Krippes, J.M.E. Chemicals

Introduction

CLEANING in preparation for applying a conversion coating is of the utmost importance. It enhances the coating weight and quality of the conversion coating. Cleaning the metal surface before contact with the conversion coating bath will provide the maximum corrosion protection and paint adhesion. Improper cleaning will inhibit the reaction of the conversion coating and the metal surface. Valuable reaction time is lost if the conversion coating must first penetrate contaminant soil. More information on the application and corrosion resistance of conversion coatings is available in the articles "Phosphate Conversion Coatings" and "Chromate Conversion Coatings" in this Volume.

Cleaners consist of different components that work together to produce the desired result. Time, temperature, equipment, and concentrations are variables that must be considered and adjusted in order to maximize the cleaning and to minimize the attack of the cleaner on the metal surface. To prepare the surface for a conversion coating, the cleaner should:

- Remove all contaminants from the metal surface and prevent their redeposition

- Prohibit or minimize the formation of cleaner-produced metal compounds on the metal surface that are detrimental to the conversion coating
- Rinse free with clean, hot water

Contaminants and Some Methods of Removal

Any substance that inhibits or interferes with the application of the conversion coating, the adhesion and reactivity of the conversion coating, and/or the subsequent adhesion of the organic coating is a contaminant that must be removed. Some contaminants are easier to remove than others. Most nonadhering contaminants can be flushed off with the cleaner, but contaminants that are part of the metal surface must first be put into solution by the cleaner. Some contaminants are too difficult for the cleaner alone to remove; therefore, they are mechanically removed with abrasive brushes (see the article "Painting" in *Surface Engineering,* Volume 5 of the *ASM Handbook*). In some cases, an acid pickle may be required to remove such surface contaminants as aluminum and carbon smut, metal fines, surface rust, and scale.

A nonuniform reaction of the conversion coating with the metal surface will cause adhesion failure of the conversion coating and the subsequent organic coatings. Different contaminants prevent reaction of the conversion coating to the metal surface in different ways. Residual organic soil prevents contact of the aqueous conversion coating with the metal surface. Inorganic soil undermines the integrity of the conversion coating. Metal oxides that remain on the surface will be sites of future galvanic action under the subsequent organic coating. This can result in premature failure of the finished product because of underfilm corrosion.

Oils. Several different types of oils may be deposited on the surface of the metal. Stamping oils, rolling oils, machining oils, corrosion protection oils, and combinations of these are some of the types that may be encountered. The quantity of oil and the ease of removal depend on the length of time and the conditions of storage, the original use of the oil, and the type of metal to be protected. Lubricating oils are easier to remove than rust-preventive oils. Lubricating oils usually have emulsifiers to facilitate cleaning, but rust-preventive oils have additives that enhance their water-repellent qualities.

Because oil is insoluble in water, it interferes with the proper deposition of aqueous conversion coatings. To remove oils from the metal surface, several different surfactants (surface-active agents), such as detergents or wetting agents, can be added to the cleaner. The surfactants reduce the surface tension of the water and permit the cleaning solution to contact the metal surface. The concentration of surfactants in a cleaner has significant effect on the time required to penetrate the soil. Inadequate quantities will slow the cleaning process.

Cleaning time is decreased as the concentration of surfactants is increased, until a point is reached at which the addition of more surfactant does not reduce the cleaning time. This point may vary with changes in temperature, soil conditions, and type of metal being cleaned. The optimum surfactant concentration is determined by the percentage that will penetrate the soil in a required time at a minimum cost (Fig. 1).

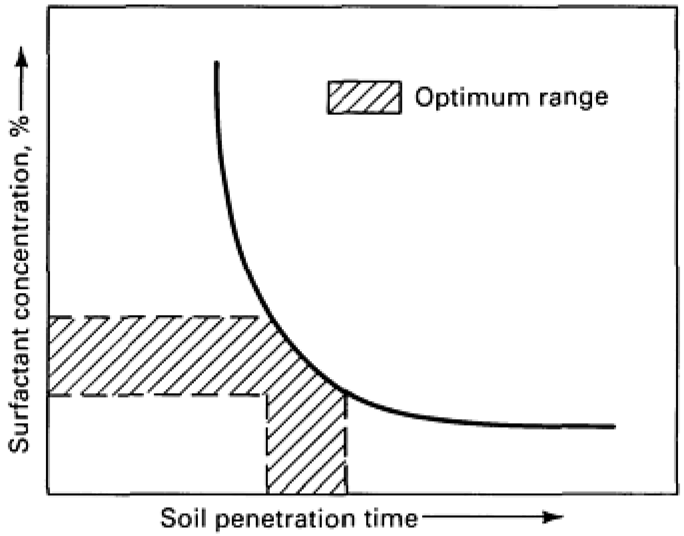

Fig. 1 Relationship between concentration of surfactants in a cleaner and cleaning time

Detergents, in addition to being surfactants, may emulsify the oils. Most of the strong synthetic detergents can be categorized as anionic, cationic, or nonionic. Anionic detergents are surfactants in which the active portion is a negative ion (anion). This type of detergent usually has the best detergency, along with high-foam characteristics. Cationic detergents are surfactants in which the positive ion (cation) is the active portion. These are usually good emulsifiers. Nonionic detergents do not ionize. They are valued for their low-foaming characteristics and are the most commonly used type of detergent.

Carbon is often found on products that are rolled from hot ingots or are continuously cast. One source of carbon is when rolling oil is subjected to the excessive temperature encountered during the reduction process. Carbon residue is very difficult to remove because of its nonreactive nature. Carbon that is left on the metal surface can cause voids or bridges within the conversion coating that appear later as poor adhesion. One method for testing the amount of carbon on the metal surface is the Ford LECO Swab Test (Ford specification ESB-M2PX).

If the amount of carbon on the surface is not too high, it can be removed by mechanical means, such as brushing. The type of brushes used will vary with the type of metal to be cleaned. Generally, if the surface carbon is determined to exceed 6.5 mg/m^2 (0.6 mg/ft^2) as measured by the Ford test, additional acid pickling must be done to clean the surface adequately. For a chemical cleaner to remove carbon, additives that have a greater attraction for carbon than the attractive force between carbon and the metal surface must be incorporated into the cleaner.

Metal Fines and Scale. Certain rolling practices often leave metal dust or small pieces of metal adhering to the metal surface. These are called metal fines. Scale is the oxidized surface of steel, produced during heating for working the steel, that has been rolled into the surface of the metal. These contaminants shield the metal surface from the conversion coating, but when under stress, they may later separate from the metal surface, leaving it unprotected. A cleaner can lower the surface tension to wash off the metal fines, or it can dissolve them. Mechanical means are also used. The method of removal is determined by the quality of metal fines as well as the type of metal being cleaned.

Scale, if it cannot be dissolved, must also be mechanically removed. A preliminary cleaning in an acid-pickling solution is often necessary. More information on pickling ferrous metals is available in the article "Pickling and Descaling" in *Surface Engineering,*Volume 5 of the *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Passivation coatings are applied to electroplated zinc, hot-dip zinc, and zinc-aluminum alloy coatings applied on steel substrates. Passivation treatments are applied at the time of production to prevent white rust during transportation and storage. Examples of some types of passivation coatings are straight chromic acid (H_2CrO_4), sodium dichromate-sodium silicate ($Na_2Cr_2O_7$-Na_2SiO_3), and blends of various additives in conjunction with $Na_2Cr_2O_7$ and/or H_2CrO_4). Some types of conversion coatings can be properly applied over some types of passivation coatings, but others cannot. Passivation coatings containing resins or silicate will not permit any conversion coating over the passivation coating. If the conversion coating cannot be applied to the particular passivation coating, the passivation coating must be removed.

Removal of the passivation coating from the metal surface can be extremely difficult, especially if the passivation coating has aged and completely reacted. Cleaner solutions have difficulty in removing reacted passivation coatings. Mechanical means must be relied on; therefore, uniformity of cleaning is very difficult to achieve with passivated substrates.

Metal oxides are the products of corrosion or high-temperature oxidation of the metal surface. Metal oxides are formed through the natural reaction of the metal surface with oxygen, usually in the presence of moisture. They form a loose, spongy matrix that is not conducive to good adhesion of organic coatings on the metal surface. Metal oxides will not react with the conversion coating to form a corrosion-inhibiting barrier. Left on the surface within a conversion coating, they

will accelerate further corrosion of the remaining substrate. For these reasons, metal oxides must be removed before the conversion coating is applied.

Selection of the cleaner is based on the metal to be cleaned and the type of equipment available. Metal substrates such as zinc, aluminum, steel, or combinations of these metals vary in solubility in the type of cleaner used. For example, aluminum oxide is usually only slightly soluble in acid cleaners, but it is very soluble in alkaline cleaners. Zinc oxide is soluble in both acid and alkaline cleaners. Iron oxide is soluble in acid cleaners.

The primary constituents of an alkaline cleaner may be sodium hydroxide (NaOH) or potassium hydroxide (KOH). An acid cleaner can be based on an organic phosphate or an acid, such as phosphoric acid (H_3PO_4) or acetic acid. These constituents are usually referred to as the backbone of the cleaner. Care should be taken to ensure that the backbone does not react with nonoxidized metal on the surface. When this is permitted to occur, metal compounds are deposited on the surface that interfere with the formation of the conversion coating and its adhesion. Aluminum hydroxide ($Al(OH)_3$) (aluminum smut), zinc hydroxide ($Zn(OH)_2$), and zinc phosphate ($Zn_3(PO_4)_2$) are examples of these metal compounds. The formation of these metal compounds is prevented by the use of buffers that inhibit the reaction of the cleaner with the metal surface. If this is not effective, additional processing steps, such as smut removal, must be taken.

A buffer consists of an acid or an alkali in the form of a salt, such as borate, phosphate, or silicate. A buffering agent enables the use of a higher concentration of the cleaner. If silicates are used as the buffer, adequate rinsing should be provided because of their poor rinsing qualities. More information on alkaline and acid cleaners is available in the articles "Alkaline Cleaning" and "Acid Cleaning," respectively, in *Surface Engineering,* Volume 5 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Equipment

Equipment will vary depending on the type and shape of metal to be processed. Cleaning is usually accomplished by dip or spray, followed by a hot-water-rinse. Mechanical assistance, such as the use of brushes and/or the use of spray pressure and impingement of the cleaning solution, is important. Pressure, nozzle size, and pattern are all considered when designing equipment for various cleaning applications. Preformed parts are usually suspended from a conveyor; coiled metal is continuously unwound through the cleaning stages and then rewound at the end.

The speed at which the metal is moved through the stages will vary, depending on its shape as well as the amount and type of soil on the surface. Generally, the cleaning time allotted is twice the amount of time required to apply the conversion coating. Rinsing time is one-fourth to one-half the cleaning time. Temperatures range from room temperature to 75 °C (170 °F), depending on soil conditions and length of cleaning time.

Cleaning times for preformed parts are usually 1 to 2 min. Because preformed parts cannot be squeegeed between stages, a weaker cleaner is used to minimize contamination of the rinse water. Also, it is difficult to reach all sections of a preformed part. For these reasons, preformed parts require more time in the cleaner bath for soil removal than coiled metal does.

The time required to clean coiled metal is 6 to 12 s, which is substantially less than that for preformed parts. Metal in a coil can receive a uniform spray pattern, which enhances cleaning. The use of squeegees between stages permits higher concentrations of cleaners with minimum contamination of the rinse. Figure 2 shows the equipment used to clean coiled sheet metal.

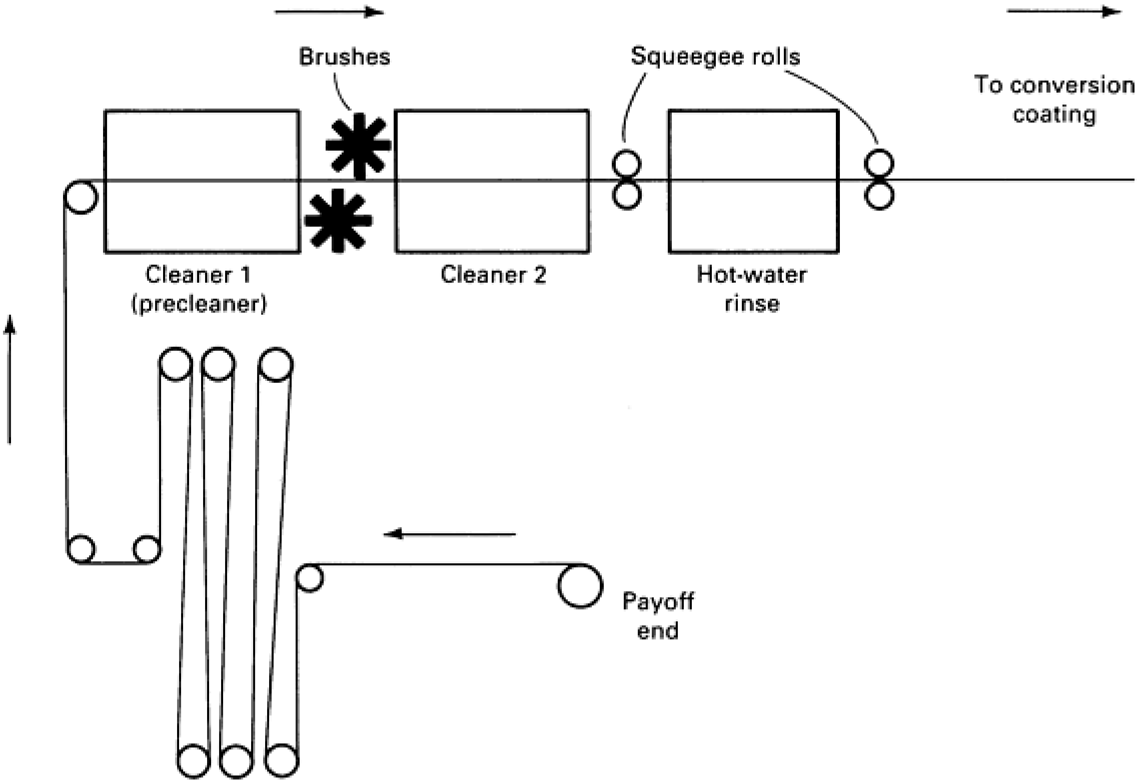

Fig. 2 Schematic of the cleaning section of a coil-coating line

To maximize cleaning efficiency and to minimize contamination of the treatment tanks, various arrangements of cleaner and rinse tanks are used. Some possible combinations area:

- Preclean, clean, hot rinse
- Clean, clean, hot rinse
- Clean, brush, clean, hot rinse
- Clean, hot rinse

The use of two cleaning tanks or a preclean and cleaning tank serves several purposes (Fig. 2). First, it maintains a relatively clean and uncontaminated cleaner immediately before the water rinse. This reduces the chance of redepositing soil on the surface of the metal before rinsing. Second, two cleaner tanks allow the use of different types of cleaners. The first tank is usually a cleaner that will lift and float easily removed soil to the surface of the tank to be skimmed off later. The second cleaner is one that will emulsify oil and finalize the cleaning process.

Equipment maintenance is very important. Sequestrants (agents that help to keep contaminants in solution) and water softeners are incorporated into cleaners to aid in maintenance. Their purpose is to prevent or reduce the precipitation of hard water salts, metals salts, and flocculents out of the cleaner bath. Spray nozzles must not be allowed to clog, or heat exchangers to cake over with these precipitate. Sequestrants and water softeners prevent a precipitate from forming before contaminants can be removed by a controlled throwaway. A controlled throwaway is when a percentage of the old bath is removed and new bath is added. The old bath is usually skimmed off the top in conjunction with the removal of any contaminants that have floated to the surface.

Cleaner Formulation

Liquid Cleaners. When formulating a cleaner, the decision must be made regarding whether the cleaner will be a liquid or a powder. Liquid cleaners can be more easily incorporated into automatic controls. They can also contain a greater percentage of surfactants. However, in liquid cleaners, the surfactants are not always soluble in the cleaner concentrate. This causes the surfactants to split off and form a layer on the top of the cleaner. Couplers are added to hold the surfactants in solution in the concentrated cleaner. The selection of the coupler is based on the ratio of surfactants to coupler; some couplers also contribute other benefits to the cleaner, such as detergency or wetting capabilities, in addition to coupling.

Figure 3 illustrates the composition of a typical liquid cleaner. The surfactant percentage usually consists of two or more different surfactants. Use of more than one surfactant provides a wider range of cleaning capability.

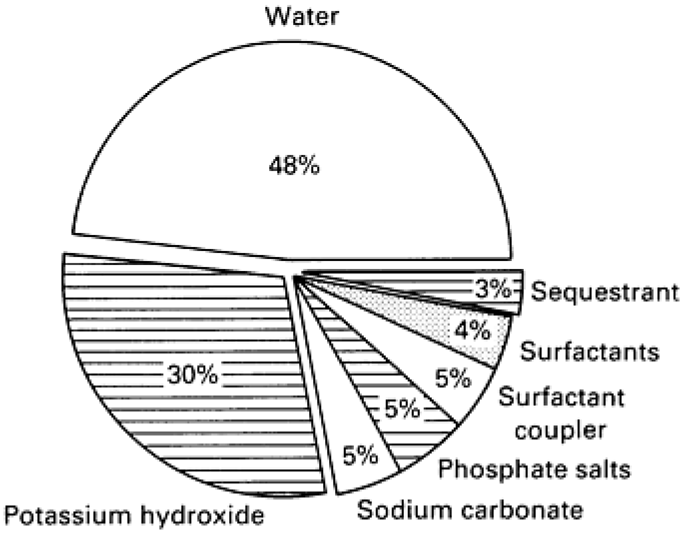

Fig. 3 Composition of a typical liquid alkaline cleaner

Powder cleaners are usually less expensive than liquid cleaners and can be shipped more economically, but they have a tendency to harden during storage. Therefore, care should be taken to avoid absorption of moisture from the air during blending and storage. It may be necessary to incorporate an anticake agent into the powder product. The percentage of liquid surfactants should also be limited. Some surfactants are available in a powder form and are more easily incorporated into a powder product. Figure 4 illustrates the composition of a typical powder cleaner. The sodium carbonate is usually referred to as a filler; other than some benefit to waste treatment, it contributes very little to cleaning. The specific percentage used in the example may vary, depending on the desired strength of the cleaner concentrate.

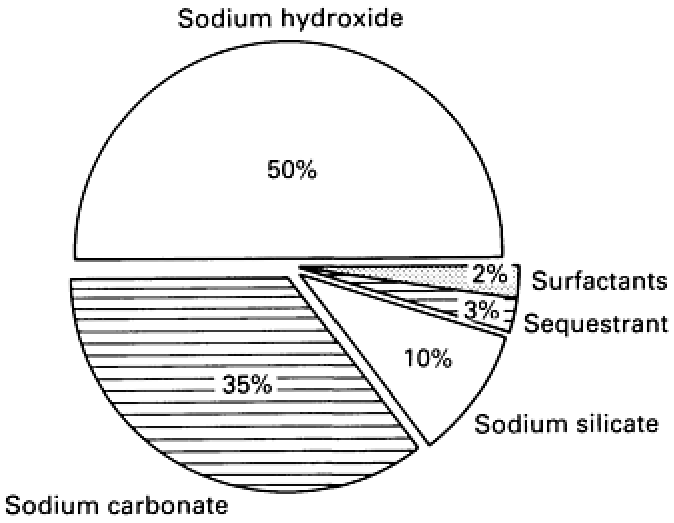

Fig. 4 Composition of a typical powder alkaline cleaner

High-Temperature Versus Low-Temperature Cleaners. Low-temperature cleaners have been developed to conserve energy and to lower costs. Typically, the only differences between a high-temperature cleaner (60 to 75 °C, or 140 to 170 °F) and a low-temperature cleaner (40 to 55 °C, or 100 to 130 °F) are the types and quantities of surfactants. Surfactant selection for low-temperature cleaners is primarily based on the low temperature foaming characteristics and cleaning capabilities of the surfactant. Low-temperature cleaners are usually run at higher concentrations and are limited in the variety of metals and types of soil that can be cleaned.

When the cleaning job is difficult, high temperatures are a requirement. Heat mobilizes the soil so that it may be removed faster and more easily.

Control of the Cleaner Bath

Control of the cleaner bath is usually achieved by titrating for free alkalinity and total alkalinity (in alkaline cleaners) or by titrating for free acid and total acid (in acid cleaners). For alkaline cleaners, the free alkalinity reading indicates the concentration of the cleaner solution. Phenolphthalein is often used as the indicator for this reading. The total alkalinity reading is then taken, usually with methyl-orange as the indicator. The difference between the readings indicates the concentration of dissolved metals in the cleaner bath. The acceptable level of dissolved metals for a particular cleaner will be determined by experimentation. Typically, when the difference between the readings equals or exceeds the free alkalinity reading, it is time to dump the bath.

Automatic control of the cleaner bath is usually accomplished by measuring the conductivity of the bath. Conductivity increases with the concentration of the cleaner solution. If a liquid cleaner is used, the controller may be connected to a pump, which will activate below a certain conductivity to replenish the bath and shut off above that conductivity. Powdered cleaners usually require a small off-line tank in which a slurry is made by adding water to the powder cleaner. Constant agitation is necessary to maintain the slurry. In this form, the controller may activate a slurry pump for additions to the bath.

Testing for Surface Cleanliness

The evaluation of whether the material is clean and ready for the conversion coating is sometimes very difficult. The speed of the line and the shape of the equipment does not allow easy examination of the material. To determine if the bath is capable of cleaning, it is advisable to obtain a small sample of the material and to hand dip it. The sample is cleaned and rinsed according to the time and sequence of the line. The surface of the sample is then wet with fresh cold water, and the wet film is observed for water break (discontinuities in the water film). If the sample is not free of water break, then it is not clean.

The other test consists of wiping the cleaned and rinsed surface with a wet, white cloth. If smut and soils remain on the surface, the cloth will darken from this residue.

Waste Treatment of Old Cleaner Bath

In the waste treatment of cleaner baths, one of the first tasks to be accomplished is the removal of oils from the bath. The bath is given time to cool; this allows the oil to rise to the surface where it can be skimmed. If an emulsion has been formed, acids may be used to lower the pH and to aid in splitting off the oil.

The bath is then treated so that the metals and other soil in the bath precipitate out. The precipitate is drawn off the bottom through a filter. The bath is given time to settle before filtration. Flocculents and adjustments to the pH are used to enhance the formation of this precipitate. It may be necessary to lower the levels of sequestrants in the cleaner in order to aid in the precipitation of dissolved metals in the cleaner bath. These additions and adjustments also improve the quality of the filtration cake. The filter cake must be firm, dry, and easily removed from the filter. Carbonate salts are used for this purpose.

To reduce the amount of waste to be treated and to lower the cost of cleaning, it is sometimes advisable to reclaim the usable portion of the old bath. This can be accomplished by selecting a cleaner that does not form an emulsion with oils. The equipment necessary is an off-line holding tank with a cone bottom that can decant the top layer of the bath. By decanting the top oily layer and removing the bottom precipitate, the remainder of the bath may be reused with only a small addition of fresh cleaner.

Phosphate Conversion Coatings

Thomas W. Cape, Chemfil Corporation

Introduction

PHOSPHATE CONVERSION COATINGS are applied to various metal substrates to enhance corrosion resistance, increase paint adhesion, or both. This article will discuss the types, uses, and theory of phosphate coatings; the tests for bath control and coating performance; and the equipment used in processing. More detailed information is available in the Selected References given at the end of this article.

Much information on phosphating bath formulations and processes is also contained in patents. Although these can be sources for much information, it must be remembered that the use of such information is limited by the patent.

The primary use of phosphate coatings is to enhance corrosion resistance, but there are other applications. These include the use of phosphate conversion coatings for their electrical insulating properties (for example, in electric motor laminations) and for lubricity (for example, to increase the formability of sheet metals). However, such applications are beyond the scope of this article.

Types of Phosphate Coatings

Phosphating processes are categorized in a number of different ways: by the types of metal ions present, by gross variations in coating weight, by the type of accelerators used, by the number of stages used, or by the end use of the phosphate coating. In this article, the basic categorization of phosphate coatings will be as follows:

- Iron phosphates--lightweight, amorphous phosphate coatings that do not contain significant amounts of divalent metal ions from solution. Coating weights range from 0.16 to 0.80 g/m^2 (15 to 75 mg/ft^2)
- Zinc phosphates--medium-weight, crystalline phosphate coatings that contain divalent metal ions from the solution and/or the metal surface. Coating weights range from 1.4 to 4.0 g/m^2 (130 to 370 mg/ft^2)
- Heavy phosphates (manganese phosphates)--heavy coatings that contain divalent metal ions from

solution and from the metal surface. Coating weights range from 7.5 to 30 g/m^2 (700 to 2800 mg/ft^2)

There are two major categories for the uses of phosphate coatings: bare corrosion protection and painted corrosion protection. Bare phosphate means simply that the phosphate coating is not painted.

Because of the crystalline nature of zinc phosphates and manganese phosphates, these coatings can hold oils and waxes so well that the corrosion resistance of the metal is increased much more than is expected based on either the phosphate or the oil separately. Similarly, the phosphate coating holds paint physically. The fact that painted applications of phosphate coatings are categorized separately from bare phosphate is a reflection of the great importance of painted applications, rather than any fundamental difference in the mechanism of corrosion inhibition.

Processing Sequence

The basic processing sequence for applying a phosphate conversion coating is cleaning, phosphating, and sealing. Depending on the type of phosphate coating being applied, some of these basic operations may be eliminated. Typical processing sequences for the three basic types of phosphate coatings are described below.

Iron Phosphate. A standard iron phosphate coating is applied by cleaning and rinsing the metal, coating the metal in the phosphate bath, rinsing again, and sealing for enhanced corrosion protection and improved paint adhesion. The sealing step is sometimes omitted to reduce costs.

Zinc Phosphate. Metals that are to be given a zinc phosphate coating are cleaned (twice, if possible), rinsed, and conditioned in some cases before the phosphate coating is applied. After the coating is applied, the metal is again rinsed; it is then sealed and rinsed again (the rinse after sealing is omitted in some situations).

In heavy phosphate coating, the metal surface is cleaned, rinsed, and pickled, if necessary, to remove rust. The processing sequence is then the same as that for zinc phosphate coatings, with conditioning and the rinse after sealing being optional for some systems.

General Phosphate Theory

Coating Formation. The basic process involved in the formation of any phosphate coating is the precipitation of a divalent metal and phosphate ions (PO_4^{3-}) on a metal surface. Phosphate salts, particularly divalent metal salts, are soluble in acid solutions and insoluble in neutral or basic solutions. The phosphate baths are acidic enough to keep the ions in solution. When metal is exposed to the solution, the acid attacks the metal surface. Two changes occur in the solution directly adjacent to the metal surface. First, the acid is neutralized and the pH rises. Second, the concentration of metal ions increases. Typical metals phosphated, such as steel or galvanized steel, will increase the concentration of iron or zinc ions, respectively, in this boundary layer between the metal surface and the bulk of solution.

The basic chemical reactions involved in the phosphating process are:

$$2H^+ + M \rightarrow H_2 + M^{2+} \qquad \textbf{(Eq 1)}$$

$$2H_2PO_4^- + 3M^{2+} \rightarrow M_3(PO_4)_2 + 4H^+ \qquad \textbf{(Eq 2)}$$

where M^{2+} is one of several possible metal ions. The consumption of acid (H^+) causes Eq 2 to proceed to precipitation. The production of metal ions (M^{2+}) pushes Eq 2 to precipitation of $M_3(PO_4)_2$. Equation 2 is applicable to many crystalline phosphate coatings, but other phosphates that might precipitate are shown in Eq 3:

$$5M^{2+} + 4H_2PO_4^- \rightarrow M_5H_2(PO_4)_4 + 6H^+ \qquad \textbf{(Eq 3)}$$

The composition of the phosphate coating depends on the composition of the metal surface and on the bath exposed to the metal. Common phosphate compositions are given in Table 1. For example, a zinc phosphate bath that is treating steel will contain hopeite ($Zn_3(PO_4)_2 \cdot 4H_2O$) and phosphophyllite ($Zn_2Fe(PO_4)_2 \cdot 4H_2O$). The relative proportion of phosphophyllite in the phosphate coating is called the P-ratio:

$$\text{P-ratio} = \frac{\%\ \text{phosphophyllite}}{\%\ \text{phosphophyllite} + \%\ \text{hopeite}} \quad \textbf{(Eq 4)}$$

The P-ratio will be affected by the substrate. Iron in the metal being phosphated is necessary for phosphophyllite formation. Similarly, a phosphate bath that does not have zinc will not form phosphophyllite on steel. Table 2 gives the general composition of the phosphate coating as a function of substrate and divalent metal in the bath. In addition to these obvious effects, more subtle changes in bath chemistry affect the amounts of phosphophyllite. Some of these factors, as well as factors that affect composition in other phosphate baths, will be discussed later in this article.

Table 1 Phosphate compounds found in conversion coatings

Compound name	Chemical formula
Vivanite	$Fe_3(PO_4)_2 \cdot 8H_2O$
Iron-hureaulite[(a)]	$Fe_5H_2(PO_4)_4 \cdot 4H_2O$
Strengite	$FePO_4$
Hopeite	$Zn_3(PO_4)_2 \cdot 4H_2O$
Phosphophyllite[(a)]	$Zn_2Fe(PO_4)_2 \cdot 4H_2O$
Scholzite	$Zn_2Ca(PO_4)_2 \cdot 4H_2O$
Phosphonicollite[(b)]	$Zn_2Ni(PO_4)_2 \cdot 4H_2O$
Phosphomangallite[(a)]	$Zn_2Mn(PO_4)_2 \cdot 4H_2O$
Manganese-hureaulite[(a)]	$Mn_5H_2(PO_4)_4 \cdot 4H_2O$ $AlPO_4$

(a) Phosphophyllite is $(Fe,Mn)Zn_2(PO_4)_2 \cdot 4H_2O$; Hureaulite is $(Mn, Fe_5)H_2(PO_4)_4 \cdot 4H_2O$. The names used in this article were chosen to avoid confusion as to the actual composition.

(b) No mineralogical name known

Table 2 Phosphate coatings formed on various substrates

Type of coating (Divalent metal ion)	Metal substrate		
	Iron/steel	**Zinc**	Aluminum
Iron phosphate (none)	$Fe_3(PO_4)_2\cdot 8H_2O$[(a)], iron oxides	$Zn_3(PO_4)_2\cdot 4H_2O$	**$AlPO_4$**
Zinc phosphate (Zn^{2+})	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Fe(PO_4)_2\cdot 4H_2O$	$Zn_3(PO_4)_2\cdot 4H_2O$	**$Zn_3(PO_4)_2\cdot 4H_2O$**
Zinc phosphate (Zn^{2+}, Ni^{2+})	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Fe(PO_4)_2\cdot 4H_2O$, $Zn_2Ni(PO_4)_2\cdot 4H_2O$	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Ni(PO_4)_2\cdot 4H_2O$	**$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Ni(PO_4)_2\cdot 4H_2O$**
Zinc phosphate (Zn^{2+}, Ca^{2+})	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn,Fe(PO_4)_2\cdot 4H_2O$, $Zn_2Ca(PO_4)_2\cdot 4H_2O$	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Ca(PO_4)_2\cdot 4H_2O$	**$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Ca(PO_4)_2\cdot 4H_2O$**
Zinc phosphate (Zn^{2+}, Mn^{2+})	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Fe(PO_4)_2\cdot 4H_2O$, $Zn_2Mn(PO_4)_2\cdot 4H_2O$[(b)]	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Mn(PO_4)_2\cdot 4H_2O$[(b)]	**$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Mn(PO_4)_2\cdot 4H_2O$[(b)]**
Manganese phosphate (Mn^{2+})	$Mn_5H_2(PO_4)_4\cdot H_2O$, $Fe_5H_2(PO_4)_4\cdot 4H_2O$	$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Mn(PO_4)_2\cdot 4H_2O$[(b)]	**$Mn_5H_2(PO_4)_4\cdot H_2O$**
Iron phosphate (Fe^{2+})	**$Fe_5H_2(PO_4)_2\cdot 4H_2O$, $FePO_4$**	**$Zn_3(PO_4)_2\cdot 4H_2O$, $Zn_2Fe(PO_4)_2\cdot 4H_2O$, $Fe_5H_2(PO_4)_2\cdot 4H_2O$**	. . .

(a) Because of the amorphous nature of this coating, x-ray diffraction cannot provide a complete description of the coating. Vivanite has been observed.

(b) The form of manganese in the phosphate coating has not been positively identified. In addition to phosphomangallite, manganese-hureaulite ($Mn_5H_2(PO_4)_2\cdot H_2O$) could be the manganese-containing species.

Accelerators. Modern phosphating uses additives called accelerators to hasten the phosphating process. These accelerators often help remove iron from the bath. The acceleration is accomplished by replacing H^+ in Eq 1 with a better oxidizing agent. The most common accelerators are nitrite (NO_2^-) and chlorate (ClO_3^-). Other common accelerators are nitrate (NO_3^-), peroxide (H_2O_2), and organic nitro compounds (such as nitrobenzene sulfonic acid and nitroguanidine). The advantages and disadvantages of each individual accelerator are listed in Table 3. Most baths that treat steel will build up iron in the bath as a harmful contaminant unless treated. Chlorate, peroxide, and nitrite will readily oxidize iron so that it will precipitate as $FePO_4$. Many phosphates use combinations of two or more accelerators. Common combinations are nitrite/nitrate, nitrite/chlorate/nitrate, and chlorate/ nitrobenzene sulfonic acid. Some accelerators form by-products that over time will build up in a bath and could be detrimental to performance.

Table 3 Accelerators used for phosphate coatings

Accelerator	**Advantages**	Disadvantages
Nitrite	No harmful by-products; removes iron from bath; very active	**Unstable in bath--constant additions must be made**
Chlorate	Stable in bath; removes iron from bath; very active	**Harmful by-products**
Nitrate	No harmful by-products; stable in bath	**Low activity; does not remove iron**
Hydrogen peroxide	No harmful by-products; very active; removes iron from bath	**Unstable in bath--constant additions must be made; high sludging; bath conditions critical**
Nitroguanidine	Very active	**Not available as liquid concentrate; does not remove iron; cannot be shipped pure**
Nitrobenzene sulfonic acid	**Very active**	**Does not remove iron; harmful by-products**

If it is economically feasible to change baths on a regular basis, then this problem is minimized. Chlorate, for example, is a good accelerator for an iron phosphate bath because the bath is inexpensive enough to replace often as the chloride builds up. On the other hand, chlorate is a poor accelerator for a high-nickel zinc phosphate bath, because the bath is too expensive to replace often.

There are three methods of acceleration beyond the chemical methods described above. First, higher agitation produces a coating more quickly. If an immersion phosphate process is converted to a spray process, the processing time is decreased. Similarly, an immersion process can be accelerated by increasing agitation. Second, the temperature can be raised to increase the rate of coating formation. Most phosphating processes have an optimum operating range for temperature, but the upper end may be more applicable than the lower end. Third, electrical currents are known to accelerate some processes. Currently, this process is not in widespread use, because chemical acceleration is more desirable.

Sludge and Scale. Phosphating is a precipitation process, and as such, the precipitation sometimes occurs in undesirable ways that are classified as sludge and scale. Sludge is the precipitation that occurs in the bath but does not go onto the workpiece. One source of this sludge is the oxidation of iron or manganese to form highly insoluble phosphates. In addition, the precipitation for coating formation may produce some phosphate that does not deposit on the workpiece. Scale is the phosphate coating formed on processing equipment. A major cause of scale is excessive heating of the bath. Because most divalent metal phosphates are less soluble at higher temperatures, the localized heating that occurs with raising or maintaining the bath temperature will cause scale to form on heating elements.

Testing

There are three basic types of tests for phosphating: phosphate bath testing, phosphate coating analysis, and paintability testing.

Phosphate Bath Testing

Acid Type and Concentration. The primary methods of bath control are acid-base titrations that measure the amount and type of acid present. Free acid is the amount (in milliliters) of 0.1 *N* sodium hydroxide (NaOH) needed to neutralize the strong acidity from 10 mL of the bath. Total acid is the amount (in milliliters) of 0.1 *N* NaOH needed to neutralize all the acid in 10 mL of solution. Consumed acid is the amount (in milliliters) of 0.1 *N* sulfuric acid (H_2SO_4) needed to

restore weak acid to 10 mL of bath so that any more acid added will be strong acid. Results are stated in points--for example, 2 mL = 2 points.

Nitrite Concentration. Another important bath-testing parameters is NO_2^- concentration. Because NO_2^- decomposes in solution, it is critical to be able to measure the concentration. Two general methods can be used:

- Permanganate titration: This reaction has some interferences; therefore, it is important to follow the directions of the supplier exactly
- Gas generation: There are two chemicals used for this reaction: urea and sulfamic acid. A standard volume of bath is exposed to an excess of sulfamic acid or urea, and the volume of resultant gas is measured

In deference to tradition, the results are stated in points.

Other Bath Parameters. In addition to the basic control procedures, a variety of ion-specific tests can be run. First, fluoride (F^-) is determined most efficiently by the use of an ion-sensitive electrode. This would be of particular interest in a zinc or heavy phosphate bath that is processing a significant portion of aluminum, because one of the important uses of F^- is to keep the concentration of aluminum down by the formation of AlF_6^{3-} ions. Second, the zinc concentration can be checked by an EDTA (a strong metal complex) titration. Because other divalent metal ions (N^{2+}, Mn^{2+}, Ca^{2+}) can interfere with the titration, the supplier should be consulted for an exact procedure. Third, a test for ferrous ions (Fe^{2+}) may be desirable as a monitor of Fe^{2+} level or as a check for the presence of Fe^{2+}. Typically, Fe^{2+} can be titrated with the permanganate solution used for checking NO_3^- or with ammonium dichromate, such as that often used for standardizing the ferrous ammonium sulfate solution in the titration for chromate final rinses. If only a check for Fe^{2+} ion is desired, the phosphate supplier should have papers that will indicate the presence of Fe^{2+}.

The purpose of all of the above tests is to help control the replenishment of the phosphate bath. Typically, the replenishment is accomplished by metering and checking free acid, total acid, or the concentration of the accelerator. Bath monitoring and control can be accomplished by two automated feedback systems. One is based on automatic titration. The results of these titrations automatically control bath replenishment.

Although this is the proper automatic method, it suffers from mechanical complexity and therefore reduced reliability. The second method, conductivity measurement, overcomes this problem. Conductivity can be related to the concentration of the basic constituents for a given bath and thus can serve as a test for replenishment. Conductivity measurements are simple to run on a phosphate bath; therefore, they are more widely used than titrometric-type controllers. Unfortunately, because conductivity does not directly measure the relevant parameters, some systems require adjustment of replenishment levels as the phosphate bath ages and require recalibration when a new bath is built up.

Phosphate Coating Tests

Coating Weight. The most common method of evaluating phosphate coatings is determination of the coating weight. This is usually accomplished by the gravimetric method, in which test panels are weighed before and after stripping to determine coating weight. Gravimetric determination of coating weight involves the following steps:

- The area to be stripped (MA) is measured
- The panel is baked at 95 °C (200 °F) for 5 min
- The panel is accurately weighed to obtain initial weight (IW)
- All areas that are not to be stripped are masked using electroplater's tape
- For steels, the panel is stripped in 5% chromic acid (H_2CrO_4), typically at 70 °C (160 °F) for 15 min
- For galvanized steels, the panel is stripped with ammonium hydroxide (NH_4OH) inhibited with 1 g/L ammonium dichromate ($(NH_4)_2Cr_2O_7$) at room temperature for 15 min
- The panel is rinsed, and any tape that was previously applied is removed
- The panel is baked again at 95 °C (200 °F) for 5 min
- The panel is reweighed to obtain the final weight (FW)

- Coating weight is calculated using the equation (IW - FW)/MA

The panel must be clean of all oils; gloves should always be worn for handling test panels.

Two other methods are commonly used for the determination of phosphate coating weights. First, it is common to determine zinc phosphate coating weights, especially on steel, by specular reflectance infrared absorption. This method is especially effective for quick determination of relative coating weights. Unfortunately, the range of coating weights that can be measured is limited to that of commonly used zinc phosphates (not iron phosphates or heavy phosphates). In addition, there is a dependency on the type of metal substrate used--for example, steel, galvanized steel, or aluminum. A more general method is x-ray analysis for phosphorus. This can be done by using a portable analyzer or the x-ray analyzer on a scanning electron microscope. Both the infrared and x-ray techniques must be carefully calibrated.

The use of coating weight as a quality control technique is limited by the fact that within fairly broad ranges coating weight alone is a poor indicator of quality. It is more useful as a test of the consistency of the bath. Thus, if there are wide variations in coating weight, quality is suspect. Coating weights are more important for iron phosphate than for zinc phosphate or heavy phosphate simply because other quality control tests are less useful.

Coating Morphology. Of primary consideration in the quality of zinc and heavy phosphate coatings is the structure of the coating. This includes two factors: the shape and the size of the phosphate coating. Unfortunately, there are few general rules that are applicable to all systems. The interaction of primer and phosphate dictates optimum performance, but once a good crystal size and crystal shape are determined, holding them constant will hold good performance. This of course assumes that the other properties do not deteriorate.

Typically, coating morphology is checked using optical microscopy. Zinc phosphate coatings can usually be observed adequately at 400×. Heavy phosphate can be seen at lower magnifications. Iron phosphate generally cannot be observed by optical microscopy. Scanning electron microscopy can be used for all phosphates, but it is generally used only when a problem has been identified.

Completeness of Coating. Complete coverage of the metal surface is the most important test parameter for phosphate coatings. Typically, this can be checked by one of three methods:

- Visual observation of a matte finish. A shiny area would typically be an indication of unphosphated areas. In general, iron phosphates will have a shinier surface than zinc phosphate, which is shinier than heavy phosphate. Also finer, more uniform crystal size will appear shinier
- Microscope observation. Often, uncoated areas are readily observable during a check of coating morphology
- The Ferro test. A solution of sodium chloride (NaCl), potassium ferricyanide ($K_3Fe(CN)_6$), and a surfactant on filter paper is placed on a phosphated steel panel. The blue color indicates uncoated spots

The composition of a phosphate coating can affect performance and therefore is often monitored. Generally, only heavy or zinc phosphates are analyzed, not iron phosphates. One composition test is the determination of phosphophyllite (Table 1) content in a phosphate coating. There are three methods for this determination:

- Direct analysis of the iron content of the solution obtained by determination of coating weight
- X-ray crystallographic determination of the relative proportions of hopeite and phosphophyllite
- X-ray analysis for zinc and phosphorus. This is based on the difference in ratio of zinc to phosphorus between hopeite and phosphophyllite.

The first and third methods have the advantage of also allowing analysis for other elements that may be present, such as calcium, magnesium, or nickel. These other elements are of greater importance for galvanized steel.

Phosphate coating adhesion is a measure of how well the phosphate coating stays intact on the metal surface. Two common techniques are the tape pull test and the thumbnail test. The tape pull consists of determining how much, if any,

of the phosphate coating can be removed by a standard tape, such as Scotch No. 600. A good coating will not lose any phosphate to the tape. The thumbnail test consists of scratching the phosphate coating and observing the mark left. The more obvious the mark, the worse the adhesion of the phosphate coating. It should be noted, however, that all phosphate coatings leave some mark; this is often used as a test to determine if a piece has been phosphated.

Corrosion Resistance. These tests measure the ability of the phosphate coating to resist corrosion. Typical tests would expose the phosphated panels to a corrosive environment and measure the amount of rust after a set period of time. Common corrosive environments include salt fog or condensing humidity. The phosphate coating may be oiled or waxed if its final use will be oiled or waxed. Corrosion tests of unpainted phosphate coatings are generally not used if the final application is painted.

Paintability Tests

These tests can generally be divided into three categories: accelerated corrosion testing, exposure corrosion testing, and adhesion testing. It is beyond the scope of this article to detail all of the commonly used test procedures, but a general outline can be given.

Paint Weakening. Many paint systems are so strong that in order to measure phosphate failure in a timely manner in paint system must be weakened. Common methods of weakening the system include scribing with a carbide tool, bending, drawing, undercuring the paint, and applying a thinner-than-standard paint film. The type of paint weakening used or whether it is used at all depends on the system.

Painted Corrosion Resistance. The commonly used accelerated tests can be divided into three categories: continuous testing, cyclic testing, and actual-exposure testing.

Continuous tests, such as the salt spray (ASTM B 117), water soak (ASTM D 870), or condensing humidity tests, have one basic corrosion condition. A variation on this procedure is that some tests have an initiation procedure prior to the test.

Cyclic tests use a variety of conditions cycled on a set schedule. Typically, these tests use saltwater exposure, controlled humidity or water exposure, and a drying period. Often, one or more of the conditions are at elevated temperatures. Among the conditions less commonly used are cold exposure and gravelometer damage. Cycles typically last from 6 h to a week, and the entire test lasts from 3 to 12 weeks.

Atmospheric exposure tests often use outdoor exposure under conditions of actual use or of most severe use. Examples of these tests include scribing automotive test panels and exposing them to an industrial atmosphere with salt solution twice a week (an accelerated test) and exposing painted building panels to typical outdoor exposure (not an accelerated test).

Iron Phosphating

The general characteristics of iron phosphate coatings are given in Table 4. There are three types of iron phosphating that will be discussed: iron phosphates that do not require precleaning (cleaner/coaters), iron phosphates that require precleaning (standard iron phosphates), and organic phosphates. Before describing these different systems, it is appropriate to discuss some aspects common to all systems:

- Iron phosphates historically have been used primarily on steel, but some systems can be used on galvanized steel or aluminum
- The standard accelerators used are NO_3^-, NO_2^-, and ClO_3^-, although molybdate (MoO_4^{2-}) is also used
- Final rinses are considered optional, although the improvement seen with final rinses is most dramatic with iron phosphates

Table 4 Characteristics of phosphate coatings

Characteristic	Type of coating		
	Iron phosphate	**Zinc phosphate**	Heavy phosphate
Coating weight	0.16-0.80 g/m^2 (0.0005-0.0026 oz/ft^2)	1.4-4.0 g/m^2 (0.0045-0.013 oz/ft^2)	**7.5-30 g/m^2 (0.025-0.1 oz/ft^2)**
Types	Cleaner/coater Standard Organic phosphate	Standard Nickel-modified Low-zinc Calcium-modified Manganese-modified	**Manganese phosphate** **Zinc phosphate** **Ferrous phosphate**
Common accelerators	Nitrite/nitrate Chlorate Molybdate	Nitrite/nitrate Chlorate Nitrobenzene sulfonic acid	**None** **Chlorate** **Nitrate** **Nitroguanidine**
Operating temperatures	Room-70 °C (160 °F)	Room-70 °C (160 °F)	**60-100 °C (140-212 °F)**
Free acid, points	-2.0 to 2.0	0.5-3.0	**3.6-9.0**
Total acid, points	5-10	10-25	**20-40+**
Prephosphate conditioners	None	Titanium phosphate None	**Manganese phosphate** **Titanium phosphate** **None**
Primary use	Paint base for low-corrosion environments	Paint base for high-corrosion environments	**Unpainted applications**
Limitations	Low painted corrosion resistance; low unpainted corrosion resistance	Poor unpainted corrosion resistance	**Expensive, long processing times**
Materials needed for tanks	Low-carbon steel	Low-carbon steel, stainless steel, or plastic-lined steel	**Stainless steel or low-carbon steel**
Application method	**Spray and immersion**	**Spray and immersion**	**Immersion only**

Cleaner/Coaters. These iron phosphates combine the functions of cleaning and phosphating into one stage. These have the advantage of requiring less floor space in the plant because of the elimination of the cleaner and rinse stages. In addition, maintenance is proportionally easier. Iron phosphates are generally used because they are less expensive that zinc or heavy phosphates; therefore, the cost savings of these cleaners/coaters greatly enhances their popularity. The disadvantages of cleaner/coaters include lower phosphate quality and the fact that two cleaner/coater stages are sometimes required so that the workpiece is cleaned better.

Standard iron phosphates are generally five-stage systems (see the section "Processing Sequence" in this article). These systems usually produce the best phosphate coating quality among the three types of iron phosphates. In addition, the phosphate bath lasts longer, and the workpiece can be cleaned better. On the other hand, there is additional work in maintaining both a cleaner and phosphate stage, and more floor space is required for the extra stage.

The organic phosphating process involves an iron phosphate process in a chlorinated solvent. The workpiece is vapor degreased by the refluxing solvent prior to entry into the bath. In addition, it is rinsed by vapor degreasing after phosphating. Organic phosphating has the advantage of being a one-stage phosphating process. The primary disadvantages are lower phosphate quality and exposure to chlorinated organic vapors. Typically, the system is run without a final rinse.

Applications of Iron Phosphates. Iron phosphates are usually used when the primary consideration is good paint adhesion and low cost. Applications that are not exposed to corrosive environments or that require forming of parts after painting are suitable for iron phosphates. Parts formed after painting can be, and often are, pretreated with a zinc phosphate, chromate, or mixed oxide coating when galvanized steel or aluminum is used as the metal substrate. If low cost was the primary consideration, a steel substrate would have been used.

Zinc Phosphate

Zinc phosphates (Table 4) are based on the formation of crystalline tertiary phosphates with the general formula $Zn_2M(PO_4)_2{\cdot}4H_2O$, where M can be zinc, iron, nickel, calcium, or manganese. The inclusion of nickel, calcium, or manganese comes from the addition of these elements to the phosphating baths, and the inclusion of iron comes from inclusion of the iron in steel into the phosphate coating. These additions delineate some of the different types of zinc phosphates. In addition, several of these modifications can be made to the same bath. One example would be a nickel-modified low-zinc zinc phosphate.

Standard Zinc Phosphate. This type of phosphate has no divalent metal ions other than zinc. In general, lower performance and lower costs are seen with these baths as opposed to the other zinc phosphate baths. Extensive cleaning and preconditioning are often not used to save floor space. Typically, these standard zinc phosphates are a compromise between low-cost iron phosphates and the higher performance of other types of zinc phosphates. Further, they are often restricted to use on steel.

Nickel-Modified Zinc Phosphate. Nickel in the zinc phosphate bath produces inclusion of small quantities of nickel in the phosphate coating. This causes large improvements in the painted performance of the phosphate coating, especially on galvanized products. Most zinc phosphates contain some nickel, which gives the liquid concentrates their familiar green color. Traditionally, relatively low levels of nickel have been used (0.15 to 0.5 g/L), primarily because of the high cost of nickel. Higher levels of nickel (0.6 to 4.0 g/L) are being introduced because of the greater performance of these phosphate baths.

Low-Zinc Zinc Phosphate. Traditional phosphate baths have zinc concentrations in the range of 1.0 to 3.0 g/L. Low-zinc baths have zinc concentrations of 0.5 to 1.0 g/L. These baths were developed to optimize the formation of phosphophyllite on steel. It was subsequently found that these baths also use nickel more efficiently. Thus, low-zinc baths were found to improve performance on all substrates through greater formation of phosphophyllite or phosphonicollite. The only significant disadvantage with these baths is that the zinc concentration must be controlled carefully.

Calcium-Modified Zinc Phosphate. The addition of calcium to zinc phosphate baths produces many of the performance advantages of nickel in the phosphate baths without the associated higher costs. Calcium-modified zinc phosphate coatings have found application in the appliance industry.

Manganese-Modified Zinc Phosphate. Manganese-modified zinc phosphates have recently been introduced, particularly in automotive phosphating. One advantage obtained has been lower operating temperatures. Currently, there is debate as to the degree of improvement in performance afforded by these phosphate systems.

Prephosphate Conditioners. Titanium phosphates are known to have substantial benefits to the phosphate coatings when applied prior to phosphating. Although a number of other chemicals, such as oxalic acid or finely divided zinc phosphate salts, have a similar effect, virtually all prephosphate conditioners used in zinc phosphate systems are based on titanium phosphate technology. Currently, many zinc phosphate systems are totally dependent on the conditioning stage

to deposit a beneficial zinc phosphate coating. The conditioner can be applied either as a portion of the final cleaning stage, or preferably, as a separate stage between cleaning and phospating.

The theory as to why these titanium salts help the formation of a phosphate coating is not well developed. What is known is that the use of these colloidal suspensions produces phosphates coatings that have smaller crystal size and a more complete coating. It is believed that this is accomplished by the formation of many more active sites for initiation of phosphate coating formation. Because there are more sites for initiation, the crystals do not get a chance to grow as large, and the probability that a given area will not be coated decreases.

Applications of Zinc Phosphates. Zinc phosphate coatings can be used as a paint base or as a structure to hold oils or waxes. These two applications cannot be implemented at the same time. If an oil or wax has been used, paint will not adhere to the metal. In protection from corrosive environments, paint usually shows much better performance than waxes and oils. There are applications, however, in which paint is not preferred over oils and waxes.

Zinc phosphates are used when good paint adhesion and good painted corrosion resistance are desired. Companies usually find it most cost effective to put their effort and money into applying the most effective zinc phosphate possible. In most cases, the cost of the paint system is much greater than the cost of the phosphate system. Zinc phosphates usually cannot be used for coil-coating applications in which the painted sheet must be formed. Zinc phosphates can be effectively applied to coiled steels only if the end use does not require drawing of the steel for the final product. In addition, zinc phosphates are not used in applications in which maximum corrosion resistance is needed and paint cannot be used.

Heavy Phosphates

Heavy phosphates (Table 4) are divided into three categories: zinc phosphates, manganese phosphates, and ferrous phosphates. These phosphates form a coarse crystalline coating. Typically, the heavy phosphates are much more expensive than zinc phosphates in chemical, heating, and floor space costs. Their advantage is in increased unpainted corrosion resistance.

Manganese phosphates are used when maximum corrosion resistance is needed for unpainted applications. If adequate rinsing can be obtained, an accelerated process is used. When accelerators are used, NO_3^- is usually the one of choice, with small amounts of nickel being beneficial.

Manganese phosphates build up Fe^{2+} ions with use, which can lead to lower performance. The iron level in the bath is typically controlled with H_2O_2. The phosphate supplier should be contacted regarding the nature of this addition.

Manganese phosphates are sensitive to the effects of cleaning. Use of an acid or strong alkali cleaner produces coarser coatings. This can be overcome to a large extent by conditioning the surface immediately before phosphating with a suspension of finely divided manganese phosphate. This is especially important if the workpiece is rusted and requires pickling prior to phosphating.

Zinc Phosphate. The same basic chemicals used to make a zinc phosphate coating for a paint base can be used to make a heavy phosphate. The concentration, temperature, and time are all increased to accomplish this. Despite these increases, a zinc phosphate can be applied faster and at a lower temperature than a manganese phosphate. As with zinc phosphates used for a paint base, a titanium phosphate or (less likely) an oxalate conditioning stage is very beneficial.

Ferrous phosphates in many ways combine the worst attributes of the other heavy phosphates. Their corrosion resistance is not as good as manganese phosphates. Neither can they operate at the lower temperatures or shorter times of zinc phosphates. However, ferrous phosphates operate at a higher acidity, which means that rust can be more effectively removed during the phosphating process, eliminating the need for pickling.

Final Rinses

To achieve maximum corrosion resistance for any of these phosphates, the coatings should be sealed before use. The process of phosphating and either painting or applying an oil or wax provides the best corrosion resistance if the pores in the phosphate coating where corrosion is most likely to be initiated are treated to make those areas more corrosion resistant. Historically, the sealer of choice is chromate (hexavalent chromium, CrO_4^{2-}). Regardless of which final rinse is

used, the optimum pH is in the range of 3.8 to 4.8. Recently, trivalent chromium (Cr^{3+}) and nonchromium final rinses have become increasingly popular for environmental reasons.

Chromate Rinses. There are two basic types of chromate sealing rinses. One type contains only CrO_4^{2-}, and the other is a mixture of CrO_4^{2-} and Cr^{3+}.

Hexavalent chromium (chromate) sealing rinses are the oldest type of currently used sealing rinses. They are used without rinsing just prior to painting and can be used for any type of phosphate, but poorer quality coatings benefit the most.

Hexavalent/trivalent chromium rinses are used when the workpiece is rinsed again after this stage. The corrosion resistance of CrO_4^{2-} final rinses is greatly diminished upon rinsing, probably because of the good solubility of CrO_4^{2-}. Addition of Cr^{3+} eliminates this effect because an insoluble chromate compound is formed.

Both of these baths are controlled by monitoring CrO_4^{2-} concentration. The CrO_4^{2-} is titrated with a standardized ferrous sulfate ($FeSO_4$) solution.

Trivalent Chromium Rinses. The concern over the high cost of environmentally safe final rinses have led to development of chromate-free rinses. One effective group is those rinses that contain Cr^{3+}. This group has produced very effective final rinses, some of which are as good as chromate final rinses.

Nonchromium Final Rinses. Because even Cr^{3+} must be treated for disposal, much work has been devoted to developing chromium-free final rinses. There are two basic types of nonchromium rinses that are being developed: environmentally safe metal salts and polymers or oligamers. At this point, it should be noted that in order for a final rinse to be proved effective it must be better than if it were not used. To show that on a given test it is equivalent to a chromate final rinse is insufficient, because most accelerated tests cannot differentiate between effective and ineffective final rinses.

Methods of Application

The two basic methods of applying phosphate conversion coatings are spraying and immersion. In general, spray coating is less expensive, but immersion coating provides better quality.

Spray phosphating involves pumping the bath through a series of risers that have spray nozzles aligned to coat all areas of the workpiece. For complex parts, this sometimes means that internal portions will receive little or no coating. Spray coating results in rapid coating formation with lower bath concentrations than those needed for immersion coating. Spraying also gives better cleaning of external surfaces of parts because of impingement of the coating bath, has lower equipment costs, requires less floor space, and uses smaller bath volumes than immersion coating (this reduces recharging costs).

Immersion coating gives more uniform coatings than spraying. It is slower and requires much larger bath sizes than spraying, but these disadvantages can be partially offset by the use of higher bath concentrations. Immersion baths require more floor space and higher equipment costs than spraying, and because of their greater volume, they are more expensive to recharge and to dispose of. The advantages of immersion coating include better cleaning and coating on internal surfaces of the workpiece, better coating uniformity, better drainage between stages with less drag-through of contaminants from one stage of the process to another, less maintenance and repair, lower bath heating costs, and generally better coating performance than sprayed coatings. Also, the large baths required for immersion coating are less sensitive to such changes as depletion of chemicals or bath contamination, and temperatures are more stable in the larger baths. Nickel can be included in the coating more efficiently in immersion baths than in spray baths, which improves the corrosion performance of zinc and manganese phosphate coatings on galvanized steels. Immersion phosphation produces changes in the phosphate coating composition that results in better painted performance with some paint systems.

The selection of an application method should be based on the particular requirements of the workpiece. However, the following general guidelines may be helpful in choosing a coating process:

- Heavy phosphate coatings are usually applied by immersion because of the prohibitive heat loss

involved in spray operations

- Iron phosphate coatings are usually applied by spraying because the emphasis is on low cost. The exception is organic phosphates, which are typically applied by one-stage immersion
- The more complex the configuration of the workpiece, the more advantageous immersion becomes. Thus, spraying is often used for strip applications, but complex parts are more likely to be immersion phosphated

Equipment Considerations

Materials. Alkali cleaners, conditioners, and final rinses may use low-carbon steel for the bulk of the tank. Phosphate systems may require stainless steel, depending on the presence of F^- or NO_3^-, acidity, operating temperature, and the desired lifetime of the tank. Type 316 stainless steel is preferred. Nozzles must be stainless steel. Plastic or plastic-lined steel can be substituted for stainless steel in some circumstances, but the use of plastics is limited to lower-temperature applications.

Heating and Circulation. The optimum method of heating depends on the specifics of the operation, but the following points should be kept in mind:

- Because phosphates precipitate at higher temperature, any source of heat should be easy to clean
- Spot heating should be avoided
- The heat source should not be on the bottom of the tank, because the sludge settling will insulate it

The common methods of heating are steam or how-water coils, electric heating, gas heating, water jackets, and external heat exchangers. For immersion phosphating, the last method would also be a useful source of agitation. The solution must be pumped in spray phosphating, but solution pumping is also necessary to obtain optimum results in some immersion systems. Barrel phosphating can provide considerable agitation around the part by rotation of the barrel; additional agitation is usually not required. Conveyor applications may or may not need additional agitation.

Sludge and Scale. Because phosphating is a precipitation process and is not 100% efficient, some precipitation occurs in the bath. Precipitation on the equipment is called scale, and precipitation that is suspended in the bath is called sludge. The sludge usually settles to the bottom; it can then be pumped to a filtration unit. In some cases, most of the solution is pumped to a temporary storage tank, and the sludge-rich solution from the bottom is removed. Scale is more difficult to remove. The most expedient method is to use an inhibited acid to dissolve it.

Chromate Conversion Coatings

Karl A. Korinek, Parker Chemical Company

Introduction

CHROMATE CONVERSION COATINGS are formed by a chemical or an electrochemical treatment of metals or metallic coatings in solutions containing hexavalent chromium (Cr^{6+}) and, usually, other components. The process results in the formation of an amorphous protective coating composed of the substrate, complex chromium compounds, and other components of the processing bath.

Chromate conversion coatings are applied primarily to enhance bare or painted corrosion resistance, to improve the adhesion of paint or other organic finishes, and to provide the metallic surface with a decorative finish. Chromating processes are widely used to finish aluminum, zinc, steel, magnesium, cadmium, copper, tin, nickel, silver, and other substrates. Chromate conversion coatings are most frequently applied by immersion or spraying, but other methods of application, such as brushing, roll coating, dip and squeegee, electrostatic spraying, or anodic deposition, and used in special cases.

Technology of Chromating Processes

Chromate coatings are applied by contacting the processed surfaces with a sequence of processing solutions. The processing baths are arranged in a series of tanks, and the surfaces to be processed are transferred through the sequence of stages by using manual, semiautomatic, or automatic control. The chromate coatings are usually applied to metal parts or to a continuous metal strip running at speeds to 5 m/s (1000 ft/min).

The basic processing sequence consists of the following six steps: cleaning, rinsing, conversion coating, rinsing, posttreatment rinsing or decorative color rinsing, and drying. In many applications, this sequence is expanded to accommodate pickling, deoxidizing, dyeing, brightening, and other rinsing stages, or the sequence can be shortened when cleaning or posttreatment rinsing is not necessary. Some typical processing sequences are given in Tables 1, 2, and 3. The key processing steps are discussed in the following sections.

Table 1 Typical process sequences for chromating of aluminum, zinc, and their alloys

Step	Decorative finish
1	**Vapor degreasing: solvent (optional for heavy oils)**
2	**Cleaning: alkaline (single or double stage)**
3	**Rinsing: hot water**
4	**Deoxidizing or desmutting: inorganic acids (optional)**
5	**Rinsing: water**
6	**Conversion coating: chromate**

7	**Rinsing: cold or warm water**
8	**Dyeing: dye solution (optional)**
9	**Rinsing: cold or warm water**
10	**Drying: warm air**

Step	Painting
1	**Vapor degreasing: solvent (optional for heavy oils)**
2	**Cleaning: alkaline (single or double stage)**
3	**Rinsing: hot water**
4	**Conversion coating: chromate or chromium phosphate**
5	**Rinsing: cold or warm water**
6	**Posttreatment: chromate or deionized water (optional)**
7	**Drying: warm air**
8	**Painting: single or double coat**

Table 2 Typical process sequences for chromating of continuous galvanized strip

Step	Electrogalvanized strip
1	**Electrogalvanizing**
2	**Rinsing: warm water, multiple stages, neutralizing (optional)**
3	**Conversion coating: chromate**
4	**Rinsing: cold or warm water**
5	**Posttreatment: chromate (optional)**
6	**Drying: warm air**

7	**Oiling or painting (optional)**

Step	Hot-dip galvanized strip
1	**Hot-dip galvanizing**
2	**Surface conditioning: heat treatments**
3	**Conversion coating: chromate**
4	**Drying: warm air**
5	**Oiling (optional)**

Table 3 Typical process sequences for no-rinse treatments

Step	Process
1	**Cleaning: alkaline (single or double stage)**
2	**Rinsing: hot water**
3	**No-rinse chromating**
4	**Drying or curing**
5	**Painting: single or double coat**

Cleaning. Surface preparation before chromating is very important for the quality and performance of the coatings. Alkaline cleaners are used to remove organic soils and metallic impurities from the surface. Where oils and greases are very heavy, a precleaning step may be necessary before alkaline cleaning. In some cases, an acid deoxidizer, acid pickle, or mechanical brushing is needed to reduce the oxide layer substantially and to activate the surface. Freshly prepared surfaces, such as electroplated or hot-dip coated metals, can be chromated directly or after rinsing. Occasionally, the freshly electroplated surfaces are treated with an acidic or alkaline neutralizing rinse before chromating.

Rinsing. The alkali-cleaned metal must be thoroughly rinsed, preferably in hot water. The rinse water should be overflowed at a rate that will keep it free of scum and contamination. Maintaining the rinse in good condition not only improves the quality of the processed parts but also prevents contamination of subsequent stages. This is very important because the replenishing chemicals for the chromating bath are formulated to maintain the operating baths in the recommended ranges under normal rinse drag-in conditions. Excessive drag-in could lead to acid or alkali contamination, which, for the processes controlled by pH or conductivity, could result in the addition of too much or too little replenishing chemical. In the long term, this could lead to seemingly unexplainable problems with coating quality.

Chromating. The composition of the chromating bath depends on the metal to be treated, the type of application, and the specific requirement for the final product. The chromating bath is usually built up from one or more chemical concentrates (makeup chemicals) and is maintained by the addition of one or more concentrates that constitute the replenishing chemicals. The replenishing chemicals serve to maintain the concentrations of the key bath components and

the bath pH in the desirable range and to bind any reaction products in a form that does not interfere with the coating reaction or the quality of the produced chromate coating. Several different replenishers may be required to maintain a constant bath composition during the processing of different substrates.

A great variety of solution compositions, many of them proprietary, are available for chromating. Selection of the proper process usually begins with the coating performance definition for the metal substrate to be treated, and it depends on the type of processing equipment available. For a given coating, maximum performance is achieved when the process is maintained within the specification of the supplier and when the coating weights are within the recommended range. The most important parameters for the control of chromating processes are time, temperature, chromate concentration, pH, reaction products, and accelerator concentration.

To maintain optimum quality in chromate coatings, it is important to produce coatings that have the desired composition and are within the desired coating weight range. The optimum processing parameters are usually established for each production facility. Once these processing conditions are established, it is good operating practice not to deviate substantially without conducting an appropriate evaluation, which should confirm that the proposed process modification does not affect final product quality. Control of the specified parameters within the recommended ranges will normally ensure that the coating composition is also maintained. The amount of chromate coating applied to the surface can be estimated from the coating appearance or can be accurately measured by using methods for determining coating weight (see the section "Properties of Chromate Coatings" in this article).

The coating weight increases with time and temperature. It usually also increases with chromate concentration, but a substantial increase above the recommended concentration range could lead to a different coating composition or could change other bath components and result in lower coating weights. The pH of the chromating solution must be in the range in which the substrate metal is dissolved, but also must allow for deposition of the coating. In zinc chromating processes, the zinc dissolution rate reaches an appreciable level below pH 4. Below pH 1, coating deposition is slow, but it increases with pH to a specific pH value, after which a further increase in pH will gradually decrease the rate of coating formation. Few chromating processes for such metals as magnesium or silver can be practiced in the neutral or alkaline pH range.

For the chromating processes that use accelerators (see the section "Control and Testing" in this article), it is important to maintain their level in order to ensure a good coating reaction. This is accomplished by controlled addition of an appropriate replenishing chemical.

A special group of chromate coatings, mainly used in striplined applications, is applied by no-rinse or dry-in-place processes. Unlike conventional chromating baths, which must be autodrained or occasionally dumped when reaction product accumulation prevents coating formation, these processes result in full use of the chemical. The coatings are formed by a application of a uniform wet chromate film of controlled thickness by using roll coating, dip and squeegee, or other methods and must be dried completely prior to being exposed to a physical contact. The applied solutions are more concentrated than those used in conventional processes. The chromium coating weight depends only on the wet film thickness and the concentration of chromium. These processes do not require rinsing or posttreatment, but drying and in some cases a degree of curing are necessary. Their primary advantage lies in the elimination of chromium-containing process wastewaters, which makes them very attractive from an environmental standpoint.

Rinsing. With the exception of no-rinse chromating treatments and some chromate posttreatments that are dried without rinsing, good rinsing after chromating is essential. The chromated surfaces should be rinsed with cold water immediately after treatment. The rinse should be continuously overflowed at a rate that will keep it free of excessive drag-in contamination. Double cold rinsing is frequently recommended. In spray operations, fresh water can be introduced through the last riser to induce tank overflow. Static rinse tanks and acidic or hot rinses must be avoided.

Posttreatment. After rinsing, chromate conversion coatings are often treated with a posttreatment solution. The chromium-containing posttreatments are applied to increase the corrosion resistance of chromate coatings substantially in bare and painted applications. These posttreatments also provide an improved substrate for adhesion of paint or other organic finishes. For optimum performance, the control ranges recommended by the supplier should be maintained. Chromate-base posttreatments are also used in phosphating (see the article "Phosphate Conversion Coatings" in this Volume).

Coloring. The appearance of chromate coatings can be modified for decorative purposes by coloring with dyestuffs or pigments. Dyeing is usually carried out, after chromating and rinsing, by immersion in a dilute solution of a dyestuff. The

dyestuffs are either physically absorbed into the coating or can chemically react with the film. Some colored chromate films are applied directly by a no-rinse process in which the applied chromate coatings contain a dye or a pigment. After the posttreatment or coloring step, some processes may require water rinsing, while others produce better results without rinsing.

Drying is the final processing step in the formation of chromate coatings. The coatings produced by conventional processes require only enough heat to dry the surface. Drying should be carried out in a stream of clean, warm air. For thick chromate films, it is important to avoid high drying temperatures, which can cause the formation of brittle, cracked coatings that provide reduced corrosion protection. A maximum processing temperature of 60 °C (140 °F) is often recommended for chromate coatings on aluminum. No-rinse processes often require curing and must be processed through an oven to reach the specified level of cure.

Methods of Application and Equipment

In chromating, the processed surfaces are contacted with a sequence of processing solutions. The choice of equipment depends on the nature of the articles being processed. Most chromating processes can be applied by spray or immersion.

A typical spray line consists of a completely enclosed tunnel in which various processing solutions are applied to the processed surfaces in separate stages. These stages are equipped with reservoir tanks, pumps, spray risers, and nozzles. The sprayed solutions are collected and returned to the reservoir tanks, which are usually located under the spraying section. Various types of monorail conveyors are used to move the processed parts through the tunnel. Figure 1 shows a schematic of a section of a spray chromating line. To minimize drag-in, drainage zones are provided between the individual stages. Misting is sometimes necessary to keep the surfaces wet during processing. The primary advantage of spray processing is improved cleaning uniformity due to the spray impingement. Spray line processing is applicable only to parts that can be suspended on hooks, jigs, or other structures or to the processing of a continuous strip. Figure 2 shows a schematic of a continuous coil-coating line.

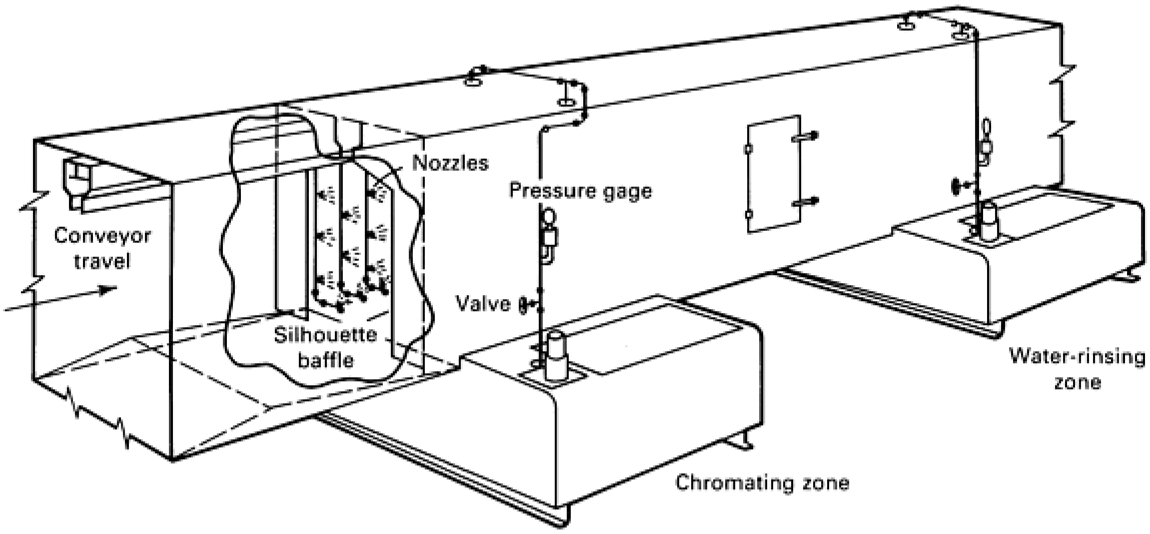

Fig. 1 Schematic layout of a spray chromating section. Courtesy of Parker Chemical Company

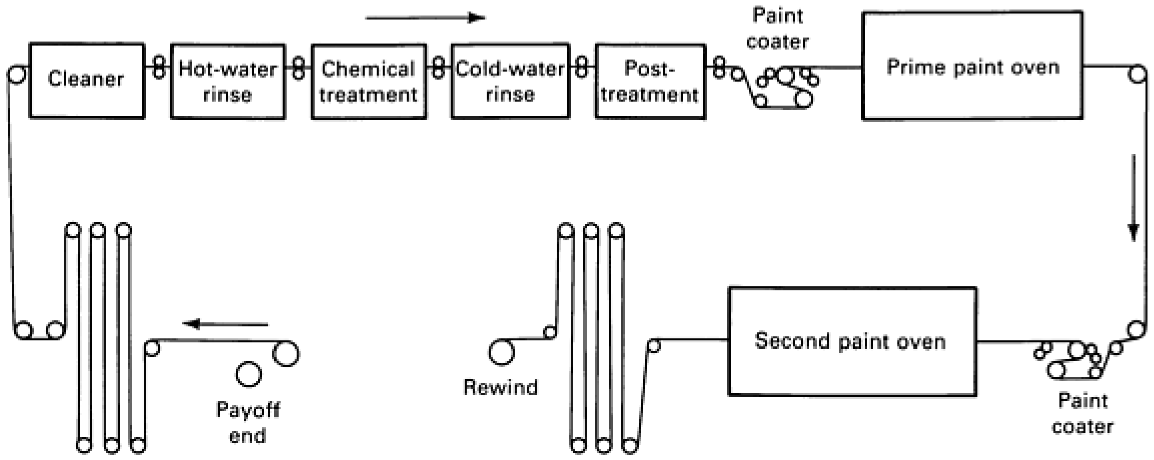

Fig. 2 Schematic of a continuous coil-coating line

Several types of nozzles can be used on the spray chromating line. The cleaner and cleaner-rinse stages use high-impingement nozzles having flat spray patterns with uniform distribution and tapered edges. This provides uniformity of spray distribution as patterns overlap in multiple-nozzle installations. In coil-coating installations, flat spray nozzles are usually positioned throughout all stages of the time. In monorail installations, the first time of sprays in the chromating stage will normally use wide-angle flat-flooding nozzles, followed by hollow-cone whirl-type nozzles in the rest of the section. The rinses after chromating generally use flooding-type spray nozzles to prevent damage to or removal of the chromate coating. If there is a possibility of drying between the spray zones, wetting nozzles should be provided. Smaller whirl-type nozzles are often used for this purpose.

Processing by immersion is more common, and it is preferred for its equipment simplicity, easier access of the chromating solution to recessed areas, simple handling of small parts, and ease of maintenance. Electrochemical conversion coatings must be applied by immersion. The parts, mounted on jigs or hooks, are transferred from one processing tank to another by a monorail conveyor. The conveyors have different degrees of automation, ranging from a simple manual to a fully automated programmed transfer control. Small parts are treated in baskets or barrels. The barrels are rotated during immersion. Rotation is important for the development of good, complete coatings. Rotation rates of 0.2 to 1.0 rpm provide for good mixing and do not damage the coatings.

In the processing of a continuous strip, the immersion treatment is accomplished in specially designed reaction cells in which the strip is submersed in a recirculating treatment bath. The treatment solution is stored in a reservoir tank; it is then usually pumped to both ends of the reaction cell. An adjustable weir maintains the required solution level. The recirculating pump is sized to change the solution in the cell approximately once per minute.

The processing tank, piping, and reservoir tank used for chromating solutions should be constructed of AISI type 316 stainless steel or low-carbon steel lined with type I (normal impact) polyvinyl chloride (PVC). The heat exchanger, pump, and nozzles should be of type 316 stainless steel. Chemical-metering pumps for adding concentrates should have type I PVC machined reagent heads and fittings with diaphragms faced using polytetrafluoroethylene (PTFE) or a similar substance. Polyethylene tubing is recommended for the concentrate supply lines to the main tank.

Control and Testing

As the metal is processed through the bath, its composition undergoes changes resulting from the coating reactions, bath drag-out, and mechanical losses. Maintenance of bath composition requires analytical monitoring and replenishing with chemical concentrates and water. The buildup of reaction products often slows the coating reaction and therefore must be controlled by a continuous discharge of a small volume of the working bath or by periodic dumpings of the bath.

Ideally, the chromating bath is operated under steady-state conditions. The reaction products are continuously removed by autodraining, and the replenisher is added to replace consumed or discharged chemicals. The main parameters used in

monitoring and controlling the chromating bath are Cr^{6+} concentration, free acid level, and total acid level. Monitored less frequently are pH and concentration of accelerators, free fluoride, and Cr^{3+} concentration.

Hexavalent Chromium Concentration. Chromic acid (H_2CrO_4) and its salts are present in solution in several ionic forms. Above pH 6, H_2CrO_4 forms chromate ion (CrO_4^{2-}); between pH 2 and 6, $HCrO_4^-$ and dichromate ion ($Cr_2O_7^{2-}$) are in equilibrium; below pH 1, the main species is H_2CrO_4. The equilibria and equilibrium constants, *K*, are:

H_2CrO_4 € $HCrO_4^- + H^+$ **(Eq 1)**
$K = 4.1$

$HCrO_4^-$ € $CrO_4^{2-} + H^+$ **(Eq 2)**
$K = 1.3 \times 10^{-8}$

$H_2O + Cr_2O_7^{2-}$ € $2HCrO_4^-$ **(Eq 3)**
$K = 3 \times 10^{-2}$

$2CrO_4^{2-} + 2H^+$ € $Cr_2O_7^{2-} + H_2O$ **(Eq 4)**
$K = 4.2 \times 10^{14}$

A common method for measuring the Cr^{6+} concentration is by a redox titration using, for example, a 0.1 *N* ferrous sulfate ($FeSO_4$) solution. The method is simple, accurate, and provides a rapid means of monitoring Cr^{6+}. A good redox indicator is a 0.1% solution of 1,10 phenanthroline ferrous complex (ferroin). According to:

$$CrO_3 + 3Fe^{2+} + 6H^+ \rightarrow Cr^{3+} + 3Fe^{3+} + 3H_2O \quad \textbf{(Eq 5)}$$

each millimeter, or point, of 0.1 *N* $FeSO_4$ corresponds to 3.33 mg of CrO_3 or 1.73 mg of Cr^{6+}.

Free and Total Acid. The concept of free acid and total acid monitoring is the most common approach to bath control. The values correspond to the number of milliliters of a standard alkali solution (usually 0.1 *N* NaOH) required to titrate a standard bath sample (normally 10 mL) to the end point at a pH of 4.5 (bromcresol green indicator end point) for the free acid, and to the end point at a pH of 9.5 (phenolphthalein indicator end point) for the total acid. Chromic acid, expressed as anhydride, will titrate:

$$2CrO_3 + 2NaOH \rightarrow Na_2Cr_2O_7 + H_2O \quad \textbf{(Eq 6)}$$
Free acid

$$CrO_3 + NaOH \rightarrow NaHCrO_4 \quad \textbf{(Eq 7)}$$

$$CrO_3 + 2NaOH \rightarrow Na_2CrO_4 + H_2O \quad \textbf{(Eq 8)}$$
Total acid

According to Eq 6 7 8, each milliliter of 0.1 *N* NaOH solution corresponds to 10 mg CrO_3 (5.2 mg Cr^{6+}) in the free acid titration and to 5 mg CrO_3 (2.6 mg Cr^{6+}) in the total acid titration.

Other acids and salts may also contribute to the free or total acid titration values. For example, phosphoric acid (H_3PO_4) titrates according to:

$$H_3PO_4 + NaOH \rightarrow NaH_2PO_4 + H_2O \quad \textbf{(Eq 9)}$$
Free acid

$$H_3PO_4 + 2NaOH \rightarrow Na_2HPO_4 + H_2O \quad \textbf{(Eq 10)}$$

Total acid

From Eq 9 and 10, it can be seen that each milliliter of 0.1 *N* NaOH corresponds to 9.5 mg of phosphate ion (PO_4^{3-}) in the free acid titration and to 4.75 mg PO_4^{3-} in the total acid titration.

The free acidity points are measures of bath acidity, which is important in the attack on the metal. For optimum performance, the bath must be operated in the recommended range for the free acid.

When the bath is operated at a constant level of Cr^{6+} by the addition of replenishing chemicals, reaction products build up, and the total acid value increases. To maintain uniform coating reaction, it is often desirable to keep the total acid value below the limit established for the process by discarding part of the solution.

Other processing parameters that must be monitored include the concentrations of accelerators (when used), free fluoride, Cr^{3+}, and the bath pH.

Accelerators. In some processes, the level of accelerator must be monitored, usually by spectrophotometric procedures. Solution standards that correspond to the low and high limits are prepared, and a color comparison is made for the working bath. This method is used, for example, in the ferricyanide ($Fe(CN)_6^{3-}$) accelerated processes for aluminum.

Fluoride. In the processing of aluminum and its alloys, it is often recommended to monitor free fluoride in the bath. This can be accomplished by using a fluoride ion (F^-) selective electrode and a suitable pH meter.

pH is another useful function for monitoring bath acidity/alkalinity. It should be measured at constant temperature or on a pH meter having temperature compensation.

Trivalent Chromium. In some processes, the level of Cr^{3+} may be important for coating quality. Spectrophotometric methods with low and high standards can be used for such monitoring.

Automatic Control. A well-established practice for monitoring the pretreatment section, particularly in smaller plants, consists of making one or two titrations per day for each bath. The bath control then relies on operator adjustments or on a timer-controlled pump that will deliver the replenisher according to adjustable settings.

With increasing demand for more continuous process control, automatic process monitoring and control are rapidly being recognized as superior to the manual methods. All of the above-mentioned bath-monitoring parameters can be adapted for continuous bath control. The instrumentation for automatic titration and spectrophotometric control is available, but it has not been widely accepted by the industry. Most of the automatic process control systems rely on conductivity and pH sensing. For most compositions, conductivity is related to bath concentration. It depends on temperature, but temperature compensation can be incorporated into the monitoring system. The low maintenance requirements and good reliability of electrodeless conductivity probes contributed to the broad acceptance of this control method. Continuous pH monitoring is also used for some chromating baths, but the electrodes require more frequent checks. Figure 6 shows a schematic of a chromating-state controlling system.

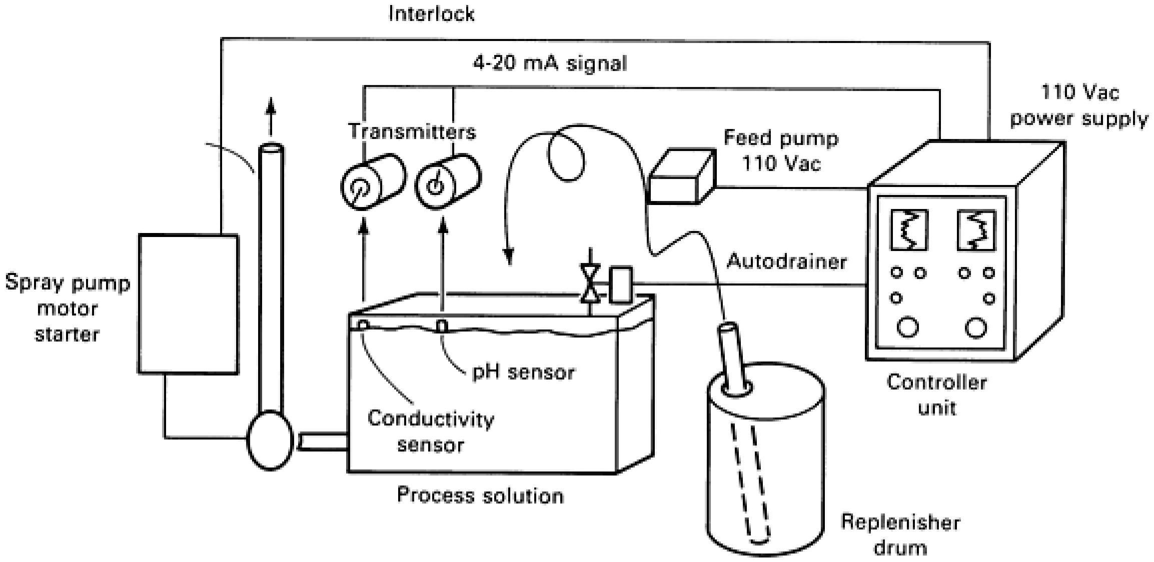

Fig. 6 Schematic diagram of an automatic process control system. Courtesy of Parker Chemical Company

The conductivity and pH controls can also be applied to other stages of the pretreatment section, and the information from the individual stages can be linked to a central process control unit. The unit can be equipped to provide complete process control, documentation reports, and communication with other plant computer control systems.

Chromate Coatings on Specific Metals

Aluminum. Because of its good corrosion resistance and attractive appearance, aluminum has found significant applications in the building, packaging, transportation, defense, and appliance industries. In most of these applications, aluminum is painted with decorative or functional organic finishes. The natural oxide, which is always present on aluminum surfaces, does not provide adequate corrosion protection or paint adhesion. Paint adhesion and under-paint corrosion resistance can be substantially increased by chromate conversion coatings. The four types in use are alkaline oxide, chromium phosphate, chromate, and no-rinse.

Alkaline Oxide. The alkaline chromating process was the first chemical treatment for aluminum, and it is still used for some appliances and for military equipment (Ref 4). The coatings are applied by immersion in 20- to 30-point alkali chromate/carbonate baths of pH 10 to 11 for up to 20 min at temperatures approaching 95 °C (200 °F). Typical coating weights are between 100 and 500 mg/ft^2, with colors ranging from light to brownish green.

Chromium phosphate coatings were first introduced in 1945 (Ref 5). The coatings are used as a paint base for architectural extrusions in doors, windows, and other exterior applications. Because the coatings do not contain Cr^{6+}, they are widely used for aluminum can end stock and rigid aluminum food containers made from prepainted coil sheet.

The coatings are applied by spray or immersion from processing baths that contain H_2CrO_4, H_3PO_4, and F^-, that have 6 to 30 chromium concentration points, and that usually have a pH less than 2. The coating weights range from 5 to 500 mg/ft^2, and the colors range from colorless to emerald green. Paint base coatings are applied for 5 to 60 s at 25 to 50 °C (80 to 120 °F), depending on the coating weight required. Decorative coatings require dwell times of 1 to 3 min and temperatures of 40 to 60 °C (100 to 140 °F).

The can stock coatings are usually applied in the 5- to 15-mg/ft^2 range, are colorless, and provide excellent lacquer adhesion. In architectural applications, coating weights from 15 to 100 mg/ft^2 form an excellent base for paint. The higher coating weights, up to 500 mg/ft^2, have good bare corrosion resistance and are also suitable for decorative applications. Recent work on the composition of chromium phosphate films has shown that they consist primarily of hydrated chromium phosphate ($CrPO_4$), Cr_2O_3, and aluminum oxides (Ref 6).

Chromate coatings were first introduced in the early 1950s and are now widely accepted by the aluminum-finishing industry for such applications as domestic appliances, small parts, aircraft and electronic equipment, and continuous coil coating of architectural aluminum (Ref 7). The films provide excellent paint adhesion and superior painted and unpainted corrosion resistance. The low contact resistance of bare films is useful in spot welding.

The processing baths contain H_2CrO_4, HF, other mineral acids, and accelerators; they are typically run between 6 and 30 points. The original accelerator was $Fe(CN)_6^{3-}$. Other accelerators, such as molybdate (MoO_4^{2-}) (Ref 8), have recently become more accepted because they eliminate the problem of $Fe(CN)_6^{3-}$ waste treatment and disposal.

Coating weights range from 15 to 200 mg/ft^2, with colors ranging from iridescent yellow to brown. For most paint base applications, coating weights are from 15 to 30 mg/ft^2. The coatings from the $Fe(CN)_6^{3-}$-accelerated process were characterized by XPS and reported to consist of microcrystallites of hydrated chromium oxides covered with an adsorbed monolayer of the accelerator (Ref 9). The MoO_4^{2-}-accelerated coatings have similar compositions, with the accelerator uniformly distributed through the film. Paint base coatings are applied within 5 to 60 s at 25 to 60 °C (80 to 140 °F). Longer times may be required for bare corrosion coatings applied by immersion.

No-rinse processes are finding increasing use in the coil coating of aluminum. In terms of corrosion protection and adhesion, these processes can often provide quality equaling that of conventional processes. An interesting comparison of the options for conversion coatings for aluminum is given in Ref 10.

The applied compositions contain Cr^{6+} and Cr^{3+} as well as other ingredients, such as F^- or PO_4^{3-}. Some formulations include organic compounds. For most paint base applications, the coating weights range from 5 to 25 mg/ft^2. Because the process does not include rinsing after the treatment, the coating weights are directly proportional to the thickness of the applied wet film and the solids content of the coating solution.

Zinc and Galvanized Steels. Although zinc and zinc-coated steels provide better atmospheric-corrosion resistance than bare cold-rolled steel, the natural resistance of zinc surfaces to atmospheric corrosion remains low. Most articles made of, or coated with, zinc by electroplating or hot-dipping are further protected. Chromating is widely used to provide corrosion protection and a decorative finish in bare applications; it can also be used as a pretreatment before painting. The chromate coatings are formed on zinc surfaces from acid solutions containing Cr^{6+}, usually other mineral acids, and accelerators. Chromate coatings on zinc can be categorized as clear, iridescent, and colored.

The largest area for the application of clear coatings is the passivation of hot-dip galvanized steel. Most unpainted zinc and zinc-aluminum coated steel sheet products used for roofs and walls of industrial and farm buildings are chromated on hot-dip galvanizing lines. These chemical treatments are applied in the coating weight range of 1 to 2 mg Cr/ft^2, with the upper limit usually defined by the color acceptable to the coated sheet users. On the strip line, coatings are applied by immersing or spraying the freshly prepared galvanized strip in chromating solutions for 1 to 3 s immediately before a set of squeegee rolls, which remove the excess solution from the strip. Broad ranges of chromium concentration (10 to 80 points) and temperatures of 40 to 70 °C (100 to 160 °F) are used to achieve the desired coating weights. The corrosion protection provided by the chromate coatings increases with their color. Typical salt spray corrosion data are given in Table 4.

Similar bath compositions are used in monorail applications, and the coatings find use in domestic appliances, automotive parts, military hardware, and other areas. The chromate coatings on zinc are also especially suitable for dyeing.

Chromate coatings can be deposited electrolytically from baths containing CrO_4^{2-}, PO_4^{3-}, F^-, and other anions. The resulting coatings, which are grey to black in appearance, have superior corrosion resistance and hardness when compared to the conventional conversion coatings (Table 4).

The use of chromates as a paint base is well established. Chromate treatments are often the best choice when the production schedule requires the coating of zinc and aluminum (also known as mixed production). The use of MoO_4^{2-}-, vanadate-, and tungstate-accelerated chromating baths is also well established. These baths can be used over a concentration range of 5 to 30 points at temperatures between 40 and 70 °C (100 and 160 °F), and with contact times from 5 to 60 s. Table 5 compares the corrosion and adhesion test results of chromate/molybdate coatings on hot-dip

galvanized steel and aluminum. No-rinse chromate processes with compositions similar to those used for aluminum are finding increasing acceptance because of the environmental advantages.

Table 5 Test performance of chromate/molybdate coatings

The paint system consisted of an epoxy primer and a polyester top coat.

Type of test	**Ref**	Ratings[a]	
		Hot-dip galvanized steel	Aluminum alloy 3003
Adhesion			
Impact (ASTM D 2794)	15	10	**10**
T-bend (ASTM D 3794)	14	0T,1T[b]	**0T,1T**
Accelerated corrosion			
Salt spray (ASTM B 117)	3	0-1[c]	**N**
Humidity (ASTM D 2247)	**12**	**10**	**10**

(a) 10, best; 0, worst; N, perfect.

(b) Designation of bend configuration; see Ref 14.

(c) Number given is the creepage from the scribed mark in $\frac{1}{16}$ of an inch.

Steel. Both chemical and electrochemical methods for chromating steel have been used. The chemical method requires high temperatures and prolonged contact times. No-rinse chromate treatments are used on continuous strip lines for paint base applications. They are applied using chemical compositions and wet film thicknesses to give coating weights in the 15- to 35-mg/ft^2 range and provide excellent paint base properties. Electrolytically produced chromium/chromium oxide coatings, better known as tin-free steel, are extensively used in the metal-packaging industry.

Magnesium is more susceptible to oxidation than aluminum, and it is frequently protected against corrosion by chromating during storage. Before chromating, the natural oxides should be removed by mechanical cleaning or acid pickling in dilute HNO_3 or HF. A mixture of HNO_3 and sodium dichromate ($Na_2Cr_2O_7$), used at ambient temperatures and contact times of 30 to 120 s, will etch the surface and produce greyish chromate coatings.

Electrochemical coatings can be deposited from solutions of H_3PO_4, $Na_2Cr_2O_7$, and ammonium bifluoride (NH_4HF_2). The coating characteristics can be modified by varying the time or current density to form thin paint base coatings or heavy films, which provide maximum bare corrosion protection.

Cadmium chromating processes use the same or similar compositions and treatment conditions as for zinc.

Testing Methods and Standards for Coatings

Testing methods for chromate coatings have been developed to assess the quality of the bare coatings and, in the case of painted applications, the performance of the entire coating system. The tests are used to evaluate several characteristics of the chromate coatings that are important to performance, as follows.

Appearance. The coatings are visually examined for uniformity, color, scratches, and visible defects. The apparent nonuniformity of iridescent coatings is usually not significant.

Coating weight is the most important quantitative parameter measurable for the coating. Corrosion protection and paint adhesion vary, depending on coating weight. The recommended ranges should be maintained.

Abrasion Resistance. The stability of the coatings can be tested by rubbing the surface with a finger wrapped in a soft white tissue. Removal of a large portion of the coating may be significant for adhesion of the coating or a paint or for dusting or buildup on dies.

Corrosion. Many different accelerated corrosion tests are used. For bare coatings, the most frequently conducted tests are the neutral salt spray test (Ref 3), the different water immersion tests, the humidity test (Ref 12), and the stack tests. For painted surfaces, the neutral salt spray test and the humidity test are the most common, but acetic acid salt spray (Ref 13) is often preferred for aluminum.

Adhesion. Standard adhesion tests for painted chromate coatings include T-bend (Ref 14), impact (Ref 15), cross hatch adhesion, various forming tests, and adhesion tests after exposure to salt spray or boiling water.

Outdoor exposure is the ultimate test for bare and painted surfaces. Outdoor exposure tests are conducted at selected sites representing rural, coastal, and industrial environments. These tests provide the best information about the performance of any coating system.

Many of the testing methods are established as national and international standards, while others are a part of well-established quality control practices developed by metal producers, finishers, and end users. Some of the standard recommended practices and specifications for chromate conversion coatings are listed in Table 6.

Table 6 Standard recommended practices and specifications for chromate conversion coatings

Safety and Waste Treatment

When handling any chemicals, it is a good working practice to consult the Material Safety Data Sheets (MSDS), which contain useful information on the chemicals and the possible hazards associated with handling and storage. The MSDS will also list all hazardous ingredients, special precautionary information, and first aid procedures in case of an accidental exposure.

Chromating baths and the concentrates used for their buildup are usually acidic and can irritate the skin and eyes upon contact. Some chromium compounds have also been identified as possible carcinogens. Both the National Toxicology Program and the International Agency for Research on Cancer report that there is sufficient evidence for the carcinogenity of chromium and certain chromium compounds in animals and humans. Recent studies have shown that aqueous solutions of Cr^{6+} administered directly into the lung have caused an increased incidence of lung cancer in animals. Although the potential for inhalation exposure with the chemicals in the concentrated form is very low, heating and spray processing may increase the possibility of inhalation.

The disposal of spent solutions and rinse waters requires waste treatment. Hexavalent chromium must be reduced to Cr^{3+} before neutralization and precipitation. Sodium pyrosulfite ($Na_2S_2O_5$) is usually used as the reducing agent in smaller operations, while for larger plants, sulfur dioxide (SO_2) is preferred for economic reasons. Wastewater treatment sludges from chromating operations are considered hazardous waste unless classified otherwise.

Aluminum Anodizing

Jeff Pernick, International Hardcoat, Inc.

Introduction

ALUMINUM ANODIZING is an electrochemical method of converting aluminum into aluminum oxide (Al_2O_3) at the surface of the item being coated. It is accomplished by making the workpiece the anode while suspended in a suitable electrolytic cell. Although several metals can be anodized, including aluminum, titanium, and magnesium, only aluminum anodizing has found widespread use in industry.

Because a wide variety of coating properties can be produced through variations in the process, anodizing is used in almost every industry in which aluminum can be used. The broadest classification of types of anodize is according to the acid electrolyte used. Various acids have been used to produce anodic coatings, but the most common ones in current use are sulfuric (H_2SO_4) and chromic (CrO_3) acids. Although CrO_3 anodizing is standardized, there are two main types of H_2SO_4 anodizing. The first is a room-temperature H_2SO_4 process termed conventional anodizing, and the second is a low-temperature H_2SO_4 process termed hardcoat anodizing. In addition to CrO_3, conventional, and hardcoat anodizing, a process known as sealing can be used to enhance certain characteristics. A number of standard tests are used in the industry to test the quality and characteristics of anodic coatings.

The three common types of anodize described above are usually controlled and described through the use of military specification MIL-A-8625 (Table 1). It has become standard in the industry to describe anodic coatings with the type and class nomenclature outlined in this specification.

Table 1 Classification of anodize according to MIL-A-8625

Type	Class	Description	Dye	Seal	Thickness	
					µm	mils
I	1	CrO_3 anodize	No	Yes	1.3-2.5	**0.05-0.1**
I	2	CrO_3 Anodize, dyed	Yes	Yes	1.3-2.5	**0.05-0.1**
II	1	H_2SO_4 anodize	No	Yes	7.5-15	**0.3-0.6**
II	2	H_2SO_4 anodize, dyed	Yes	Yes	7.5-15	**0.3-0.6**
III	1	Hardcoat anodize	No	No	46-56	**1.8-2.2**
III	**2**	**Hardcoat anodize, dyed**	**Yes**	**Yes**	**46-56**	**1.8-2.2**

The articles "Corrosion of Magnesium and Magnesium Alloys" and "Corrosion of Aluminum and Aluminum Alloys" in this Volume contain information on the corrosion resistance of anodized magnesium alloys and aluminum alloys. More information on the anodizing process for aluminum is available in the article "Anodizing" in *Surface Engineering,* Volume 5 of *ASM Handbook.*

Chromic Anodize

Chromic anodize (type I; see Table 1) is formed by immersing the workpiece in an aqueous solution of CrO_3. Current is then applied, with the workpiece being positively charged. Typical operating parameters for the CrO_3 anodizing process are:

- *Electrolyte concentration:* 50 to 100 g/L CrO_3
- *Temperature:* 37 ± 5 °C (100 ± 9 °F)
- *Time in bath:* 40 to 60 min
- *Voltage:* Increase from 0 to 40 V in 10 min; hold at 40 V for balance of time
- *Current density:* 0.15 to 0.30 A/dm^2 (1.4 to 4.3 A/ft^2)

Chromic Anodized Coatings. The CrO_3 anodizing process produces a coating that is nominally 2 µm (0.08 mils) thick. It is relatively soft and susceptible to damage through abrasion or handling. The color of the class 1 coating ranges from clear to gray, depending on whether the coating is sealed and on the alloy coated. The coating can be dyed to produce a class 2 coating; however, this is not generally done, because the coating is thin and does not retain the dye color well. About two-thirds of the coating thickness penetrates the base metal; one-third of the coating builds above the original base metal dimension. Thus, for a coating thickness of 2 µm (0.08 mils) per side, the dimensional change of the workpiece would be 0.7 µm (0.028 mils) per side.

Although the industry has adopted the penetration/buildup terminology, the terms are somewhat misleading. Actually, when the aluminum is converted to Al_2O_3 it takes up more space--approximately 133% of the space previously occupied by the aluminum converted. The penetration/buildup terms are used only as a convenience in predicting dimensional change in a coated article. The corrosion resistance of this coating is very good. The coating will pass in excess of 336 h in 5% salt (NaCl) spray per ASTM B 117.

Advantages. Although CrO_3 anodizing is the least used of the three types of anodize, it has several advantages that make its use desirable. First, because CrO_3 is much less aggressive toward aluminum than H_2SO_4 it should be used whenever part design is such that rinsing is difficult. Difficult rinsing designs would include welded assemblies, riveted assemblies, and porous castings. Second, a typical CrO_3 anodize buildup is 0.7 μm (0.028 mils) per side with good repeatability. Therefore, it is a very good coating to use when it is necessary to coat a precise dimension to size. Third, because CrO_3 anodize produces the least reduction in fatigue strength of the three coatings, it should be used where fatigue strength is a critical factor. Fourth, the color of CrO_3 anodize will change with different alloy compositions and heat-treat conditions; this makes it useful as a test of the homogeneity of structural components. Lastly, when properly applied, CrO_3 anodize can be used as a mask for subsequent hardcoat anodize operations.

Suitable Alloys. Most alloys can be successfully coated by the CrO_3 process. Exceptions are high-silicon die-cast alloys and high-copper alloys. The rule for suitability is that any alloy containing more than 5% Cu, 7% Si, or total alloying elements of 7.5% should not be coated by this process.

Relative Costs. Chromic anodize costs more than H_2SO_4 but less than hardcoat anodize.

Sulfuric Anodize

Sulfuric anodize, or type II anodize, is formed by immersing the item in an aqueous solution of H_2SO_4. Current is then applied, and the workpiece is positively charged. Typical operating parameters for the H_2SO_4 anodizing process are:

- *Electrolyte concentration:* 15% H_2SO_4
- *Temperature:* 21 ± 1 °C (70 ± 2 °F)
- *Time in bath:* 30 to 60 min
- *Voltage:* 15 to 22 V, depending on the alloy
- *Current density:* 1 to 2 A/dm^2 (9.3 to 18.6 A/ft^2)

Sulfuric Anodized Coatings. This process produces a coating that is normally 8 μm (0.31 mils) in minimum thickness. Although harder than type I coatings, H_2SO_4 anodize may still be damaged by moderate handling or abrasion. The color of the class 1 coating is yellow-green because of the preferred sealing method of immersion in sodium dichromate ($Na_2Cr_2O_7$). Clear coatings can also be produced by sealing in hot water. Clear coatings should be specified by the notation "class 1, clear." This coating can also be dyed to produce a class 2 coating. This type of anodize produces the most pleasing colors of the three anodizing methods. Dyed H_2SO_4 anodize coatings have deep colors with good repeatability. Like CrO_3 anodize. H_2SO_4 anodize coatings penetrate the base metal for two-thirds of their thickness and build above the original base metal dimension for one-third the total thickness. As with all types of anodize, the corrosion resistance of H_2SO_4 anodize is very good; it has an ASTM B 117 salt spray resistance of at least 336 h.

Advantages. Sulfuric anodize is the most widely used type of anodize and has many desirable benefits. First, because it has a fairly hard surface, it can be used in situations that require light-to-moderate wear resistance. Applications included lubricated sliding assemblies and items subject to handling wear, such as front panels. Second, because it is the most aesthetically pleasing type of anodize, it should be used where final appearance is important. It can be dyed almost any color and produces deep, rich shades that make the item appear to be made of a material bearing a color throughout, rather than an applied coating. Lastly, because corrosion resistance is good, it should be used whenever corrosion resistance is needed and the specialized benefits of the other two anodize types are not required.

Suitable Alloys. With the exception of high-silicon die-cast alloys, all alloys can be successfully coated with H_2SO_4 anodize. Clarity and depth of color of the anodize increase with the purity of the alloy. Therefore, alloys should be chosen for maximum purity consistent with the physical requirements needed in the item.

Relative Cost. Sulfuric anodize is the least costly and most widely available type of anodize.

Hardcoat Anodize

Hardcoat anodize, or type III anodize, is formed by immersing the item in an aqueous solution of H_2SO_4. Current is then applied, with the workpiece being the anode. The operating parameters for a generic hardcoat anodize process are:

- *Electrolyte concentration:* 22 to 24% H_2SO_4
- *Temperature:* 0 ± 1 °C (32 ± 2 °F)
- *Time in bath:* 20 to 120 min
- *Voltage:* constantly increased to maintain current density at 2.5 to 4.0 A/dm^2 (23.2 to 37 A/ft^2)

Hardcoat Anodize Coatings. This process produces a coating that is normally 50 μm (2 mils) thick, although other thicknesses can be specified. The coating is extremely hard. It is described as file hard (equal to about 60 to 70 HRC). The color of the class I coating ranges from gray to bronze to almost black, depending on the alloy coated, the coating thickness, and the electrolyte temperature. The coating can be dyed to produce a class 2 coating. Because thick coatings are naturally very dark, only colors darker than natural are possible. Generally, this limits the dying of hardcoat to black in common processes. If a more extensive color choice is required, there are several proprietary hardcoat processes available to accomplish this.

Hardcoat penetrates the base metal for one-half of its thickness and builds above the original base metal dimension for one-half of its thickness. Thus, for a thickness of 50 μm (2 mils) per side, the dimensional change of the workpiece would be 25 μm (1 mil) per side. Commercially available coating thickness tolerances are the greater of ±5 μm or ±10% of the total targeted thickness. The corrosion resistance of the unsealed class 1 coating is very good and comparable to the other types of anodize. When the hardcoat anodize is sealed, as in a class 2 coating, it becomes the most corrosion-resistant type of anodize.

Advantages. Hardcoat anodize, because of its variety of desirable properties, has found widespread use in manufactured products. First, because of its extreme hardness, it is used in situations in which wear resistance is required. Applications include valve/piston assemblies, drive belt pulleys, tool holders and fixtures, and many other items requiring wear resistance.

Second, because of its excellent resistance to corrosion, hardcoat is used on aluminum components in harsh environments. These include outside exposure in salt air, marine components, automobile wash equipment, components for the aircraft and aerospace industries, and food preparation machines.

Third, because hardcoat is an excellent electrical resistor, it can be used to insulate heat sinks for direct mounting of electrical or electronic equipment. Also, it is used in welding fixtures where some areas may need to be insulated from work.

Fourth, because hardcoat is a naturally porous substance, it is used in many areas in which the bonding or impregnation of other materials to aluminum is needed. This coating bonds very well with paints and adhesives. Also, it can be impregnated with teflon (polytetrafluoroethylene, or PTFE) and many dry film lubricants to impart lubricating properties to the coating.

Lastly, because of its desirable properties and also because it produces a buildup of coating, it is widely accepted as a salvage coating to restore worn or improperly machined parts to usable dimensions. Coating thicknesses in excess of 250 μm (10 mils) per side are possible on some alloys with certain proprietary hardcoat processes.

Suitable Alloys. Although almost all alloys can be coated, the 6000-series aluminum alloys produce the best hardcoat properties. As with the other anodize types, high-silicon die castings produce the lowest-quality coatings. Also, because the hardcoat process is sensitive to copper, alloys in the 2000 series should be avoided if possible. Alloys containing copper can be hardcoated, but only a relatively few commercial sources have the ability to coat these alloys with reliability.

Relative Costs. Hardcoat anodize is the most expensive type of anodize. It is generally twice the cost of H_2SO_4 anodize and 50% more than CrO_3 anodize.

Sealing of Anodized Coatings

Because all of the anodic processes produce porous Al_2O_3 coatings, it is often desirable to seal the coating to close these pores and to eliminate the path between the aluminum and the environment. Sealing involves immersing the coating in hot water; this hydrates the Al_2O_3 and causes the coating to swell in order to close the pores. Conventional sealing is generally done at a minimum temperature of 95 °C (200 °F) for not less than 15 min. There are also several proprietary nickel-base sealing agents available that are said to produce sealing at low temperature through catalytic action. Chromic and sulfuric anodizes are almost always sealed. However, because sealing softens the coating somewhat, hardcoat anodize is usually not sealed unless criteria other than hardness have the maximum importance in the finished coating.

Testing of Anodized Coatings

There are six commonly used tests to determine the quality of anodized coatings. These are visual, corrosion resistance, wear resistance, adhesion, thickness, and coating weight. Only a brief overview will be given here; extensive instructions are available in specification MIL-A-8625.

Visual inspection often indicates the overall quality of a coating. The anodic film should be uniform in appearance and free from breaks, scratches, and powdery areas.

Corrosion resistance is most often tested by salt spray. A coated panel is suspended in a salt fog for a period of time (typically 336 h) and then examined for pits and corrosion.

Wear resistance is tested through an abrasive cycle. A test panel is weighed, abraded for a number of cycles, and weighed again to determine the coating weight lost through the abrasion.

Adhesion is tested by bending a coated panel around a mandrel and checking for delamination.

Thickness is commonly checked by using one of three methods. The first is by metallographic examination of the coating under a calibrated microscope. Second, thickness can be determined by measuring a dimension of the coated part, stripping the coating, and measuring again to determined dimensioned change. Third, coatings can be measured using eddy-current instruments.

Coating weight is an indication of the density of the coating in relation to its thickness. Coating weight is determined by weighing a coated panel of known area, stripping the coating, reweighing the panel, and dividing the weight loss by the panel area for the indication of weight loss per unit area.

Table 2 lists standard test methods for anodize. More information on the testing of anodize is available in the section "Electrochemical Methods of Corrosion Testing" of the article "Laboratory Testing" in this Volume.

Table 2 ASTM standard test methods for anodized coatings

Method	Standard
Coating thickness	
Eddy current	**B 244**
Metallographic	**B 487**
Light section microscope	**B 681**
Coating weight	**B 137**

Sealing	
Dye stain	**B 136**
Acid dissolution	**B 680**
Impedance/admittance	**B 457**
Voltage breakdown	**B 110**
Corrosion resistance	
Salt spray	**B 117**
Copper-accelerated, acetic acid salt-spray	**B 368**
Ford anodized aluminum corrosion test	**B 538**

Stripping of Anodized Coatings

Stripping a part that has been anodized always results in some loss of dimensions as compared to the original size of the part. This is because the aluminum that was consumed to form the coating is removed since it has now become part of the coating. Thus, while a type II coating 7.5 μm (0.3 mils) thick would result in a 2.5-μm (0.1-mil) increase from original dimensions, stripping would decrease this by at least 7.5 μm (0.3 mils), depending on the precision of the operation.

There are three main methods of stripping, with varying degrees of controllability. Controllability is defined as the ability to remove only the anodize and not damage the aluminum base metal. The least controllable method is by immersion in warm sodium hydroxide (NaOH). This is known as caustic etching. In addition to removing anodize, this process also dissolves aluminum at a fast rate. A more controllable method is by immersion in a H_2SO_4-CrO_3 solution. These solutions are generally classified as deoxidizers. This process will also dissolve aluminum, but at a much slower rate than etching. The most controllable method is by immersing the part to be stripped in a CrO_3-H_3PO_4 solution at a minimum temperature of 95 °C (200 °F). This solution will dissolve only the coating and will not harm the aluminum.

Organic Coatings and Linings

Kenneth B. Tator, KTA-Tator, Inc.

Introduction

THE TOTAL national yearly cost of metallic corrosion in the United States was estimated at $167 billion in 1985. This total includes replacement costs and lost production costs as well as the decrease in lifetime and the expected replacement value of a given component subject to damage by corrosion. The cost of corrosion also includes the means by which the effects of corrosion are mitigated, such as the use of cathodic protection, inhibitors, alternative materials of construction, overdesign, and protective coatings.

This latter category, the use of protective coatings, is in itself a very substantial category. In 1975, in a more detailed survey, the National Association of Corrosion Engineers (NACE) estimated the cost of direct expenditures by NACE members to combat corrosion at $9.67 billion. Of this amount, $2.9 billion was spent for protective coatings and services. Coating application accounted for $805 million; purchase of coatings for atmospheric service, $531 million; marine coatings, $502 million; external pipeline coatings, $310 million; and miscellaneous expenses, $750 million.

Therefore, the use of protective coatings and linings and the costs associated with such use are considerable. More metal surfaces are protected by organic coatings and linings than by all other methods combined. In addition to protecting against corrosion, coatings often beautify and provide an aesthetic appeal. Safety colors are used to mark pipes, to indicate their contents, and to provide warnings of hazardous or dangerous work areas.

The Effect of Legislation on the Coatings Industry

Legislation concerning worker health and environmental protection has had a marked impact on the coatings industry. For example, although the practice of blast cleaning a steel surface and applying an alkyd, vinyl, or epoxy coating system remains one of the best methods or corrosion protection for many steel surfaces, the alkyds, epoxies, and vinyls themselves have changed as a result of legislation restricting the release of volatile organic compounds (solvents) and the use of toxic pigments.

Surface preparation techniques have also changed drastically; silica sand as a blast-cleaning abrasive has been banned in virtually all Western countries except the United States and Canada (and there is a strong movement to ban it in these countries as well). The containment and safe disposal of spent blast-cleaning abrasives are required in many localities to prevent environmental damage caused by the leaching into water supplies of lead, chromate, and other toxic paint pigments removed during blast cleaning. Therefore, although a paint layer over a properly cleaned surface still acts as a barrier against a corrosive environment in most cases, the components that constitute this barrier have changed considerably within the past 10 years, and the means by which the surface is properly cleaned are rapidly changing at the present time.

This article will present an overview of the different types of coating and lining materials available, along with information on the various means of surface preparation and the equipment and techniques of coating application. However, it must be recognized that all facets of coating technology are strongly influenced by legislative decree; the alkyds, vinyls, and epoxies currently in use are being reformulated, and within a few years, although the names will be the same, the compositions of these coatings (and their potential protective capabilities) may be considerably different. Furthermore, surface preparation and application techniques in current use are also under considerable legislative pressure and are expected to change considerably in the near future.

Coating Industry Response to Legislative Pressure

The coating industry has been very responsive to enacted legislation and to proposed legislation limiting the use of potentially harmful or toxic raw materials or surface preparation and/or application techniques. As a result of this positive industry reaction, the legislators as a whole have been pragmatic in their laws. For example, it is widely recognized that lead, when ingested by the body, results in anemia, damage to the central nervous system, disruption of the reproductive

system, and retardation in child development. Therefore, in 1973, Congress, under the impetus of the Food and Drug Administration, limited the lead content in all paints used for consumer use to 0.06% solids by weight.

This law effectively banned the use of lead pigments in all paints used around the home. However, because lead-containing paint pigments, such as red lead, lead chromate, and lead suboxide, are perhaps the best pigments in use for corrosion protection, they were not outlawed for paints used for corrosion protection purposes in industry. In fact, even today, no legislation restricts the use of such pigments for industrial and marine corrosion protection purposes.

However, recently enacted legislation regarding worker and environmental protection is drastically curtailing the use of lead pigments as well as other toxic pigments, such as those in the chromate, mercury, and tin families. Although such pigments can be legally used in a paint, the substantial costs due to worker protection and the high costs associated with containment and disposal of paints containing such pigments are effectively precluding their use in most new coating formulations.

Similarly, restrictions regarding volatile organic compounds in coatings have been gradually enacted over the last 10 years in order to allow formulators to develop comparable paint materials with complying solvents. Although solvent restrictions were originally enacted against what were believed to be photochemically reactive solvents (solvents that reacted under the influence of ultraviolet light and degraded to form smog and to deplete the ozone layer), it was later found that virtually all volatilizing solvents photochemically degraded and were therefore environmentally detrimental. This realization, together with the potential for further legislative restriction, has motivated coating formulators to develop water-base paints or high-solids (low-solvent) coating materials.

Volatile organic content (VOC) legislation has been mandated in California for many architectural coatings. This rule prohibits the manufacture, sale, or use of designated industrial maintenance primers and topcoats if the VOC content exceeds 420 g/L (3.5 lb/gal.). Most coating formulators were prepared for this ruling, and the quality of water-base and high-solids coating formulations is fast approaching, and in some cases exceeding, the performance of conventionally formulated solvent-containing coating systems.

Conversely, there are many industrial facilities and highway bridges that are coated with old lead-containing paints. Environmental Protection Agency (EPA) legislation requires the disposal of removed paints (and spent abrasive) in hazardous waste disposal sites if the leachate after acid digestion (pH 5) contains more then 5 ppm of lead or chromate and 2 ppm of mercury. The costs of such a disposal, not including collection costs, are estimated by many painting contractors to be from six to ten times as much as disposal costs in a normal sanitary landfill. The cost of containing the spent abrasive and paint, as opposed to letting the spent abrasive fall to the ground during blast cleaning, may in itself double or triple the cost of a paint job.

To date, enactment and enforcement of legislation have been very spotty, and many paint contractors or plant painting forces have not had to strictly comply with the law. However, this situation is expected to change in the very near future, and it is felt that the high costs associated with the repainting of many existing bridges and structures will lead to the development of new surface preparation concepts and enclosure techniques. The surface preparation equipment required for large-scale coating removal projects will become much more capital intensive, and it is possible that those coating contractors who tend to disregard specification requirements regarding the extent of surface preparation or coating thickness, and so on, will find another means of evasion, namely the violation of environmental legislation regarding containment and disposal of toxic paint residues.

Despite the pending health and environmental legislative influences and the rapidly occurring changes in the coatings industry, corrosion continues, and painting for corrosion protection must be done. Therefore, the following sections will discuss the more commonly used coating and lining materials; their characteristics, advantages, and disadvantages; surface preparation equipment and techniques; application and inspection methods; and equipment.

Coating and Lining Materials

Paints or linings that act as a protective film to isolate the substrate from the environment exist in a number of different forms. Sheet linings, commonly of the vinyl or vinylidene chloride family, are one such type of coating that can be either adhered to the surface to be protected or suspended as a bag within a tank, for example, to provide protection. Hot-applied organisols, or plastisols, again usually of the vinyl family, can also be applied to a surface, typically by dipping or flow coating, to provide a protective film.

Powder coatings are being increasingly used to protect concrete-reinforcing rod, as pipeline coatings, and as coating materials in the original equipment manufacturing markets. Fine powders produced from high molecular weight resins of the thermoplastic vinyl and fluorinated hydrocarbon families or from thermoset resins of the epoxy and polyester families are applied to the surface to be protected by either electrostatic spray or fluidized-bed deposition. The metal being protected is usually preheated at the time of application, and after application it is reheated to an elevated temperature (generally from 150 to 315 °C, or 300 to 600 °F). The specific time/temperature baking schedule depends on the metal temperature at the time of application and the type of powder being applied.

Alternatively, some coating systems are characterized by the application method used. For example, for coil-coated metal sheet (commonly steel or galvanized steel), very specialized high-speed roller application equipment is used to coat the sheet steel as it is unwound from a coil. The paint used in the coil-coating process can be of virtually any generic type, although alkyds, polyesters, epoxies, and zinc-rich epoxy coatings are the most prevalent.

Certain lining materials, such as hand lay-up fiberglass-reinforced plastics, are also used to protect steel from corrosion. Such coating systems usually consist of an epoxy primer applied to a blast-cleaned steel surface, followed by one or more polyester gel coats, with one or more layers of a fiberglass veil or woven roving mat laid within the gel coats as reinforcement. The system is then sealed with a layer of the polyester gel coat (a semiclear, 100% solids resin coat). Similarly, rubber linings are used to protect against corrosion. There are various types of rubbers, but they can generally be categorized as prevulcanized or postvulcanized (vulcanized after application). Similarly, rubbers can be formulated with different hardnesses and chemical resistances. Commonly, a rubber lining is a composite of two or three different types of rubbers adhered to each other and to the surface.

The coatings and linings discussed above are mentioned here in summary only; a more thorough description is beyond the scope of this article. Powder coatings and coil coatings are discussed in more detail in the article "Painting" in *Surface Engineering,* Volume 5 of *ASM Handbook.*

This article will be limited to the liquid-applied (usually by brush, roller, or spray) coating and lining materials that are commonly used for corrosion protection in atmospheric or immersion service. The rate of base metal corrosion where such coatings or linings are used should not exceed approximately 1.3 mm/yr (50 mils/yr). For corrosion rates above this, both in atmospheric and immersion service, or where catastrophic failure is of concern, liquid-applied coatings probably should not be used, and corrosion-protective measures should include the use of more corrosion-resistant alloys, sheet or rubber coatings and linings, fiberglass lay-ups, and so on.

The coating systems discussed in this article will be categorized by the generic type of binder or resin and will be grouped according to the curing or hardening mechanism inherent in that generic type. Although the resin or organic binder of the coating material is most influential in determining the resistances and properties of the paint, it is also true that the type and amount of pigments, solvents, and additives such as rheological aids will dramatically influence the application properties and protective capability of the applied film. Furthermore, hybridized systems can be formulated that are crosses between the categories. For example, an acrylic monomer or prepolymer can be incorporated with virtually any other generic type of resin to produce a product with properties that are a compromise between the acrylic and the original polymer. In many cases, this is advantageous, as in the mixing of vinyls and acrylics or heat-curing alkyds and acrylics. In other cases, such as with an epoxy, acrylic modification may be a detriment. Table 1 lists the advantages and limitations of the principal coating resins.

Table 1 Advantages and limitations of principal coating resins

Resin type	**Advantages**	**Limitations**	Comments
Alkyds	Good resistance to atmospheric weathering and moderate chemical fumes; not resistant to chemical splash and spillage. Long oil alkyds have good penetration but are slow drying; short oil alkyds are fast drying. Temperature resistant to 105 °C (225 °F)	Not chemically resistant; not suitable for application over alkaline surfaces, such as fresh concrete or for water immersion	**Long oil alkyds make excellent primers for rusted and pitted steel and wooden surfaces. Corrosion resistance is adequate for mild chemical fumes that predominate in many industrial areas. Used as interior and exterior industrial and marine finishes**

Epoxy esters	Good weather resistance; chemical resistance better than alkyds and usually sufficient to resist normal atmospheric corrosive attack	Generally the least resistant epoxy resin. Not resistant to strong chemical fumes, splash, or spillage. Temperature resistance: 105 °C (225 °F) in dry atmospheres. Not suitable for immersion service	**A high-quality oil-base coating with good compatibility with most other coating types. Easy to apply. Used widely for atmospheric resistance in chemical environments on structural steel, tank exteriors, etc.**
Vinyls	Insoluble in oils, greases, aliphatic hydrocarbons, and alcohols. Resistant to water and salt solutions. Not attacked at room temperature by inorganic acids and alkalis. Fire resistant; good abrasion resistance	Strong polar solvents redissolve the vinyl. Initial adhesion poor. Relatively low thickness (0.04 to 0.05 mm, or 1.5 to 2 mils) per cost. Some types will not adhere to bare steel without primer. Pinholes in dried film are more prevalent than in other coating types.	**Tough and flexible, low toxicity, tasteless, colorless, fire resistant. Used in potable water tanks and sanitary equipment; widely used industrial coating. May not comply with VOC regulations**
Chlorinated rubbers	Low moisture permeability and excellent resistance to water. Resistant to strong acids, alkalies, bleaches, soaps and detergents, mineral oils, mold, and mildew. Good abrasion resistance	Redissolved in strong solvents. Degraded by heat (95 °C, or 200 °F, dry; 60 °C, or 140 °F, wet) and ultraviolet light, but can be stabilized to improve these properties. May be difficult to spray, especially in hot weather	**Fire resistant, odorless, tasteless, and nontoxic. Quick drying and excellent adhesion to concrete and steel. Used in concrete and masonry paints, swimming pool coatings, industrial coatings, marine finishes**
Coal tar pitch	Excellent water resistance (greater than all other types of coatings); good resistance to acids, alkalies, and mineral, animal, and vegetable oils	Unless cross linked with another resin, is thermoplastic and will flow at temperatures of 40 °C (100 °F) or less. Hardens and embrittles in cold weather. Black color only, will alligator and crack upon prolonged sunlight exposure, although still protective	**Used as moisture-resistant coatings in immersion and underground service. Widely used as pipeline exterior and interior coatings below grade. Pitch emulsions used as pavement sealers. Relatively inexpensive**
Polyamide-cured epoxies	Superior to amine-cured epoxies for water resistance. Excellent adhesion, gloss, hardness impact, and abrasion resistance. More flexible and tougher than amine-cured epoxies. Temperature resistance: 105 °C (225 °F) dry; 65 °C (150 °F) wet	Cross linking does not occur below 5 °C (40 °F). Maximum resistances generally require 7-day cure at 20 °C (70 °F). Slightly lower chemical resistance than amine-cured epoxies	**Easier to apply and topcoat, more flexible, and better moisture resistance than amine-cured epoxies. Excellent adhesion over steel and concrete. A widely used industrial and marine maintenance coating. Some formulations can be applied to wet or underwater surfaces.**
Coal tar epoxies	Excellent resistance to saltwater and freshwater immersion. Very good acid and alkali resistance. Solvent resistance is good, although immersion in strong solvents may leach the coal tar.	Embrittles upon exposure to cold or ultraviolet light. Cold weather abrasion resistance is poor. Should be topcoated within 48 h to avoid intercoat adhesion problems. Will not cure below 10 °C (50 °F). Black or dark colors only. Temperature resistance: 105 °C (225 °F) dry; 65 °C (150 °F) wet	**Good water resistance. Thicknesses to 0.25 mm (10 mils) per coat. Can be applied to bare steel or concrete without a primer. Low cost per unit coverage**
Polyurethanes (aromatic or aliphatic)	Aliphatic urethanes are noted for their chemically excellent gloss, color, and ultraviolet light resistance. Properties vary widely, depending on the polyol coreactant. Generally, chemical and moisture resistances are similar to those of polyamide-cured epoxies, and abrasion	Because of the versatility of the isocyanate reaction, wide diversity exists in specific coating properties. Exposure to the isocyanate should be minimized to avoid sensitivity that may result in an asthmaticlike breathing condition upon continued exposure. Carbon dioxide is released upon exposure to humidity, which may result in gasing or bubbling of the coating in	**Aliphatic urethanes are widely used as glossy light-fast topcoats on many exterior structures in corrosive environments. They are relatively expensive, but extremely durable. The isocyanate can be combined with other generic materials to enhance chemical, moisture, low-temperature, and abrasion**

	resistance is usually excellent.	humid conditions. Aromatic urethanes may darken or yellow upon exposure to ultraviolet radiation.	**resistance.**
Asphalt pitch	Good water resistance and ultraviolet stability. Will not crack or degrade in sunlight. Nontoxic and suitable for exposure to food products. Resistant to mineral salts and alkalies to 30% concentration	Black color only. Poor resistance to hydrocarbon solvents, oils, fats, and some organic solvents. Do not have the moisture resistance of coal tars. Can embrittle after prolonged exposure to dry environments or temperatures above 150 °C (300 °F), and can soften and flow at temperatures as low as 40 °C (100 °F)	**Often used as relatively inexpensive coating in atmospheric service, where coal tars cannot be used. Relatively inexpensive. Most common use is as a pavement sealer or roof coating.**
Water emulsion latex	Resistant of water, mild chemical fumes, and weathering. Good alkali resistance. Latexes are compatible with most generic coating types, either as an undercoat or topcoat.	Must be stored above freezing. Does not penetrate chalky surfaces. Exterior weather and chemical resistance not as good as solvent or oil-base coatings. Not suitable for immersion service	**Ease of application and cleanup. No toxic solvents. Good concrete and masonry sealers because breathing film allows passage of water vapor. Used as interior and exterior coatings**
Acrylics	Excellent light and ultraviolet stability, gloss, and color retention. Good chemical resistance and excellent atmospheric weathering resistance. Resistant to chemical fumes and occasional mild chemical splash and spillage. Minimal chalking, little if any darkening upon prolonged exposure to ultraviolet light	Thermoplastic and water emulsion acrylics not suitable for any immersion service or any substantial acid or alkaline chemical exposure. Most acrylic coatings are used as topcoats in atmospheric service. Acrylic emulsions have limitations described under "Water emulsion latex."	**Used predominantly where light stability, gloss, and color retention are of primary importance. With cross linking, greater chemical resistance can be achieved. Cross-linked acrylics are the most common automotive finish. Emulsion acrylics are often used as primers on concrete block and masonry surfaces.**
Amine-cured epoxies	Excellent resistance to alkalies, most organic and inorganic acids, water, and aqueous salt solutions. Solvent resistance and resistance to oxidizing agents are good as long as not continually wetted. Amine adducts have slightly less chemical and moisture resistance.	Harder and less flexible than other epoxies and intolerant of moisture during application. Coating will chalk on exposure to ultraviolet light. Strong solvents may lift coatings. Temperature resistance: 105 °C (225 °F) wet; 90 °C (190 °F) dry. Will not cure below 5 °C (40 °F); should be topcoated within 72 h to avoid intercoat delamination. Maximum properties require curing time of about 7 days.	**Good chemical and weather resistance. Best chemical resistance of epoxy family. Excellent adhesion to steel and concrete. Widely used in maintenance coatings and tank linings**
Phenolics	Greatest solvent resistance of all organic coatings described. Excellent resistance to aliphatic and aromatic hydrocarbons, alcohols, esters, ethers, ketones, and chlorinated solvents. Wet temperature resistance to 95 °C (200 °F). Odorless, tasteless, and nontoxic; suitable for food use	Must be baked at a metal temperature ranging from 175 to 230 °C (350 to 450 °F). Coating must be applied in a thin film (approximately 0.025 mm, or 1 mil) and partially baked between coats. Multiple thin coats are necessary to allow water from the condensation reaction to be removed. Cured coating is difficult to patch due to extreme solvent resistance. Poor resistance to alkalies and strong oxidants	**A brown color results upon baking, which can be used to indicate the degree of cross linking. Widely used as tank lining for alcohol storage and fermentation and other food products. Used for hot water immersion service. Can be modified with epoxies and other resins to enhance water, chemical and heat resistance**
Organic zinc-rich	Galvanic protection afforded by the zinc content, with chemical and moisture resistance similar to that of the organic binder. Should	Generally have lower service performance than inorganic zinc-rich coatings, but ease of application and surface preparation tolerance make them	**Widely used in Europe and the Far East, while inorganic zinc-rich coatings are most common in North America. Organic binder can be**

	be topcoated in chemical environments with a pH outside the range 5-10. More tolerant of surface preparation and topcoating than inorganic zinc-rich coatings	increasingly popular	**closely tailored to topcoats (for example, epoxy topcoats over epoxy-zinc-rich coatings) for a more compatible system. Organic zinc-rich coatings are often used to repair galvanized or inorganic zinc-rich coatings.**
Inorganic zinc-rich	**Provides excellent long-term protection against pitting in neutral and near-neutral atmospheric, and some immersion, services. Abrasion resistance is excellent, and dry heat resistance exceeds 370 °C (700 °F). Water-base inorganic silicates are available for confined spaces and VOC compliance.**	**Inorganic nature necessitates thorough blast-cleaning surface preparation and results in difficulty when topcoating with organic topcoats. Zinc dust is reactive outside the pH range of 5-10, and topcoating is necessary in chemical fume environments. Somewhat difficult to apply; may mudcrack at thicknesses in excess of 0.13 mm (5 mils)**	**Ethyl silicate zinc-rich coatings require atmospheric moisture to cure and are the most common type. Widely used as a primer on bridges, offshore structures, and steel in the building and chemical-processing industries. Used as a weldable preconstruction primer in the automotive and shipbuilding industries. Use eliminates pitting corrosion.**

Auto-Oxidative Cross-Linked Resins

These coating types dry and ultimately cross link by reaction with oxygen from the atmosphere. All such coatings in this class contain drying oils, which consist mainly of polyunsaturated fatty acids and undergo film formation by oxidative drying. The drying reaction is accelerated by the presence of metallic salts such as cobalt, manganese, and lead napthenates or octoates. The drying reaction results in a reduction of unsaturated groups, commonly ethylenic carbon double bonds. The auto-oxidation reaction occurs at a relatively fast rate shortly after application of the wet paint, and it continues throughout the life of the coating, although at a much slower rate with time.

The auto-oxidative reaction is a decomposition reaction that results in the formation of hydroperoxides. Although auto-oxidative cross linking is necessary to attain the ultimate resistant properties of the film (such properties are generally attained within weeks after application), with time, the hydroperoxides formed as a result of the auto-oxidative cross linking will decompose into organic acid constituents, leading to chemical deterioration of the film. Similarly, the auto-oxidative reaction results in the hardening and ultimate embrittlement of the film, causing reduced distensibility and flexibility with the passage of time. This brittleness and accompanying hydroperoxide decomposition result in an aging deterioration of the film and the ultimate loss of protective capability. The rate at which the coating will lose its protective capability is determined by temperature, thickness, solar exposure, and the types of pigmentation (for example, zinc oxide and lead-containing pigments are particularly useful in absorbing hydroperoxides and slowing the rate of film deterioration).

Auto-oxidatively cross-linked films, in every case, contain a drying oil; this is usually a vegetable oil, such as tung, oiticica (similar to tung; obtained from the seeds of a South American tree), castor, linseed, safflower, soybean, and tall oil, or a fish oil (menhaden). The drying oil can be mixed directly with the pigment (such as red or white lead, with the addition of the metallic dryer) to form the complete coating. More commonly, however, the drying oil is combined with a resin, such as an alkyd, epoxy ester, or polyurethane, by heating or cooking. The resin adds toughness and chemical resistance to the oil, increasing its chemical and moisture resistance.

The amount of oil combined with the resin will influence the protective capability of the applied film. Long oil modifications result in less chemical resistance and longer drying times, but increased penetrability and a greater ability to protect over a poorly cleaned surface. A lesser oil modification results in a short oil that must be applied over a relatively clean substrate and dries quickly. Short oils are commonly used in fast-drying coatings that fully cure after baking for a few minutes at about 95 °C (200 °F). Short oil coatings have good moisture and chemical resistance but are relatively hard and brittle. The medium oil modifications are a compromise between the long and short oil modifications. Most commonly, alkyds, epoxy esters, and urethane resins are used in combination with drying oils to form auto-oxidatively cross-linked coatings.

Alkyd resins are derived as the reaction product of polyhydric alcohols and polybasic acids. This definition also includes polyester resins, of which alkyds are a specific type. The basic difference between an alkyd and a polyester is that the alkyd uses a polybasic acid derived from semidrying or drying oils such that the resin so formed can undergo auto-oxidation at ambient temperatures through reaction with atmospheric oxygen at the unsaturated groups present in the

fatty acid molecules. Polyesters, on the other hand, do not undergo the auto-oxidative drying mechanism, because the dibasic acid used, commonly a glycerol, has very few free unsaturated groups available for auto-oxidative cross linking. The curing reaction of polyester resins is a free radical initiated cross linking, and polyesters are therefore described as chemically cross-linked coating systems.

The properties of alkyd coatings are derived predominantly from the properties of the drying oil used in the manufacture of the resin. Drying time, hardness, color, and moisture sensitivity all depend to a great extent on the drying oil used and its type and degree of unsaturation (available cross-linking sites). For example, the use of pentaerythritol as the polyhydric alcohol leads to faster drying, greater hardness, better gloss and gloss retention, and better water resistance than alkyds based on glycerols of equal fatty acid content. Similarly, the drying oil also affects resin properties. Soybean oil has been shown to give good drying rates and good color retention; therefore, the standard alkyds are usually soybean alkyds. Linseed oils, on the other hand, generally dry faster but darken upon light exposure. The chemical structure of a linseed oil alkyd is shown in Fig. 1. Castor and coconut oils have good color-retentive properties and are used as plasticizing resins because of their nonoxidizing character.

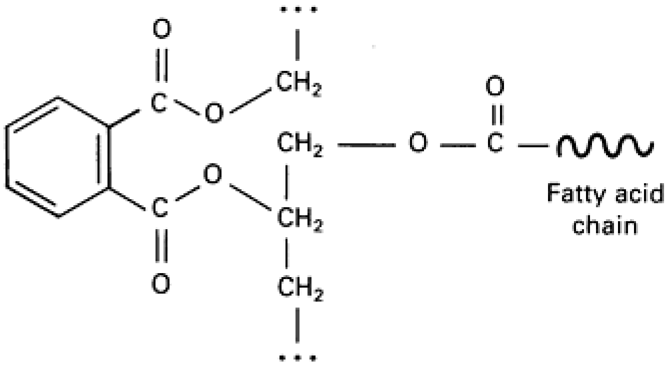

Fig. 1 Molecular structure of a linseed oil alkyd. The molecule is obtained through the reaction of a linseed oil monoglyceride and phthalic anhydride.

Phthalic anhydride and ter- and isophthalic acids are the most common polybasic acids used in alkyd preparation. The main advantage of ter- and isophthalic acids compared with phthalic anhydrides is that they provide polymers with a higher molecular weight and higher viscosity. Furthermore, they exhibit somewhat faster-drying, more flexible, tougher films, and greater thermal stability than orthophthalic alkyds.

As a class, alkyd coating systems are still the workhorse of the corrosion protection industry, accounting for perhaps as much as two-thirds of all paints sold for corrosion protection. Although they have limited chemical and moisture resistance and relatively poor alkaline resistance, their low cost, ease of mixing and application, and excellent ability to penetrate and adhere to relatively poorly prepared, rough, dirty, or chalked surfaces make them the coating system of choice on steel exposed to nonchemical atmospheric service. Thus, alkyds are widely used for structural steel exposed in chemical plants away from the chemical processes. They are also used in such applications as water tank exteriors, highway bridges, boat and ship superstructures above the waterline, and in baking formulations as coatings for containers, appliances, and machinery and equipment housings.

Alkyd Modification. Alkyds are amenable to modification with a variety of other different resins to improve specific properties, such as drying time, color retention, and moisture and chemical resistance. For example, modification with a chlorinated rubber resin results in improved toughness and adhesion as well as an increase in acid, alkali, and water resistance. Such modified paints are used on concrete floors and as highway-marking paints.

Modification with a phenolic resin improves gloss retention and water and alkali resistance. Phenolic alkyd resins have performed satisfactorily in water immersion--a service in which nonphenolic-modified alkyd resins are not suitable.

Alkyd resins with vinyl modification are commonly formulated as universal primers (primers that, after application, can be topcoated with most generic-type intermediate and topcoats). The alkyd constituent improves adhesion, film build,

solvent resistance, and thermal resistance, and the vinyl modification enhances recoatability, chemical, and moisture resistance.

Silicone modification of alkyd resins is perhaps the most widely promoted modification for corrosion-protective coatings. A silicone intermediate is added to the alkyd resin in quantities up to 30% to provide polymers with greatly improved durability, gloss retention, and heat resistance. Moisture resistance is greatly improved by the silicone modification, and such paints are extensively used as marine and maintenance paints.

Unmodified alkyds of medium-to-long oil length are familiar to homeowners as the oil-base paints used extensively around the home. Their ability to penetrate and adhere to wood and masonry surfaces, their availability in wide color ranges and glosses ranging from flat to high gloss, and their ease of application and cleanup make them ideal for a do-it-yourself homeowner.

Highly thixotropic alkyds have recently been promoted for both home and industrial use. Thixotropic paints remain in a semisolid or jellylike state when at rest, but become thinner and spread easily with the shearing action caused by brushing. As soon as the brushing action is stopped, the paints again recover their jellylike characteristics. Such paints reduce pigment settling, reduce tendencies to run or sag, and make possible the application of thicker coats that have a longer wet-edge time due to the use of slower-evaporating solvents, which otherwise cannot be used because they may cause sagging. Dripping from the brush is minimized, and the thixotropy prevents absorption on porous surfaces. Thixotropic paints are usually not recommended for spray application. The thixotropy is introduced by modification with a polyamide resin, and the jellylike behavior of the combined resin has been attributed to hydrogen bonding between the carbonyl group of the alkyd and the amide group of the polyamide coreactant.

Alkyds can be modified with polyisocyanates to improve drying rates and chemical and abrasion resistance. Such resins, commonly called uralkyds, are available in a variety of colors and generally exhibit excellent gloss and color retention. Similarly, epoxy resins are combined with the alkyd to obtain coating formulations having improved adhesion to metal, better gloss and color retention, and much improved water and chemical resistance.

Epoxy esters differ from epoxy-modified alkyds in that the epoxy is a direct esterification product of an epoxy resin and a fatty acid, such as a vegetable oil or rosin. Like alkyds, epoxy ester resins are usually prepared by reacting the drying oil with the epoxy resin at a temperature of approximately 220 to 290 °C (425 to 550 °F) in the presence of esterification catalysts. The same drying oils used to prepare alkyd resins are also used to prepare epoxy esters. As with alkyds, the oil length can be categorized as long, medium, and short, and the properties accruing to the resin derive predominantly from the amount and type of drying oil modification to the resin. As a general rule, compared with alkyds, epoxy resins have better adhesion and moisture and chemical resistance, although they are slightly more expensive.

Thermoplastic Resins

Thermoplastic resins are characterized, as their name implies, by a softening at elevated temperatures. Although the resins within thermoplastic paint systems are commonly co- or ter-polymers, the molecular structure is not cross linked into a rigid molecule, as are the chemically cross-linked or the auto-oxidized coating systems. Rather, the resinous binder is dissolved in a suitable solvent, mixed with the pigment and other constituents comprising the formulated paint, and packaged. Upon application, the solvent volatilizes, and the resinous binder, along with the pigment, is deposited onto the surface being coated as a solid film. The molecular entanglement of the relatively linear (although perhaps coiled or tangled) molecule segments provides a layering effect that, with pigmentation and sufficient thickness, provides the characteristic moisture and chemical resistance of the resin system used.

The most useful thermoplastic resins for corrosion protection are the vinyls, chlorinated rubbers, thermoplastic acrylics, and bituminous resins (coal tar and asphalt). Each resin type has its own characteristic qualities, specific resistances, and susceptibilities, and each will be discussed below in greater detail. However, in all cases, because no chemical change takes place to the resin upon application and drying, it stands to reason that the applied coating will redissolve if it is exposed to the same solvents that it was originally dissolved in upon formulation. This is precisely what happens, and such coatings have no resistance to the solvents in which they were originally dissolved or in solvents of equal or greater solvency for that particular resin. This, however, is not usually a disadvantage; although solvent resistance may be poor, such coatings are rarely, if ever, exposed in a solvent-laden atmosphere. Instead, they are called on to resist weathering, acid or alkali exposures, and moisture. As a rule, all have good resistance in these applications, and the vinyls, chlorinated rubbers, and coal tars have excellent moisture resistance as well.

Conversely, the solvent susceptibility of these thermoplastic coatings is often an advantage. When maintenance repainting is necessary, the same system can be reapplied, and the solvents in the new topcoat will partially redissolve the existing old coat, resulting in intermolecular entanglement of the new coating with the old and giving excellent adhesion. Thus, solvent solutions of these thermoplastic resins have excellent recoatability with the same system, even after extended periods of time. This cannot be said for either the auto-oxidative cross-linking coatings or the chemically cured coatings.

While the predominant characteristics of auto-oxidative cross-linking resins derive from the type and amount of drying oil incorporated into the coating, the characteristics of the thermoplastic resins derive chiefly from their molecular structure. Thus, apart from the observations described above for thermoplastic resins, a further description of the characteristics of these resins must be individually categorized.

Vinyls. Vinyl coatings are usually applied as a solvent-deposited solution consisting of either a polyvinyl chloride-polyvinyl acetate (PVC-PVA) copolymer in the ratio of approximately 86% PVC to 13 to 14% PVA or as a high molecular weight emulsion of the same copolymer in what is commonly called a latex or water-base paint.

The vinyl solution coatings are generally very low-solids high-solvent materials that, although quite widespread in use at present, will be increasingly influenced by restrictive VOC legislation. Most thermoplastic vinyl solution coatings contain solvents (generally oxygenated solvents such as ketones and glycol ethers) ranging from 75 to 90% of the total volume of the formulated paint. As a result, the VOC content far exceeds the widely used 420-g/L (3.5-lb/gal.) maximum, and where such legislation is enforced, solution vinyl coatings cannot be used.

Most vinyl resins consist of the copolymer of PVC and PVA. Polyvinyl chloride is a very inert material with high symmetry, an extremely stable carbon-to-carbon backbone, and stable carbon-to-hydrogen and carbon-to-chlorine pendant sidegroups. As a consequence, it is very inert and cannot be dissolved even by some of the stronger solvents used in coating manufacture. Polyvinyl chloride is usually heat extruded into sheets or formed by heat. Without modification by PVA or other copolymers, PVC is unsuitable for use in paint manufacturing. Polyvinyl acetate, on the other hand, while retaining the stable carbon-to-carbon backbone, does have an ester sidechain that is susceptible to solvent attack. Consequently, PVA is readily dissolved by the stronger solvents. Although PVA coatings are used, they have only limited moisture and chemical resistance and are suitable only for interior decorative coatings without further modification.

However, a copolymer of PVC and PVA in a ratio of approximately 86% PVC to approximately 13% PVA, combined with approximately 1% or less maleic acid, is the basis for most solvent-deposited vinyl coatings used for corrosion protection. Figure 2 shows an example of a PVC-PVA vinyl. Because the vinyl resin is somewhat sensitive to ultraviolet light, it is essential to use an ultraviolet scattering pigment such as rutile titanium dioxide in order to minimize chalking and ultraviolet degradation of the coating. Other pigments can be used in conjunction with titanium dioxide, but they act more as filling and reinforcing pigments. Because of the acidic nature of the vinyl resin, zinc oxide and zinc dust pigments must be used with care; they have a tendency to gel or curdle the paint while in solution.

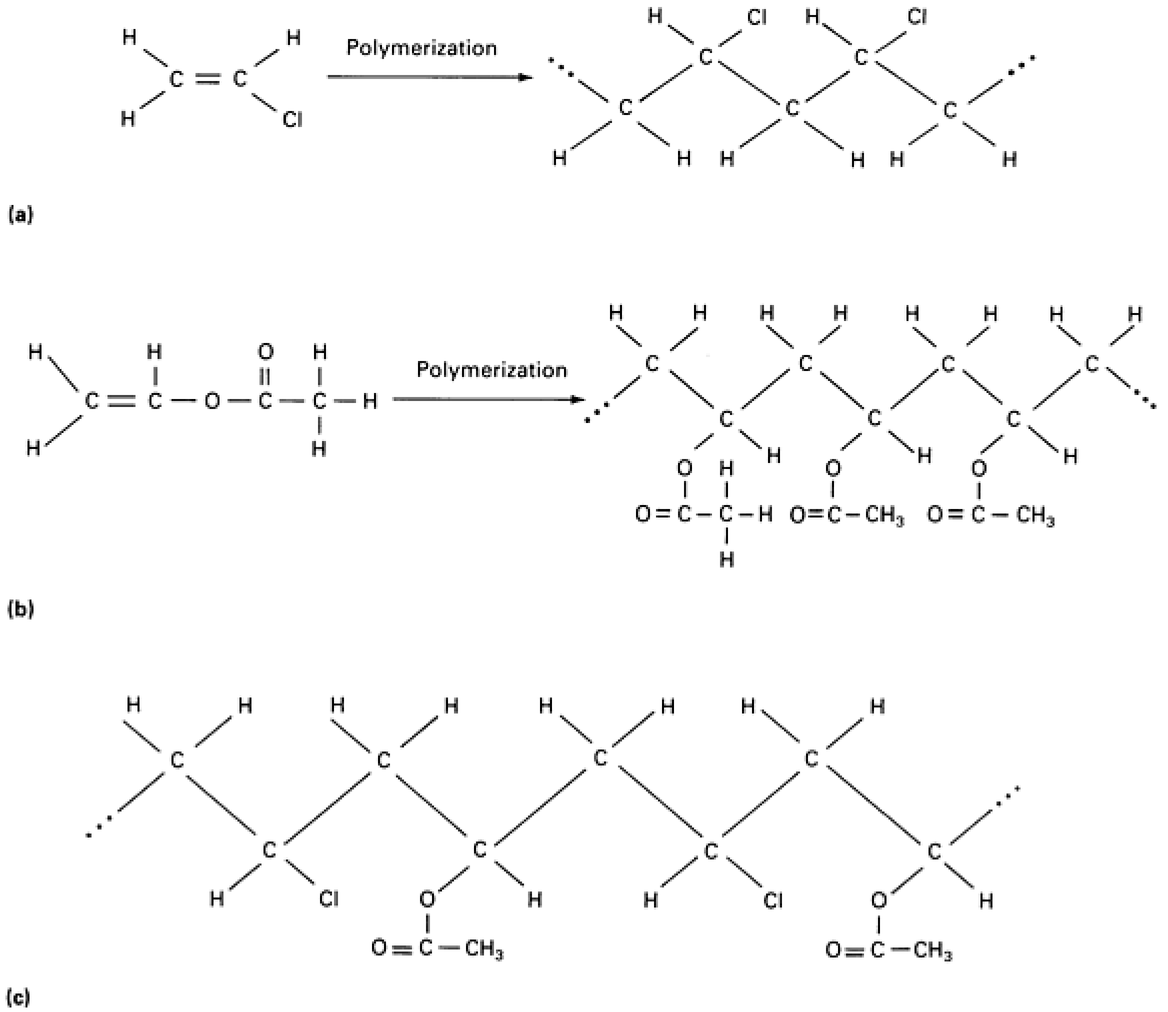

Fig. 2 Reaction of PVC and PVA polymers to form a PVC-PVA copolymer. (a) Polymerization of PVC. (b) polymerization of PVA. (c) PVC-PVA copolymer

Vinyl solution coatings are noted for their outstanding toughness and water resistance. The U.S. Army Corps of Engineers has used a five-coat vinyl system for years on steel exposed both in fresh- and saltwater immersion and in atmospheric service on locks and dam gates under their jurisdiction throughout the United States. Although the five-coat system is somewhat expensive to apply, it is extremely durable when properly applied. Total repainting intervals of over 20 years are commonplace with the Army Corps of Engineers, although maintenance repainting and touch up of deteriorated or damaged paint may be necessary at more frequent intervals. The Army Corps of Engineers formulations are presented below:

Ingredient	Percent by weight
Formula V-766e	
Vinyl resin, type 3 (VYHH)[(a)]	**5.6**
Vinyl resin, type 4 (VMCH)[(a)]	**11.6**
Titanium dioxide	**13.0**
Diisodecyl phthalate	**2.9**
Methy isobutyl ketone	**32.0**
Toluene	**34.7**
Phosphoric acid	**0.2**
Formula V-766e(AP)	
Vinyl resin, type 3 (VYHH)[(a)]	**5.4**
Vinyl resin, type 4 (VMCH)[(a)]	**11.1**
Titanium dioxide	**12.5**
Diisodecyl phthalate	**2.9**
Toluene	**11.2**
Nitropropane solvent	**48.0**
Methyl ethyl ketone	**8.7**
Phosphoric acid	**0.2**

Source: U.S. Army Corps of Engineers specification for vinyl formula V-766e.

(a) VYHH and VMCH are proprietary designations for these vinyl resins. Approximate compositions: VYHH, 86% polyvinyl chloride, 14% polyvinyl acetate: VMCH, 86% polyvinyl chloride, 13% polyvinyl acetate, 1% maleic acid.

Vinyl paints are used as complete systems (vinyl primer, intermediate, and topcoat) or as topcoats over zinc-rich primers for the protection of highway bridges throughout the United States. The relative inertness of the vinyl topcoat, coupled with good adhesion (when formulated with maleic acid), protects the relatively reactive zinc in an organic or inorganic zinc-rich primer from reaction with environmental moisture, acid rain, and other atmospheric contaminants. The zinc rich primer provides galvanic protection to the underlying steel (see the section "Zinc-Rich Coatings" in this article).

Chlorinated rubber coatings are also considered to be solvent-deposited coatings in that there is no chemical change that occurs during application, and the coating film forms on the surface after application as the solvent evaporates. Chlorinated rubber coating systems are much more widely used in Europe than in the United States, although systems based on chlorinated rubbers have excellent resistance to acids, alkalies, oxidizing agents and have very low water vapor transmission rates (approximately one-tenth that of an alkyd resin coating). In addition, they are generally nonflammable (due to their chlorine content) and nontoxic. Chlorinated rubber paints are used principally as chemical- and corrosion-resistant coatings, marine coatings, building masonry and swimming pool paints, highway marking paints, fire-retardant and mold-resistant paints, and primers for hot-applied coal tar or asphaltic enamels (to provide good adhesion to steel).

Chlorinated rubber resins are manufactured by chlorinating natural rubber with approximately 65 to 68% chlorine. The resulting resin must be plasticized and stabilized against light, heat, and gellation in order to be used as a binder in protective coatings. Heat stability is obtained by incorporating low molecular weight epoxy compounds or epoxidized oils into the resin. Light-fast plasticizers such as dialkyl phthalates and acrylic resins are used. For severe chemical service, chlorinated paraffins or chlorinated diphenyls should be used because of their high resistance to saponification.

The amount of plasticizer is very important in these coatings because it affects the properties of the film. If the coating is underplasticized, it will be harder and more brittle and will exhibit poor adhesion. If the resin is overplasticized, the coating will be softer and thermoplastic and will exhibit a tackiness that may result in a higher dirt retention. Overplasticization will also increase water transmission rates or water permeability through the film, diminishing the corrosion protection. The chemical structure of a chlorinated rubber resin is shown in Fig. 3.

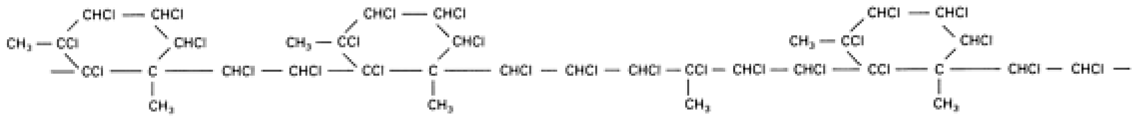

Fig. 3 Molecular structure of a chlorinated rubber resin. Source: Ref 1

The presence of ferrous or ferric ions may cause gelation of the chlorinated rubber coating. As a consequence, care must be taken during the manufacture to prevent excessive contact with iron or steel. Certain reactive pigments, metal chlorides, or ketone solvents that will aggravate gelling should not be used, and the cans in which the paint is packaged should be coated to minimize corrosion and to prevent possible contamination by ferrous or ferric ions.

Chlorinated rubber resins are sold as an off-white powder and are commonly pigmented with most of the usual pigments used in chemical-resistant coatings. Rutile titanium dioxide is a widely used pigment for white and tinted paints. Metallic pigments, particularly aluminum and copper flake powders, as described in *Powder Metal Technologies and Applications*, Volume 7 of the *ASM Handbook*, may cause gelation. Also, zinc oxide should not be used as a pigment in major amounts, because it will degrade chlorinated rubber at elevated temperatures. Zinc-rich paints based on chlorinated rubber resins are used successfully. The formulations typically contain 75% or more of zinc dust and are plasticized with a small amount of chlorinated paraffin.

Chlorinated rubber coatings are soluble in most solvents, including aromatic hydrocarbons, chlorinated hydrocarbons, esters, ketones, and some alcohol ethers. Care must be taken in the solvent blend used to form a chlorinated rubber coating: a solution that dries too rapidly may result in cob-webbing or a stringy application when sprayed or in pulling of the brush or roller when applied by brushing or rolling.

Coatings with thicknesses in excess of 0.13 mm (5 mils) should be applied in three or more coats to provide optimum protection. After drying, properly plasticized chlorinated rubber coatings will develop excellent adhesion to both steel and concrete substrates.

Because of their extremely low water vapor transmission rates, as well as their flexibility, extensibility, and ability to bridge or seal over pores or cracks, chlorinated rubber paints are excellent coatings for use in concrete swimming pools. In the United States, this is a major market for chlorinated rubber coatings. These same attributes, however, are also valuable when coating steel and other substrates (such as wood): accordingly, such coatings have found extensive use worldwide in protecting steel from corrosion in various chemical atmospheres and in salt- and freshwater immersion.

Acrylic coatings can be formulated as thermoplastic solvent-deposited coatings, cross-linked thermoset coatings, and water-base emulsion coatings. Acrylic resins that are used for protective coatings consist of polymers and copolymers of the esters of methacrylic and acrylic acid. The resulting resins, with suitable pigmentation, provide excellent film-forming coatings characterized by excellent light fastness, gloss, and ultraviolet stability. Chemical resistance to weathering environments is generally excellent, as is resistance to moisture. Most acrylic coatings are not suitable for immersion service or strong chemical environments, because of attack of the ester group present on both the polymethyl methacrylate and ethyl acrylate resins. This ester group, however, is present only as a pendant sidechain; accordingly, the carbon-to-carbon backbone chain of the acrylic resins does provide very good chemical and moisture resistance, which enables these resins to be used in most chemically moderate atmospheric services.

Coatings can be formulated with acrylate, methacrylate, or higher homopolymers. Blends of both resin types are also commonly used for corrosion protection. Generally speaking, those coatings formulated from the acrylates or from copolymers with a preponderance of the acrylate ester are softer and more flexible than the corresponding methacrylates. The ultraviolet resistance of the acrylate is somewhat lower than that of the methacrylate because of the presence of a tertiary hydrogen attached directly to a carbon comprising the molecular backbone. This active hydrogen is vulnerable to photo-oxidative and thermo-oxidative attack. Consequently, acrylate esters have a greater susceptibility to ultraviolet light and oxygen, leading to yellowing or darkening in comparison with the methacrylates. The methacrylates, although providing a harder and more brittle film with less adhesion, are more chemical and moisture resistant and have a greater heat tolerance.

With both resin types, greater flexibility, toughness, and resistance to abrasion can be obtained by increasing the molecular weight. Hardness decreases, although flexibility and elongation increase in both resin families. However, with too great an increase in molecular weight, solution viscosity becomes excessive, and solvent release in a formulated paint becomes excessively slow.

Acrylic resins are characteristically soluble in moderately hydrogen-bonded solvents, such as ketones, esters, aromatic hydrocarbons, and certain chlorinated hydrocarbons. Excellent color retention, gloss, and ultraviolet stability, coupled with very good moisture and chemical resistance, make acrylic coatings quite popular in protecting steel in atmospheric service.

Thermoplastic Acrylics. Like all thermoplastic coatings, thermoplastic acrylics are essentially solvent-deposited resins that do not undergo any chemical change after, or at the time of, application. Upon application, the solvent carrier volatilizes, and the coating system sets, hardens, and attains its final resistant properties as the solvent evaporates. Heating or baking is often used to hasten solvent evaporation.

Probably the major use of thermoplastic acrylics is in automobile finishing and refinishing. Advantages include the ease of tinting and coloration, excellent dispersion of metallic reflective pigments, high gloss and ultraviolet stability, and thermal reflow. Thermal reflow is important because, after the original factory coating is applied, minor imperfections, sanding marks, and other irregularities can be overcome by reheating the coating under heat lamps or in an oven. The surface of the coating will partially melt and reflow to form the smooth, glossy appearance one expects with an automotive finish.

Another major market is aerosol can paint, which is widely sold throughout the world. These paints are thermoplastic acrylics, and they dry and harden through solvent evaporation.

Solvent-deposited acrylics are also used for maintenance finishes, but more commonly, the acrylic monomer or copolymer is added to an alkyd. This results in an acrylic-modified alkyd with the excellent penetration properties, adhesion, and ease of application of the alkyd, combined with the improved ultraviolet resistance, gloss, and color retention of the acrylic.

Thermosetting Acrylics. Thermosetting, or cross-linking, acrylics can be obtained by combining the methacrylate or acrylate esters with reactive nonacrylic polymers. The most common cross-linking agents use are the epoxy resins, the

urea or melamine-formaldehyde resins, and the vinyl resins. Generally, the nonacrylic polymer is the predominant structure present in the coating film, and the acrylic modification is done only to enhance the color, gloss, and ultraviolet stability of the nonacrylic constituent. The resulting thermoset acrylic finishes are generally harder, tougher, and more resistant to heat and solvents than thermoplastic acrylics. On the other hand, thermoset acrylic finishes are also generally less resistant to ultraviolet light and usually require heating or baking after application to attain the desired physical properties.

Acrylic finishes based on urea or melamine-formaldehyde resins cross linked with acrylic monomers are widely used for coating such home appliances as refrigerators, washing machines, dryers, dishwashers, freezers, and air conditioners. The coatings have excellent adhesion and detergent resistance, and they have short curing times at relatively low curing temperatures. The major advantages of such coatings are the high gloss, range of colors available, and lack of yellowing or darkening upon exposure to sunlight.

Water-Base Acrylic Coatings. A major coating market for acrylics has been the acrylic emulsion paints widely used by the homeowner for indoor and exterior painting purposes. Compared to oil-base coatings, the other major homeowner-type paint, the water-base acrylics have a number of advantages. They have a much faster drying time, and can be recoated within 1 h. They have better alkali resistance, excellent adhesion, come in a variety of colors and maintain their color and gloss in the presence of sunlight and ultraviolet light, and have excellent long-term flexibility and toughness. The major advantage, of course, is the ease of cleanup with water-base paints.

The disadvantages are that the oil-base paints have greater penetrability, particularly on wood and porous surfaces, and have better initial adhesion. On smooth surfaces, water-base paints may peel or loose adhesion, while an oil-base paint may wet sufficiently to maintain good adhesion. However, acrylic paints have better resistance to blistering because of their breathing ability and have much better resistance to chalking and yellowing. Water-base coatings may provide better adhesion to damp wood and masonry substrates than oil-base paints.

The chemistry of water emulsion coatings is extremely complex. Generally, high molecular weight acrylic polymers are polymerized in a water emulsion. The desired pigments are dispersed in the emulsion, and the required additives are added, followed by tinting and color pigments. Titanium dioxide is the most widely used white-hiding pigment, although most other water-insoluble alkali-resistant organic and inorganic pigments can also be used. Wetting agents are added to ensure complete pigment wetting in the water vehicle, and antifoaming additives are used to prevent foaming during manufacture and at the time of application. Thickening additives (for proper application viscosity) are used to prevent pigment settling as well as running and sagging after application.

Surfactants are added to enhance pigment dispersion, and it is these additives that provide the water sensitivity that most water-base coatings have after application. Briefly stated, most surfactants have a hydrophobic (water-hating) and a hydrophilic (water-loving) end, which orients around the emulsified resin and the pigment particles. The hydrophobic end is adjacent to the resin particle surface, while the hydrophilic end is attracted to the water carrier. After application of the paint, many of these surfactants remain entrapped within the film cross section, and the hydrophilic end of the surfactant attracts water from the environment, which tends to soften and swell the coating. In atmospheric service, there is insufficient water--or insufficient wet time--to cause a problem. However, in prolonged water immersion, water may be attracted by the surfactant, penetrate the film, and cause softening and swelling of the coating with a loss of adhesion. Consequently, water-base coatings, as currently formulated, are not suitable for prolonged water immersion.

For most air dry (nonbaking) applications, a coalescing solvent is added. This very slow-evaporating organic solvent, which is miscible with water, is added to the water carrier. As the water evaporates, the concentration of the solvent becomes higher and higher in the water/solvent mixture. Ultimately, in the drying film, the solvent reaches a sufficient concentration that it can partially solvate the resin particles, causing them to soften and meld together upon further drying. The coalescing solvent helps convert the emulsified particles into a relatively smooth, homogeneous film. However, residual solvent may be entrapped within the film, and it too can lead to water sensitivity.

For wood or masonry surfaces where water vapor transmission may be a problem, latex paints may be suitable because they are said to breathe. This breathing occurs as a result of irregularities during the coalescence part of the film forming; the particles may not align themselves properly relative to other emulsified particles. A series of pores or defects in the coalesced film will result. Such discontinuities are extremely small, and the surface tension of water in liquid form will not enable penetration through the coating to the underlying substrate. However, water vapor may readily pass through such discontinuities, resulting in its breathing ability.

Water-base paints develop poor film properties when applied during cold, damp weather. In order for proper weather and chemical resistances to develop in a water emulsion film, water evaporation and proper drying must occur. If water evaporation is retarded and if the drying sequence is upset by becoming either too slow (or in some cases too rapid), proper coalescence and film formation do not occur. The result can be a soft, poorly adherent film that, when drying does finally occur, will show cracking; this film may also be brittle and adhere poorly. Too fast a water evaporation rate on a hot surface can lead to a powdery, poorly adherent paint film or a film with many voids, pinholes, or cross-sectional porosities.

Acrylic paints for interior use are similar to those for exterior use, except that a higher pigment volume can be used, and the pigments that are not as light-fast as those for exterior use can be used. The major competition for acrylic interior paints comes from lower-cost PVA or butadiene-styrene base latex coatings.

Photopolymerization of acrylic homeo and copolymers is for the painting industry an emerging--and very interesting--technology. The wavelength ranges of ultraviolet light (about 200 to 400 nm) and visible light (approximately 400 to 800 nm) can initiate cross linking in a susceptible binder system. Acrylic esters show a very rapid response to photoinitiation as compared to all other commonly used coating resins. Within the acrylic family, the acrylate is at least ten times more reactive to ultraviolet or visible light radiation than the methacrylate. All types of resins used in conventional paint systems (such as alkyds, epoxies, polyesters, and urethanes) can be modified with acrylate esters, and the combination can be combined with a suitable photoinitiator to aid in the radical polymerization mechanism.

High-solids, low molecular weight, light-cured coatings can be applied by brush, roller, and spray. After setting up and exposure to an intense source of ultraviolet or visible light, they cross link through a photoinitiated free radical polymerization, which leads to thorough cross linking, hardening, and almost immediate attainment of moisture and chemical resistance. The potential of this technology for exterior painting is evident; the sun itself might act as the cross-linking agent. However, such technology with regard to corrosion-protective coatings is far from perfected. Current problems include the extremely high cost of formulated paints, the requirement for intense ultraviolet or light energy in order to initiate curing, and the curing problems with pigmented coatings or coatings more than a few mils thick.

Therefore, although photochemically cured coatings for corrosion protection have not been developed, the technology is viable, and some radiation-curable coatings have been developed. Commercial applications include clear coatings, thin films of pigmented printing inks, coatings pigmented primarily with inert pigments (for example, paste fillers for particleboard), and paper coatings. Light-cured acrylic laminates and overlays, applied as an adhesive or paste on tooth enamel, have been developed for dental practice.

Bituminous Coatings. The bitumens used in the coatings industry are coal tar and asphalt. Although these materials are distinctly different physically and chemically, in appearance they are essentially identical black thermoplastic tar materials. As coatings, the bitumens can be applied as hot melts, solvent cutbacks, or emulsions.

Hot melt application involves heating the bitumen to a temperature of 175 to 245 °C (350 to 475 °F) such that its viscosity at that temperature is very low--almost waterlike. Hot melt asphalts and coal tar materials are usually applied with mops or swabs to the surface being coated, although brush, roller, or spray application is sometimes used. Flow coating of the interiors of pipes and small vessels is also done. In this method, the hot melt is flowed into the pipe or vessel, and the item is rotated or turned to cover all surfaces before the coating cools and hardens. The interiors and exteriors of pipeline sections are often flow coated at pipeline-coating facilities (see the article "Corrosion of Pipelines" in this Volume).

Asphaltic or coal tar bitumens dissolved in a suitable solvent (normally aliphatic and aromatic hydrocarbons) are termed solvent cutbacks. Dissolving the bitumen in a solvent lowers its viscosity sufficiently that the cutback can be applied by spray, brush, or roller, as appropriate. After application, the solvent volatilizes and the bitumen resolidifies into a film. The coating thicknesses of solvent cutbacks are generally considerably less than those achieved by hot melt application, but the convenience of not having to heat the bitumen at the job site immediately before application is a major advantage.

Water emulsions are prepared by suspending minute particles of the bitumen in water using emulsifying agents and by combining with inert fillers, such as pulverized talcs (hydrated magnesium and aluminum silicates), coal dust, powder silica, mica, and limestone dust. After application, the water evaporates. Coalescence occurs in the fashion typical of any emulsion coating, and a protective film is formed.

In general, hot melt application provides the best moisture and chemical resistance, followed in order by the solvent cutback and water emulsions. The use of asphaltic and coal tar bitumens as roof coatings, highway or pavement sealers,

and underground coatings or waterproofing compounds is quite common. Asphaltic materials have much better atmospheric weathering resistance and are less deteriorated by ultraviolet light than coal tar coatings are. On the other hand, coal tar coatings have much better resistance to moisture, acids, and alkalies than the asphaltics. The coal tars and asphalts are generally incompatible as a result of their chemical makeup and usually should not be used as mixtures or applied one type over another.

Coal tar enamels or pitches are derived from the coking of coal. When coal is heated in the absence of air to a temperature of approximately 1095 °C (2000 °F), it decomposes partially into a gas and coke. The gas is subsequently condensed, and coal tar is formed. Lighter fractions are removed from this tar by subsequent heating and gas extraction until the desired coal tar fraction for use in coatings is obtained. The compounds in coal tar range from low-boiling, low molecular weight benzene to complex, high molecular weight, aromatic hydrocarbons.

Essentially, there are three types of coal tar enamels:

- A straight pitch base that is relatively hard and brittle but has the greatest moisture and chemical resistance
- A plasticized enamel that is more flexible and has greater cold weather application tolerance, but the least chemical and moisture resistance
- An intermediate grade (containing about 50% of each of the first two) that is also intermediate in its properties

For best adhesion, preheating of the object being coated is preferred; if this is not feasible, a primer can be used to promote adhesion of the coal tar. Many of the primers are solvent cutbacks of coal tar pitch combined with a chlorinated rubber resin, plasticizers, highly volatile solvents, and some color pigment. The primer is of a lower viscosity and can more readily wet the steel surface. In addition, it dries faster and leaves a firmly bonded layer on the steel. Subsequently applied coal tar adheres more readily to steel that is primed in this manner.

Coal tar coatings (whether applied as hot melts, cutbacks, or emulsions) are subject to ultraviolet light degradation and resultant cracking. The cracking results from the volatilization or evaporation of lower molecular weight constituents from the surface and attendant shrinking. The surface of the coating contracts and cracks, while the underlying thicknesses remain plastic. Such "alligator" cracking (Fig. 4) is not detrimental, although it does diminish the thickness of the coating within the crack fissures. Because of this phenomenon, coal tar coatings are used in underground or immersion service, in which they are not subject to ultraviolet light. As roof coatings, they must be shielded by a subsequent coat of non-coal tar material or by gravel or pebbles applied for this purpose.

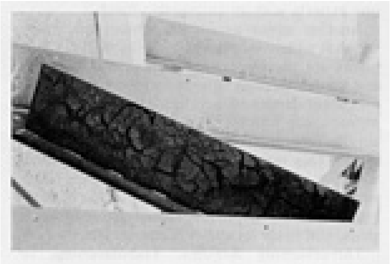

Fig. 4 "Alligator" cracking of a coal tar coating caused by volatilization of low molecular weight constituents from the surface and by coating shrinkage

Asphalts. Natural asphalt, or gilsonite, is a hard, brittle resin that is mined predominantly in Utah, Colorado, and Trinidad. Increasingly, asphalts obtained as residues from the distillation of crude petroleum are replacing the natural asphalts because of better uniformity, fewer impurities, and lower transportation costs. Asphaltic compounds are comprised of complex polymeric aliphatic hydrocarbons, and they have good water and chemical resistance; like coal tars, they are sensitive to oils and solvents. Asphaltic coatings have much greater ultraviolet resistance than coal tars do and are therefore used for above-grade applications in which coal tars will not be suitable.

Cross-Linked Thermosetting Coatings

Chemically cured coatings, in the context of this article, refer to coatings that harden or cure and attain their final resistant properties by virtue of a chemical reaction either with a copolymer or with moisture. Examples of coatings that chemically cross link by copolymerization include epoxies, unsaturated polyesters, urethanes in which the isocyanate is reacted with a polyol, high-temperature curing silicones, and phenolic linings. Chemically cured coatings that react with water include moisture-cured polyurethanes and most of the inorganic zinc-rich coatings. Although drying-oil-base coatings (see the section "Auto-Oxidative Cross-Linked Resins" in this article) are also chemically cross linked upon their reaction with oxygen from the air, they are excluded from this category because the auto-oxidative cross-linking mechanism is a sufficiently distinct category of chemical cross linking to merit a separate discussion.

The fundamental principle of chemical cross linking is to formulate a coating using a resin or binder of low molecular weight. When mixed and applied, reaction with moisture from the atmosphere or with a coreactant takes place, resulting in cross linking and a much larger three-dimensional molecular structure. In fact, it is possible to begin the application of a cross-linked coating system to the interior of a large tank or vessel, and upon completion of the application many hours later, the film may cure into one large macromolecule that may cover many thousands of square feet of surface area. Such a coating or lining, if suitably formulated, will provide a tough, flexible, and highly chemical-resistant corrosion protection barrier over the underlying substrate. Such a large macromolecule with the attendant corrosion-resistant properties would be impossible to obtain in a prereacted binder system.

Coatings and linings based on chemically converted binders can be formulated to have excellent resistance to acids, alkalies, and moisture and can be formulated to resist abrasion, ultraviolet degradation, and thermal degradation. As a general rule, toughness and flexibility of the coating increase as the molecular length increases. Similarly, chemical and moisture resistance increase as the cross-linking density increases within the macromolecule. However, as with any coating, constituent chemical groups within any molecular structure may result in characteristic strengths or weaknesses within the molecular chain. Furthermore, the arrangement and composition of pendant sidegroups may further alter the properties of any given molecular structure. Also, unreacted moieties (reactive sites) within the molecule may lead to decreased chemical, moisture, or thermal resistance.

The rate at which the molecule cross links is dependent not only on the reacting moieties, but also on the cross-linking mechanism (for example, addition, condensation, or free radical initiated cross linking). Most importantly, external factors such as temperature and (with moisture reactions) atmospheric humidity affect the rate and extent of cross linking. Thus, chemically converted coatings must set after application through solvent or water volatilization and then harden and attain their final cured properties by the cross-linking reaction, which is temperature and/or moisture dependent. Too fast a rate of reaction may lead to an overcured, hard, impervious coating that cannot be recoated or topcoated with a properly adherent subsequent coat.

This is always a problem in maintenance repainting, in which a renewal coat is applied to the original cross-linked coating system after an extended period of time. In extreme cases, however, the recoat interval within which no recoat problems may be anticipated could be as short as a few hours for certain coatings or under certain ambient conditions. Amine-cured coal tar epoxy coatings are a good example, and the recoat window may be less than 16 h, after which intercoat adhesion may become a problem.

The curing and hardening of some chemically cross-linked systems, such as most polyesters and vinyl-esters, is so rapid that plural component spray application systems are required. Such systems mix the coreactants at the time of spray application within the spray gun or outside the spray gun nozzle. The chemical cross-linking reaction occurs so rapidly that by the time the coating has deposited on the surface the coating is beginning to set up. Although such coatings are hard to the touch within minutes, solvent volatilization additional cross linking should be allowed to continue for days before to exposure in a severe chemical environment. As a general rule, curing of most chemically cross-linked systems should proceed for approximately 7 days at 25 °C (75 °F) before the coating system is exposed to severely corrosive conditions, immersion, or acid or alkali splash or spillage. The more common chemically cross-linked binders or resins used for coatings and linings will be discussed below.

Epoxies. Chemically cross-linked epoxies usually come in two packages; the first usually consists of the epoxy resin, pigments, and some solvent, and the second is the copolymer curing agent. The two packages are mixed immediately before application and, upon curing, develop the large macromolecule structure. The properties of the epoxy coating derive both from the type and molecular weight of the epoxy resin and from the copolymer curing agent that is used to cross link with it.

Epoxy Resins. For industrial maintenance coatings, the most common epoxy resin is the glycidyl ether type, particularly that derived from bisphenol-A and epichlorohydrin. The molecular structure of this type of epoxy resin is shown in Fig. 5.

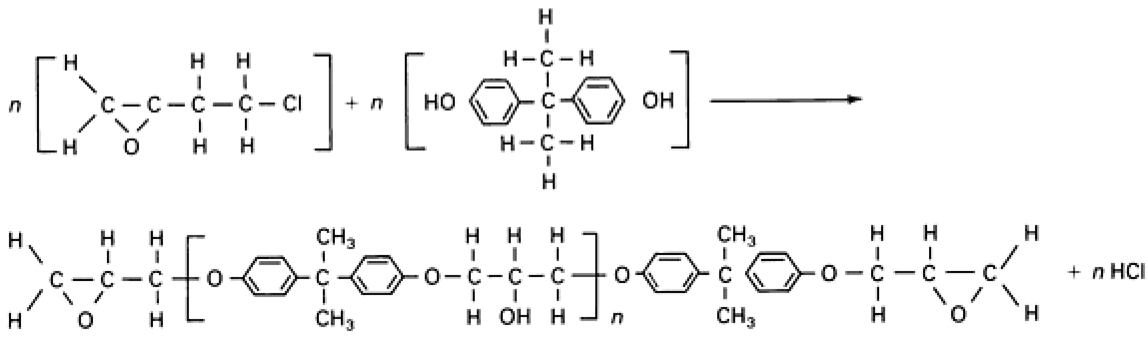

Fig. 5 Reaction of epichlorohydrin and bisphenol-A to form a glycidyl ether type epoxy resin

Cycloaliphatic epoxies have been developed that offer improvements in light stability and ultraviolet degradation, but do not exhibit the adhesion, chemical resistance, and flexibility of the resins derived from epichlorohydrin and bisphenol-A. Epoxy cresol novolacs have also been introduced, and these are said to provide greater high-temperature resistance and chemical resistance at the expense of brittleness and a lack of flexibility.

Copolymer Curing Agents. Although epoxies are generally thought of a catalyzed, the cross-linking reaction is in fact a copolymerization. The reaction occurs primarily through the epoxy ring endgroups or the mid-chain hydroxyls of the epoxy resin. The curing agent is usually an amine or polyamide, with cross linking derived through the active hydrogens attached to the amine nitrogen. Although a variety of cross-linking agents can be used (including mercaptans, polybasic acids and anhydrides, and phenol-formaldehyde and phenol resins), the most common are the polyamines, the amine adducts, and the polyamides.

The polyamines (for example, diethylene-triamine, hydroxyethyl diethylene triamine, bishydroxydiethylene triamine) are relatively small molecules with a low molecular weight compared to the epoxy resin. As a consequence, when reacted, they lead to tight cross linking and high chemical and moisture resistance. However, during the cross-linking reaction, any unreacted amine may be squeezed out of the cross-linked film to the surface, developing the so-called amine blush, a hazy white coloration on the coating surface. The blush is not detrimental in atmospheric service and can be allowed to remain on the surface. However, for immersion service, it is a good practice to wipe it from the surface (it is water soluble) before application of a subsequent epoxy coat. To minimize the formation of the amine blush, many formulators will specify a 15- to 30-min induction period after mixing prior to application. This allows the reaction to begin and initial cross linking to occur before the paint is applied. Some of the small amine molecules will partially cross link with epoxy resin molecules, reducing the tendency toward squeezing out of the smaller molecules and minimizing amine blush.

Recognizing this problem, many coating manufacturers supply the amine as a prereacted amine adduct. In this case, the epoxy pigment and solvents are packaged as before in one container, but an excess of the amine is prereacted with some of the epoxy resin to increase its molecular size. The prereacted amine adduct is then packaged in a separate container, sometimes with additional pigment and solvent. Chemical cross linking of the resultant applied film is not considered to be quite as tight as that provided by a nonprereacted amine, and the chemical resistance is said to be somewhat lower. However, application is much easier and not nearly as dependent on thorough mixing and induction time of the reactants.

Polyamide curing agents are the condensation products of a dimerized fatty acid with a polyamine. Terminal amine functionally allows cross linking to occur as with a straight amine, although the polyamide molecule is much larger. The cross-linked film has improved flexibility, improved gloss and flow, excellent water resistance, and good chemical resistance. Polyamide-cured coatings, however, have somewhat less solvent and alkali resistance than amine and amine adduct cured epoxies do.

Specially formulated polyamide-cured epoxies have the ability to displace water from the substrate surface. Such materials can even be applied and cured underwater to form corrosion-resistant coatings.

One other type of curing agent, ketimine, is worthy of note. the ketimine curing agent allows the application of a high molecular weight, high-solids, or solventless epoxy resin with standard spray equipment. These more viscous epoxies can be mixed with the low molecular weight ketimine curing agent and spray applied to the surface. No reaction will occur until the ketimine decomposes in the presence of atmospheric moisture to form a polyamine and a ketone. The ketone volatilizes from the film, and the amine reacts as described above to cross link the epoxy resin after application. These systems result in a tightly cross-linked epoxy film, but require relative humidity in excess of 50% and good ventilation to expose the ketimine to moisture and to remove the residual ketone and other solvents from the paint film. The ketimine curing reaction is shown in Fig. 6.

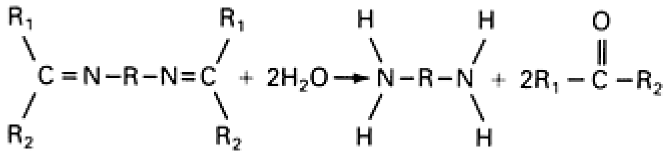

Fig. 6 Curing reaction of ketimine-cured epoxies. Ketimine decomposes in the presence of atmospheric moisture to form a polyamine plus a ketone. R, R_1, and R_2 are alkyl groups. Source: Ref 2

Coal tar epoxies are a combination of a coal tar combined with an epoxy resin packaged separately in one container. The curing agent is an amine, amine adduct, or polyamide (as described above) packaged in a separate container. The cross-linking reaction is the same as that described above. The coal tar acts as a filler within the cross-linked epoxy matrix, and the resulting film has the good toughness, adhesion, ultraviolet resistance, and thermal stability of the epoxies, combined with the extremely high moisture resistance afforded by coal tar. As might be expected, the amine-cured coal tar epoxies generally have greater chemical and moisture resistance, but are more brittle and harder to apply and topcoat than the amine adduct- and polyamide-cured coat tar epoxies. On the other hand, the polyamide coal tar epoxies are more flexible, easier to topcoat, and more tolerant of application variables.

Epoxy-Phenolic Coatings. Phenolic cross-linked epoxy coatings are extremely resistant to acids, alkalies, and solvents, and they are widely used as linings for tank cars, drums, cans, process tanks, and equipment. High molecular weight epoxies with a high proportion of hydroxyl functional groups available for reaction are used. During manufacture, the epoxy is packaged with a phenolic resin (commonly a phenolformaldehyde resin), pigment, and an acid catalyst. After mixing, the coating is applied by spraying, and it must be baked at temperatures from 150 to 205 °C (300 to 400 °F) in order for cross linking to occur. Multiple-coat systems require brief intermediate baking between coats; longer baking times are commonly used after application of the final coat.

The resulting coatings have the excellent acid and solvent resistance associated with the phenolics as well as the flexibility, adhesion, and toughness of epoxies. Epoxy phenolics have the good alkali resistance of the epoxy constituent, but straight phenolic linings have very poor alkali resistance.

The cross linking that occurs is between the hydroxyl groups along the epoxy chain and the methylol groups present in the phenolic resin. A possible secondary reaction is the reaction between the terminal epoxide groups of the epoxy resin and the hydroxyl groups of the phenolic resin.

Phenolic Linings. Phenolic resins are formed by the reaction of phenol with formaldehyde to form phenolformaldehyde. The methylol group can react on the two ortho positions and the paraposition on the benzene ring to form phenolformaldehydes with functionalities (possible reaction sites) up to 3. Upon heating, a condensation reaction occurs between methylol groups on adjacent molecules that cross link the film and liberate water. The reaction of phenol and formaldehyde to form a cross-linked film is shown in Fig. 7.

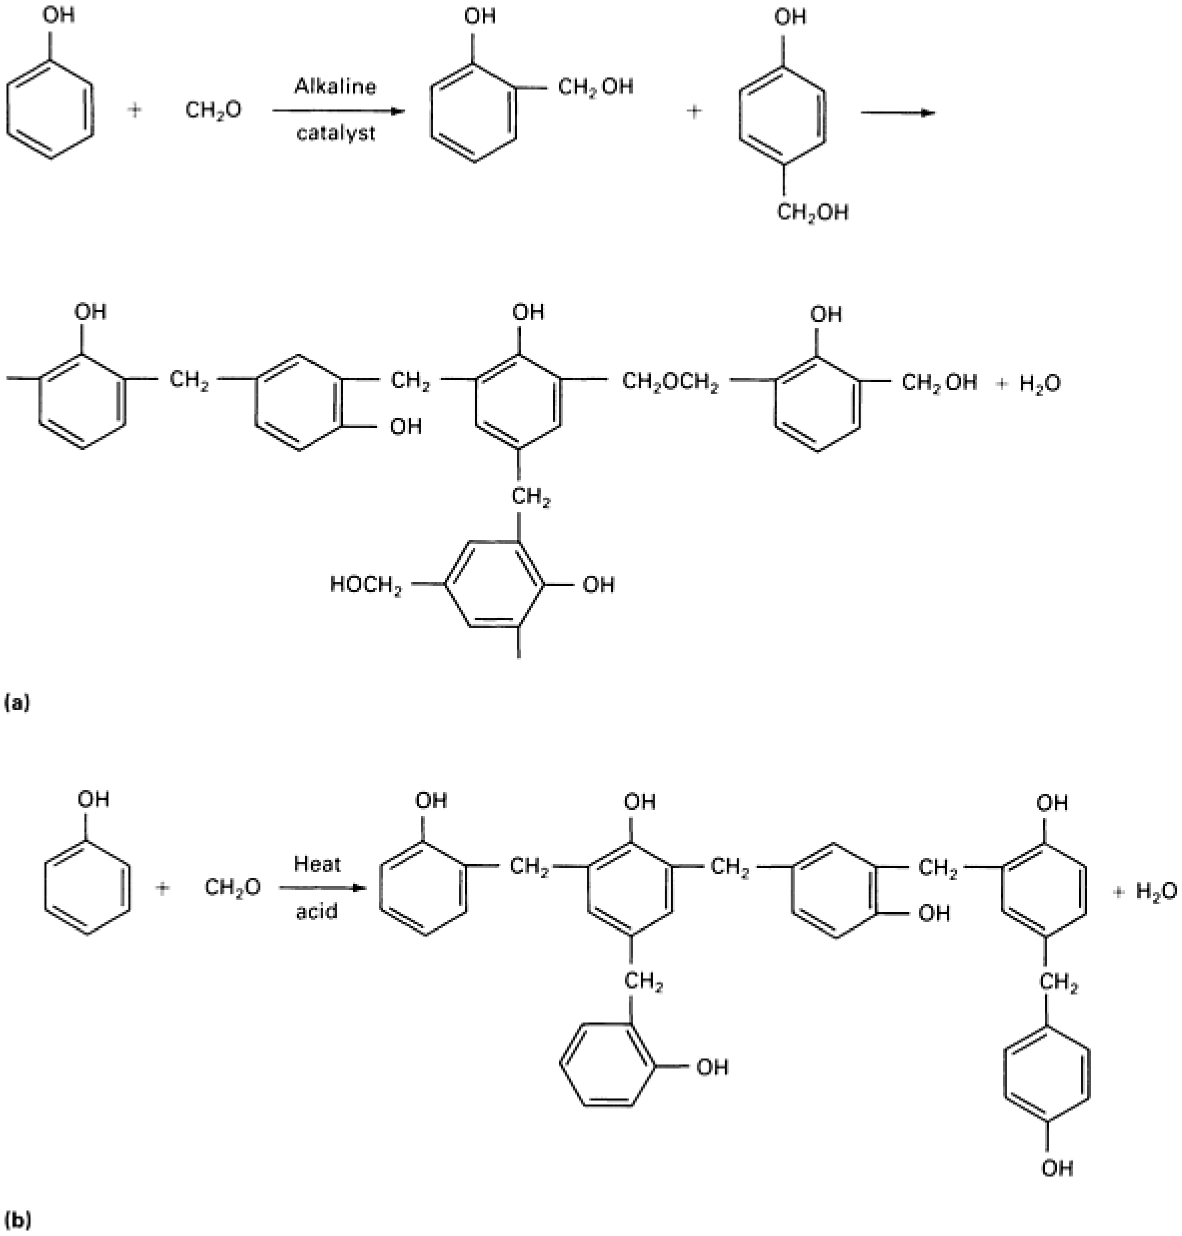

Fig. 7 Reaction of phenol and formaldehyde to form a phenolic resin. (a) Reaction using an alkaline catalyst. (b) Reaction using an acid catalyst. Source: Ref 3

The phenolformaldehyde resins are usually dissolved in alcohol and applied by spray, dip, or roller. The fact that water is liberated during the cross-linking reaction is important. The coatings must be applied in multiple-coat systems; each coat is approximately 0.025 mm (1 mil) thick and must be baked for a few minutes at 120 to 205 °C (250 to 400 °F) between coats. This partially cross links the coating, but more importantly, it volatilizes the water formed during the cross-linking reaction. Subsequent coats are applied and baked until, after the final application, a postbake at higher temperatures and longer durations is performed. It is easy to determine when the coating has been baked sufficiently to ensure proper curing and cross linking. The phenolic resin darkens upon heat exposure, and a thoroughly cured coating is a relatively uniform, light chocolate brown color.

Because they are odorless, tasteless, and non-toxic after full curing, phenolics are often applied as linings for vessels and tanks used for the processing and storage of such food products as beer, wine, and sugar syrups. They also have excellent resistance to boiling water and hot aqueous solutions of mild acids. Thus, they often find application as linings for steel subject to high-temperature freshwater and salt water as well as acid. A major weakness, however, is the lack of alkali resistance, and unless phenolic coatings are modified with epoxies, they should not be used for alkaline service.

Urethane coatings have chemical- and moisture-resistant properties similar to those of the epoxies, but they can also be formulated in a variety of light-stable colors that maintain their gloss and "wet look" upon prolonged exposure. The chemistry involved in urethane coating curing is not unduly complex and typically consists essentially of the reaction of an isocyanate-containing ($-N{=}C{=}O$) material with a polyhydroxylated ($-OH$ containing) coreactant (Fig. 8). Cross linking occurs because of the high reactivity and affinity of the isocyanate group for the active hydrogen of the polyol hydroxyl or any active hydrogen atom attached to a nitrogen or oxygen atom. The rate of this cross-linking reaction depends on a number of factors, such as the type and configuration of both the isocyanate and polyol materials and the temperature. However, the reaction is such that with most formulations cross linking can occur at temperatures as low as -18 °C (0 °F) or less.

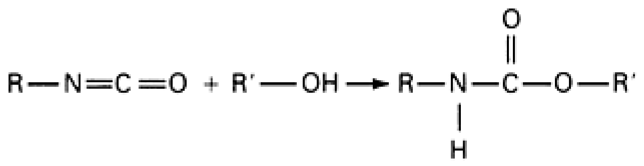

Fig. 8 Reaction of an isocyanate and a polyol to form a urethane. R and R' are different aromatic or aliphatic groups. Source: Ref 4

A number of different types of isocyanate materials are used in urethane coatings. The molecular weight and structure as well as isocyanate functionality (the number of isocyanate groups available for reaction) can affect the final properties of the coating. Similarly, different polyol structures, such as acrylics, epoxies, polyesters, polyethers, and vinyls, when reacted with a given isocyanate to form a cross-linked coating, will result in variations of physical and chemical properties. Described below are some of the general properties of the isocyanate and polyol constituents that are coreacted to form urethane coatings.

The isocyanates are commonly categorized as either aromatic (containing the benzene ring) or aliphatic (straight-chain or cyclical) hydrocarbons. The first isocyanate used in urethane coatings was an aromatic isocyanate, toluene di-isocyanate (TDI) (Fig. 9). When reacted, TDI resulted in a suitable chemical-resistant urethane coating, but it was generally undesirable because of its low viscosity and toxic irritating vapors. To form a safer, more suitable coreactant. TDI was further reacted to provide a higher molecular weight polyisocyanate that contained less than 1% of the original TDI monomer (Fig. 10).

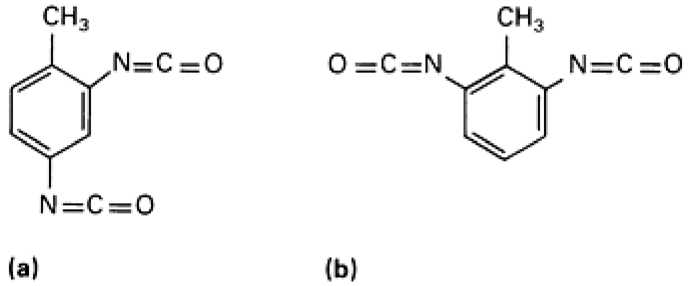

Fig. 9 Molecular structures of TDI, an aromatic isocyanate used in urethane coatings. (a) 2,4 isomer. (b) 2,6 isomer. Source: Ref 4

Fig. 10 Modifications of TDI to form higher molecular weight polyisocyanates. (a) Polymerization of TDI with an alcohol to produce a TDI alcohol adduct. (b) Condensation of TDI monomer to produce an isocyanate ring. Source: Ref 4

These higher molecular weight aromatic isocyanates, when reacted with a polyol (usually a polyester, polyether, or epoxy), formed useful chemical-resistant coatings that could be cured at low temperatures. However, the urethanes so formed tend to chalk, yellow, and darken somewhat upon exposure to sunlight.

In the early 1970s, aliphatic isocyanates were commercially developed. Although they were considerably more expensive than the aromatic isocyanates, they allowed the formulation of nonyellowing, light-stable, high-gloss finish coats. The appearance of urethane coatings formulated with aliphatic isocyanates was unmatched by the epoxies, acrylics, or any other coating material then (and now) available in the industrial marketplace. In spite of the high cost of the aliphatic polyurethanes, the coatings were increasingly specified in high-visibility applications, such as city water tanks, railroad tank and hopper car exteriors, and other areas where visibility or aesthetic appeal were paramount.

An important aliphatic isocyanate is hexamethylene diisocyanate (HDI) (Fig. 11). In its monomeric form, HDI is an irritant. Like TDI, however, HDI can be reacted (commonly with water) to form a larger molecule.

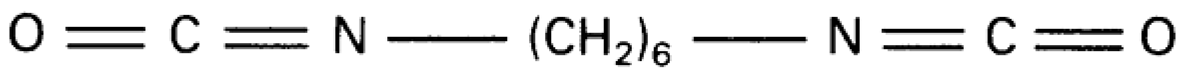

Fig. 11 Molecular structure of HDI, an aliphatic isocyanate used in urethane coatings. Source: Ref 4

Various combinations of aromatic and aliphatic isocyanates can be produced, including specialty isocyanates, to make high-solids or solvent-free coatings, elastomeric coatings, or coatings designed for baking or curing at elevated temperatures. Specialty isocyanates can be either aromatic or aliphatic; if aromatic, they will discolor. Both straight-chain and cyclical aliphatic isocyanates, although nonyellowing, are much slower to react and cross link than aromatic isocyanates.

Polyols. As stated previously, polyols coreact with isocyanates in order to form the polyurethane film. Accordingly, the polyol is packaged separately from the isocyanate, and the polyol package always contains the pigment, most of the solvent, and any additives used for flow, thixotropy, antisetting properties, and so on. The major properties of the cross-linked urethane film, such as chemical resistance, toughness, lightfastness, and flexibility, derive principally from the polyol constituent. Long, repeating carbon-to-carbon backbone chains with little branching (for example, vinyl) result in tough, flexible resins. Aromatic groups add rigidity to the chain, as does cross linking. The presence of numerous ester, ether, and urethane groups reduces chemical and moisture resistance.

For corrosion-protective coatings, the polyol coreactant is usually one of the following: acrylic, polyester, polyether, epoxy, vinyl, or alkyd. Asphalts and coal tars can be added with any of the polyols. Because they are essentially nonreactive, however, it is felt the bitumen acts predominantly as a filler in the urethane matrix, providing the cured coating with the attendant properties of good chemical resistance, high moisture resistance, and high film build at a relatively low cost.

Acrylic urethanes are perhaps the most widely used urethanes for corrosion protection in atmospheric service. These coatings, when properly formulated, have excellent weatherability, gloss, and color retention and have good chemical and moisture resistance. They can be readily tinted and pigmented to provide a variety of deep and pastel colors at a lower cost per gallon than the next most popular class, the polyester urethanes.

As with conventional acrylic coatings, the acrylate polymer family is softer and more flexible than the corresponding methacrylates, although an increase in the molecular weight of the monomers, such as methyl acrylate to butyl acrylate, leads to softer, more flexible polymers for both families. Acrylate and methacrylate blends are also used as reactive polyols.

Acrylic urethanes are not used for immersion service, and for the most part, they do not have the chemical resistance of the polyester urethanes. However, they do have excellent weathering properties when an aliphatic isocyanate is used.

Polyesters result from the condensation reaction of a dibasic acid and a polyhydric alcohol. To form a hydroxylated polyester, an excess of the hydroxyl functionality from the alcohol is allowed over that of the acid. The result is a polyester molecule with a mid-chain and end-chain hydroxyl functionality.

Because of their high isocyanate demand when coreacted, polyesters result in relatively hard chemical-resistant polymer films. Impact resistance is not as great as with the acrylic urethanes, but as a rule, chemical and moisture resistance are better. However, because ester linkages occur in the molecular backbone, alkaline attack and water sensitivity may occur at locations where the ester group is exposed, that is, at areas of low cross-link density or where less branching of adjacent molecules occurs. Accordingly, polyester urethanes, like acrylic urethanes, are not normally used for immersion service.

Polyethers are often the polyol of choice for use as elastomeric coatings, coal tar urethanes, and other urethane coatings that are sheltered or protected from light. The polyether prepolymer is considerably less expensive than acrylic or polyester polyols; polyethers, however, are sensitive to ultraviolet-induced oxidative degradation. Furthermore, the ether linkages (—C—O—C—) are water sensitive, and in polyethers, they are repeated throughout the polymer chain without separation by long water-insensitive hydrocarbon chains or aromatic groups that can minimize water sensitivity.

Epoxies. The reaction of an epoxy with an isocyanate would seem to be a natural one, because of the mid-chain hydroxyl functionality of the epoxy molecule. However, there are very few epoxy urethanes on the market, and those being promoted are used predominantly as primers or intermediate coats. This is due to:

- The tendency of the epoxy and the epoxy urethane to chalk
- The lower moisture resistance resulting from the urethane link, which gives a less chemical and moisture-resistant polymer than a straight epoxy coating
- The greater expense of a urethane epoxy compared to a conventional amine or polyamide cross-linked epoxy

As a result, most epoxy urethanes are formulated with the less expensive aromatic isocyanate and are promoted primarily as low-temperature curing epoxies or fast-curing, chemically resistant urethanes for interior use.

Vinyl urethanes use a long-chain, linear, hydroxyl-bearing PVC/PVA resin reacted with a polyfunctional isocyanate prepolymer. Urethane coatings using vinyl polyols combine the abrasion resistance of the urethane with the toughness, flexibility, and chemical resistance of the vinyl. Such urethane coatings are promoted for use where flexibility and abrasion resistance are important; vinyl urethane coatings, however, are subject to some chalking or fading upon exterior exposure and do not have the color, gloss, weatherability, or solvent resistance of the acrylics and polyesters. Because the vinyl is thermoplastic and is attacked and softened by solvents, recoatability after extended times is not a problem and is a major advantage of vinyl urethane systems.

Alkyds are commonly reacted with isocyanates to form a so-called uralkyd or urethane oil coating. The isocyanate reaction decreases the drying time of the coating and provides enhanced resistance to chemicals, moisture, weathering, and abrasion. Uralkyd (urethane oil) coatings harden by auto-oxidation of their unsaturated oleoresinous side-chains. The result is an upgraded coating system with enhanced performance over the non-urethane system. Because of the isocyanate reaction, however, the cost of such a system is somewhat higher than those systems that are not urethane modified. A uralkyd is prepared by replacing some of the dibasic acid with an isocyanate to form a urethane cross-linked polymer. The resulting urethane alkyd resin still has the oleoresineous sidechains, and although it is cross linked and upgraded by the isocyanate, it is still sensitive to water and chemicals through the ester and urethane links.

Moisture-Cured Urethanes. Isocyanates can also react with the hydroxyl group in water to form a class of coatings known as moisture-cured urethanes. Single-package moisture-cured urethanes use an isocyanate prepolymer that, when applied, reacts with the humidity in the air to form a hard, tough, resinous film. Because of their rapid rate of reaction, aromatic isocyanates are used almost exclusively in moisture-cured urethanes. The pigments must be essentially nonreactive with the isocyanate; although it is possible to use a number of pigments, aluminum leaf is most common. The reaction of a single-package urethane with moisture is illustrated in Fig. 12. It should be noted that the isocyanate/water reaction produces gaseous carbon dioxide. In fact, some carbon dioxide is evolved in the curing of all urethane coatings, because moisture (humidity) is present in the atmosphere during curing.

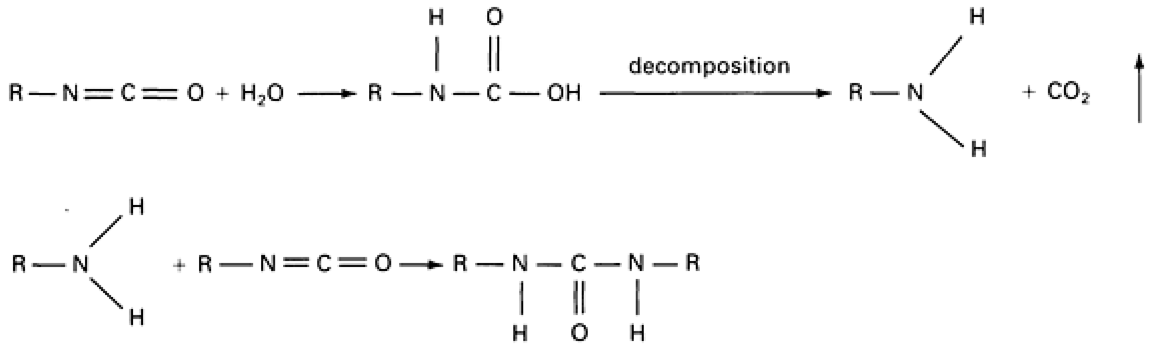

Fig. 12 Curing reaction of a single-package moisture-cured urethane. The isocyanate reacts with water to form unstable carbamic acid, which decomposes into an amine plus carbon dioxide gas. The amine then reacts with isocyanate to form a urea derivative. R indicates an aromatic or aliphatic group. Source: Ref 4

In areas where the relative humidity is expected to be low or where assurance of a more complete cure is necessary, a small amount of a tertiary amine catalyst, such as dimethyl-ethanolamine, can be added. This catalyst is packaged separately from the isocyanate and added just before use. Although it comes as a two-package system, this type of catalyzed urethane can be considered to be an extension of a single-package moisture-cured urethane.

Zinc-Rich Coatings

Zinc-rich coatings, often called zinc-rich primers, are a unique class of cross-linked coatings that provide galvanic protection to a ferrous substrate. As the name implies, the binder is highly loaded with a metallic zinc dust pigment. After the coating is applied to a thoroughly cleaned substrate, the binder holds the metallic zinc particles in contact with the steel and with each other. Thus, metal-to-metal contact of two dissimilar metals is made, resulting in a galvanic cell. In this couple, zinc becomes the anode and sacrifices itself to protect the underlying cathodic steel (the articles "Hot Dip Coatings" and "Corrosion of Zinc" in this Volume contain more information on corrosion of galvanized steels).

The major advantage of corrosion protection using zinc-rich coatings is that pitting corrosion and subfilm corrosion are eliminated, even at voids, pinholes, scratches, and abrasions in the coating system. This cannot be said of any other type of protective coating, and it is this protective capability that makes zinc-rich coatings unique and widely used.

This advantage, however, comes with certain disadvantages. The underlying steel substrate must be cleaned of all rust, old paint, and other contaminants that may interfere with metal-to-metal contact. Thus, the degree of surface preparation must be quite thorough; blast cleaning should produce a Commercial Blast Cleaning minimum and, for immersion

service, a White or Near-White surface. The Steel Structures Painting Council (SSPC). NACE, and other organizations issue standards for the surface preparation of metals for organic coatings; these are discussed in more detail in the sections"Surface Preparation" and "Coating Application" in this article. When power tool cleaning, cleaning to bright metal is necessary. Zinc-rich coatings can be applied to pickled steel, although, again, the surface must be perfectly clean.

Because of the high reactivity of the zinc-dust pigment, zinc-rich coatings are not suitable in condensing or hydrolyzing environments outside the pH range of approximately 5 to 10. Acids and alkalies will attack the zinc-dust pigment; even if topcoats are used, chemicals may penetrate through pinholes, scratches, voids, or discontinuities within the topcoat and cause aggressive attack of the zinc-rich primer.

In addition, because of the high zinc loading, the zinc-dust pigment should be suspended in the spray pot during spray application. Thus, the use of an agitator or stirrer in the spray pot is mandatory. Similarly, the weight of the paint, as a result of its high pigment loading (often 2.2 to 3 kg/L, or 18 to 25 lb/gal.), prohibits long hose lengths from the spray pot to the spray gun in order to minimize settling in the lines. If the spray gun is elevated too high above the spray pot, air pressure to the spray pot may not be sufficient to push the heavy zinc-rich coating material through the spray line to the gun.

When spraying on warm days, care must be taken that the primer does not begin to set up in the spray lines. This is a particular problem with most inorganic zincs, especially if a spray application is interrupted for more than just a few minutes without first draining the fluid (paint) hose. With no movement in a relatively warm paint hose, plugs of paint may begin drying and hardening such that when spraying operations begin the paint does not readily moved through the fluid line to the gun. Blockages occur, the gun works only intermittently, and, in the worst cases, hardening of the paint may occur to such an extent that the entire line must be discarded.

This rapid-drying characteristic, which is particularly evident with the inorganic zincs, may also result in a greater amount of dry spray than usually occurs with conventional nonzinc-rich coatings. Thus, particular care should be taken during application to ensure that the zinc-rich primer is deposited in a smooth, wet application. Because of high zinc loading over the pigment volume concentration of the binder, the zinc-rich coatings are more porous than any other generic type of paint. Because of this porosity, they are harder to topcoat. Topcoats applied over both organic and inorganic zinc-rich primers will often have voids or bubbles in their cross-sectional thickness and bubbles or pinholes extending down through their surface to the underlying zinc-rich coating. This is because of entrapped air, solvents, and moisture within the zinc-rich primer before or during topcoating. The entrapped liquids or gases must pass through the topcoat in order to escape into the atmosphere. As the topcoat dries, escaping gases are held as bubbles or blisters, or the path of such an escaping gas hardens into a pinhole.

Insufficient curing of the zinc-rich binder before application of the topcoat can sometimes lead to poor adhesion or cohesion within the zinc and can ultimately lead to peeling or disbonding of the topcoat. However, despite these disadvantages, the advantage that accrues by the elimination of subfilm and pitting corrosion makes zinc-rich coatings, either topcoated or untopcoated, one of the most widely used corrosion prevention coatings for painting steel in industrial, marine, and other severe service environments.

Zinc-rich coatings used as primers with topcoats or as complete one-coat systems are widely used for the corrosion protection of steel substrates. Organic zinc-rich systems are used in the automotive industry to protect car body rocker panels, wheel wells, and other corrosion-prone interior steel parts (see the article "Corrosion in the Automotive Industry" in this Volume). Inorganic zinc-rich coatings are also used extensively in the marine industry for the protection of exterior hulls, cargo and ballast tanks, offshore platforms, and other areas of high marine corrosion (see the articles "Marine Corrosion" and "Corrosion in Petroleum Production Operations" in this Volume). Inorganic zinc-rich coatings are used in these same environments and in applications requiring high abrasion and high heat resistance (to 370 °C, or 700 °F) when untopcoated. Both organic and inorganic zinc-rich coatings are extensively used for steel protection on bridges and highway structures, chemical and petrochemical plants, sewage and water treatment, and any area where freshwater or saltwater corrosion, mild fumes, and high humidity and resultant corrosion is a problem. The articles "Corrosion in the Chemical Processing Industry," "Corrosion in Petroleum Refining and Petrochemical Operations," and "Corrosion in Structures" in this Volume contain more information on the use of coatings in those applications.

Zinc-rich coatings can be subcategorized according to the type of binder material used. Zinc-rich coatings with organic binders are similar in many ways to the coating systems previously discussed, except that sufficient zinc-dust pigment is added to provide galvanic protection. The inorganic zinc-rich coatings, on the other hand, use an entirely different binder chemistry and are therefore quite unlike the organic zinc-rich coatings. As a general rule, organic zinc-rich coatings are

more widely used in Europe and Asia than inorganic zinc-rich coatings; in the United States and Canada, the inorganic zinc-rich coatings are more widely used.

Organic zinc-rich coatings are most commonly formulated from epoxy polyamide, urethane, vinyl, and chlorinated rubber binders. Alkyds have been used for some air dry formulations, but they are most commonly used with baking formulations, notably in the automotive industry.

To manufacture a successful organic zinc-rich coating, one does not simply substitute the zinc-dust pigment for the normal inhibitive and filler pigments commonly used. Instead, skillful formulation is required to achieve galvanic protective capability while also maintaining suitable storage, application, and physical properties of the applied film. When such formulation is achieved, the result is a protective coating having the physical attributes determined by the organic binder, along with the galvanic capability and chemical susceptibilities inherent in the use of the zinc-dust pigment.

For example, vinyl and chlorinated rubber zinc-rich primers are easier to topcoat than epoxy and urethane zinc-rich primers for the same reasons that vinyl and chlorinated rubber primers are easier to topcoat than overcatalyzed or excessively hardened epoxies and urethanes. Similarly, the heat resistance of the thermoset epoxies and urethanes is greater than that of the thermoplastic vinyls and chlorinated rubbers. However, in all cases, the untopcoated zinc-dust pigment is attacked by acids and alkalies, and even though the binder is resistant to such chemicals, organic zinc-rich primers should not be used in aggressive environments.

The drying, hardening, and ultimate curing of the organic zinc-rich coating is determined by the type of binder used. The hardening and curing mechanisms of the various binders have been described previously and are the same for zinc-rich coatings. Organic zinc-rich primers are more tolerant of deficient surface preparation because they wet more readily and seal poorly prepared surfaces where residues of rust or old paint may remain. Similarly, topcoating with the same generic type of topcoat (for example, a vinyl zinc-rich coating topcoated with a vinyl topcoat) is more readily accomplished, because organic zinc-rich coatings of all types generally have a less porous surface and are more like conventional organic coatings than the inorganic zinc-rich coatings.

Inorganic Zinc-Rich Coatings. The SSPC has categorized inorganic zinc-rich coatings as being of three major groups:

- Postcured water-base alkali metal silicates
- Self-cured water-base alkali metal silicates
- Self-cured solvent-base alkyl silicates

Although the binder, in all cases, is an inorganic silicate (essentially the same material as glass or sand), the curing of the binder is different in all three cases.

Postcured water-base inorganic silicates come as three-package systems; the zinc dust, silicate binder, and curing solution are package separately. If elevated baking temperatures can be achieved, the curing solution may not be necessary.

The earliest postcured zinc-rich coatings were based on a sodium silicate vehicle, and the most popular commercial products available have essentially the same chemistry. There are other inorganic zinc-rich coatings based on lithium or potassium silicates that will self-cure, but curing can be accelerated by the use of a curing solution, if desired. The following steps summarize the curing of postcured water-base inorganic zinc-rich coatings.

The first step is primarily a dehydration process in which the water, which is the basic solvent for the silicate, evaporates from the clean steel surface, leaving the zinc and the alkali silicate on the surface as a coating. At this point, when the coating is free of water, it is very hard and metallic. Scraping with a coin merely polishes the zinc in the coating.

Second, once the initial drying process has taken place, an acid phosphate curing solution is sprayed or brushed over the zinc-rich coating in order to wet out the surface thoroughly. The initial reaction is for the acid to gradually neutralize the sodium in the sodium silicate solution and to create a mildly acidic surface condition.

Third, during initial curing, the pigment constituents may react with the silica matrix. This, together with further neutralization of the silicate alkalinity, insolubilizes the film.

The addition of the acidic curing solution on the surface of the zinc coating ionizes the zinc in the coating as well as the lead oxide pigment mixed with it. As this takes place, there is a rapid reaction between the active silicate groups with the lead and zinc, and this reaction insolubilizes the silica matrix.

The acid phosphate also reacts with the zinc and lead to form very insoluble zinc and lead phosphates within the silicate matrix. At this point, the coating has become insoluble to water and resistant to exposure to weather.

Lastly, after initial curing, further hydrolysis and improvement of film properties continue over time. Following the application and reaction of the curing agent, the remaining soluble salts on the surface are removed with clean water or by weathering. The coating at this point is dense and relatively nonporous, insoluble in water, and resistant to marine and mild chemical atmospheres.

Postcured coatings are in the author's opinion the best performing of the inorganic zinc-rich materials. The reason for this is most likely the relatively complete, insolubilizing hard cure that is attained after application of the curing solution. By applying the curing solution and thoroughly curing the coating, the maximum protective properties of the coating are attained shortly after application. In contrast, self-cure coatings rely on ambient atmospheric conditions in order to cure completely. Recent research indicates that many self-cured coatings do not achieve their ultimate resistance and protective capability until long after their original application.

Self-Curing Water-Base Alkali Silicates. The most common of these silicate binders is based on potassium and lithium silicates or combinations of these. In addition, lithium hydroxide-colloidal silica and quaternary ammonium silicate binders are also included in this category.

The reaction chemistry of the water-base self-cure inorganic zinc-rich silicates is similar to that of the postcured sodium silicates, with the exception that the curing solution is not applied. The metal silicate vehicle, before field addition of the zinc-dust pigment, has a higher ratio of silica to metal oxides and a lower alkalinity than the postcured vehicles. Therefore, after water evaporation and insolubilization resulting from the silica reaction with the pigment, sufficient neutralization and cure are attained by further reaction with acid formed by the atmospheric hydrolysis of carbon dioxide (reaction of CO_2 and atmospheric moisture to form a weak carbonic acid).

Self-curing alkali silicate zinc-rich coatings become hard within minutes and are considered generally resistant to precipitation within 30 min after application. If a more rapid insolubilization or cure is desired, heat or an acidic curing solution can be applied. The reaction chemistry would then be essentially identical to that of the postcured sodium silicate matrix. When final curing is ultimately attained, most water-base zinc-rich coatings, whether post- or self-cured, experience a color change--often from a reddish gray or light gray to a darker bluish gray.

Self-Cured Solvent-Base Alkyl Silicates. The binders for this class of coatings are essentially modified alkyl silicates consisting of partially hydrolyzed members of the series methyl through hexyl or glycol ether silicates. Of these, the ethyl silicate type is most commonly used.

The reaction chemistry of ethyl silicates can be best demonstrated by the hydrolysis of tetraethyl orthosilicate in the presence of an acid or alkali catalyst. The reaction is carried to partial completion with a degree of hydrolysis ranging from 70 to 95%. The reaction is irreversible, because of the volatilization of the alcohol that results from the ester exchange; however, should premature gelling of the silicate occur, alcohol may be added to redissolve the gel. During the condensation phase of the reaction, the partially polymerized silicate combines with atmospheric moisture to eliminate alcohol, which vaporizes.

After complete hydrolysis, the cross-linked network forms a matrix to hold the pigment particles. In addition, it is conceivable that the zinc and other metallic pigment additives (and perhaps the underlying ferrous surface) may react with the silicate in a manner similar to that described for postcured sodium silicate.

Single-package inorganic zinc-rich primers based on the ethyl silicate chemistry described above have been developed. Instead to packaging the zinc dust separately from the ethyl silicate binder, the coating manufacturer adds the zinc dust in the manufacturing plant, along with additives that keep the zinc dust in suspension. Careful quality control of raw materials, particularly zinc-dust pigment and additives, is exercised to ensure they are dry and moisture free. Also, the

ethyl silicate vehicle is somewhat less prehydrolyzed and is usually catalyzed with an acid catalyst such that upon application and curing the reaction with moisture occurs at a faster rate than with two-package ethyl silicate zinc-rich primers.

The properties of the single-package ethyl silicate zinc-rich primers are similar to those of the dual-package primers (where the zinc dust is packaged separately from the liquid silicate binder); but in general, single-package inorganic zinc-rich coatings do not cure as hard or as fast as dual-package products, and they do not provide quite as long a corrosion protection, although corrosion protection is still excellent. On the other hand, they are much easier to mix and apply, and these application advantages have resulted in their increased use.

Comparisons of Inorganic and Organic Zinc-Rich Coatings. In general, the inorganic zinc-rich coatings provide somewhat longer galvanic protection than the organics do, but they are less tolerant of deficient surface preparation, are somewhat harder to mix and apply, generally have a greater tendency toward mudcracking at excessive thickness, and are more difficult to topcoat. The organic zinc-rich coatings have limited temperature resistances that are determined by their organic binder. In contrast, inorganic zinc-rich coatings will resist dry heat to over 370 °C (700 °F), and when topcoated with a silicone or ceramic coating, they can be used at temperatures of 650 °C (1200 °F) or higher. The abrasion and impact resistance of the inorganics are unsurpassed.

All water-base zinc-rich coatings, whether post- or self-cured, require somewhat greater surface cleanliness in order to achieve suitable adhesion and environmental protection. Water-base zinc-rich coatings have a greater tendency to mudcrack at excessive thicknesses than solvent-base inorganics do, and there is also an increased tendency to form zinc surface reaction products, particularly with sodium and lithium silicate vehicles. A major advantage of all water-base zinc-rich coatings is that they do not have a flash point and can be used in tanks, ship holds, and other confined or poorly ventilated areas without danger. However, such coatings do require good ventilation or dehumidification to cure properly. Solvent-base inorganic zinc-rich coatings that are modified to have a flash point higher than their normal 20 to 30 °C (70 to 90 °F) tag open cup often form a softer, less resistant film.

Coating System Selection

The selection of the proper corrosion-resistant coating system depends on a number of factors. This section will highlight the more important considerations.

Environmental Resistance. The coating system should be resistant to the chemical, temperature, and moisture conditions expected to be encountered in service.

Appearance. In high-visibility areas (for example, water tanks, railroad cars, and appliances), color, gloss, and a pleasing appearance may be very important.

Safety. Toxic pigments and solvents may prohibit the use of some coatings; future removal and disposal problems should be considered. Coatings with volatile explosive solvents may be dangerous in enclosed, poorly ventilated spaces.

Surface Preparation. Blast cleaning may be prohibited in some refineries or near electrical and hydraulic machinery.

Skill of the Labor Force. Certain coating systems require more application expertise than others. Generally, inorganic zincs, vinyl-esters, polyesters, vinyls, and chlorinated rubbers are less application tolerant than some of the other coating systems.

Substrate to be Coated. Coating systems for aluminum, lead, copper, and so on, may be different from those for ferrous metals.

Available Equipment. The more resistant coating systems generally require spray application over a blast-cleaned surface. For some polyesters and vinyl-esters, plural component spray equipment may be required.

Design Life. If a structure is intended to have a long service life, the use of a more resistant coating system may be justified than if a shorter service life is intended.

Cost. Generally speaking, the applied cost of a more resistant coating system is greater than the applied cost of a less resistant system.

Accessibility for Future Repair. If future repair will be difficult or expensive, perhaps a longer lasting coating system should be specified.

Consequences of Coating Failure. If a coating failure will be disastrous, such as in tanks holding highly corrosive materials or in nuclear power plants where peeling or disbonding coating may clog sumps and screens, a more resistant coating system should be selected.

Each of these factors will, to varying degrees, directly influence the choice of the coating system selected to protect a metal in a given environment. Once the choice is made, it is usually necessary to prepare appropriate specifications detailing the surfaces to be painted, and the surfaces to be protected from paint. In addition, the surface preparation and coating application details should be delineated. At a minimum, the thickness of each coat and total coating thickness should be specified, and the surface profile of a blast-cleaned surface, the interval between coats, and other factors (such as testing for holidays and pinholes and for adhesion) should also be specified. Although the preparation of a proper specification is beyond the scope of this article, a good specification is not only an important contractual document but is also the means of conveying the owner's (or specifier's) intentions and instructions regarding the painting to be accomplished. Thus, the potential importance of a good specification cannot be overestimated.

Surface Preparation

The selection of the coating material to be used to protect a given metal from an environment usually determines the surface preparation that will be required. For example, zinc-rich coatings almost always require blast cleaning, while many alkyd and oil-base coating systems can be applied over rust, mill scale, or a poorly cleaned surface. The SSPC has prepared a series of surface preparation standards that are widely used throughout North America. The National Association of Corrosion Engineers has a set of encapsulated panels showing the four degrees of blast cleaning.

Similar standards based on photographs developed by the Swedish Standards Institute are widely used in Europe and Asia. These so-called Swedish standards are photographs of four starting grades of steel that are wire brush cleaned or blast cleaned to various degrees of cleanliness. Table 2 presents an abstract of the SSPC standards with a cross reference to the appropriate NACE and Swedish standards.

Table 2 Uses and applicable standards for various surface preparation techniques

Technique	**Applicable standards**	Uses
Solvent cleaning	SSPC-SP1	**Used to remove oil, grease, dirt, soil, drawing compounds, and various other contaminants. Does not remove rust or mill scale. No visual standards are available.**
Hand tool cleaning	SSPC-SP2	**Used to remove loose rust, mill scale, and any other loose contaminants. Standard does not require the removal of intact rust or mill scale. Visual standards: SSPC-VIS I--BSt3, CSt3, and DSt3[(a)]**
Power tool cleaning	SSPC-SP3	**Same as hand tool cleaning. Visual standards: SSPC-VIS I--BSt3, CSt3, and DSt3[(a)]**
White-metal blast cleaning	SSPC-SP5; NACE 1	**Used when a totally cleaned surface is required; blast-cleaned surface must have a uniform, gray-white metallic color and must be free of all oil, grease, dirt, mill scale, rust, corrosion products, oxides, old paint, stains, streaks, or any other foreign matter. Visual standards: SSPC-VIS I--ASa3, BSa3, CSa3, and DSa3[(a)]; NACE 1**
Commercial blast cleaning	SSPC-SP6; NACE 3	**Used to remove all contaminants from surface, except the standard allows slight streaks or discolorations caused by rust stain, mill scale oxides, or slight, tight residues of rust or old paint or coatings. If the surface is pitted, slight residues of rust or old paint may remain in the bottoms of pits. The slight discolorations allowed must be limited to one-third of every square inch. Visual standards: SSPC-VIS I--BSa2, CSa2, DSa2[(a)]; NACE 3**

Brush-off blast cleaning	SSPC-SP7; NACE 4	**Used to remove completely all oil, grease, dirt, rust scale, loose mill scale, and loose paint or coatings. Tight mill scale and tightly adherent rust and paint or coatings may remain as long as the entire surface has been exposed to the abrasive blasting. Visual standards: SSPC-VIS I--BSa1, CSa1, DSa1[(a)]; NACE 4**
Pickling	SSPC-SP8	**Used for complete removal of all mill scale, rust, and rust scale by chemical reaction, electrolysis, or both. No available visual standards**
Near-white blast cleaning	**SSPC-SP10; NACE 2**	**Used to remove all oil, grease, dirt, mill scale, rust, corrosion products, oxides, paint, or any other foreign matter. Very light shadows, very slight streaks, and discolorations caused by rust stain, mill scale oxides, or slight, tight paint or coating residues are permitted to remain, but only in 5% of every square inch. Visual standards: SSPC-VIS I--ASa2-** $\frac{1}{2}$**, BSa2-** $\frac{1}{2}$**, CSa2-** $\frac{1}{2}$**, and DSa2-** $\frac{1}{2}$ **[(a)]; NACE 2**

(a) The Swedish standards (SSPC-VIS I) are the most commonly used visual standards for evaluating the cleanliness of a prepared surface. The use of these standards requires a determination of the extent of rust on the uncleaned steel; this is graded from A to D.

Although there are other national or corporate standards, the SSPC and Swedish standards are perhaps the most widely used. However, these standards (and most others) specify only the visual degree of cleaning and do not define the surface roughness or profile obtained by cleaning or by the removal of invisible contaminants.

In addition to cleanliness, the surface must be roughened to provide for a mechanical bond of the paint to the substrate. This roughening is termed anchor pattern, profile, or tooth, and it is essentially a pattern of peaks and valleys on the steel surface. This pattern is obtained by abrasive blasting, and it must be carefully controlled according to the coating system being applied. If the peaks are too high, they will project above the coating and cause pinpoint rusting. A rule of thumb for surface profile is that it should be approximately one-third of the required coating system thickness up to a coating thickness of 0.3 mm (12 mils).

The roughness or surface profile imparted to the metal during the course of cleaning preparatory to painting influences adhesion. As a rule, greater roughness results in greater adhesion, although excessive roughness may result in high spots or peaks that are not adequately covered by the thickness of the applied coating. Such peaks may be initiation sites for pinpoint rusting and corrosion. As a general rule, most mineral abrasive blast-cleaning materials impart a profile or roughness ranging from 13 to 100 μm (0.5 to 4 mils), depending on particle size and impact velocity. Metallic grits may have deeper profiles, approaching 178 μm (7 mils) or more, but metallic shot and grit, when sized properly, will usually impart profiles within the 50- to 115 μm (2- to 4.5-mil) range. Such surface roughnesses are suitable for most of the coating systems discussed in this article, although some of the more highly stressed systems, such as the vinyl-esters and polyesters, may require a deeper profile to ensure adequate adhesion.

The removal of invisible contaminants is more difficult to assess. It should be obvious that chemical contamination after surface preparation and before coating may result in blistering, poor adhesion, or other defects in the applied coating system. It is less evident that such chemical contamination may be inherent in a metal after it has been exposed and corroded in a chemical environment. Even thorough blast cleaning to white metal may not remove chemical species (notably chloride ions) that may have penetrated into the grain boundaries or microstructure of the metal. If such penetrating anions can react to form a water-soluble salt, such as ferrous chloride, then an aggressive underfilm corrosion may occur if water permeates the coating.

As might be expected, the presence of invisible water-soluble contaminants is more detrimental in immersion service than in dry atmospheric service. Methods for removing such contaminants are usually based on water blasting or water flushing in order to dissolve and flush the water-soluble contaminants from the surface. Other approaches are the use of chelating primers, which react with and complex the soluble salts and render them inactive and noncorrosive; and the application of a porous coating, such as an inorganic zinc-rich primer, that will allow passage of water-soluble corrosion products.

A major detriment to removal is, of course, the inability to adequately detect the presence of contaminants. Although indicator kits and chemically treated papers have been developed for this purpose, more work is needed in this area. Furthermore, very little work has been done to establish the tolerance of various coatings, surfaces, or exposure environments to the presence of differing amounts of contaminants.

Cleanliness is essential in the preparation of a surface that will receive protective coatings. Paint applied over rust, dirt, or oil will bond poorly (or not at all) to the substrate, and early paint failure will usually result. A clean surface is free of such contaminants as rust, flash rust, dirt and dust, salts, oil and grease, old paint, and mill scale.

Other areas of the surface also must be addressed before the actual cleaning. Coatings will generally not cover weld spatter properly. Weld spatter may also become dislodged in service, exposing the unprotected substrate. Sharp edges cause paint to draw thin because of surface tension effects and should be eliminated by grinding. Inside corners provide a collection site for excess paint and/or abrasive and should be filled. Crevices and pits should be filled with weld metal, if necessary, and smoothed. Some pits, because of their sharp, angular edges, will require extensive welding and grinding before surface preparation. Other pits, because they consist of smooth, even depressions, need only be cleaned for coating.

In addition, for maintenance painting, thick layers of stiff, old paint should be removed, and glossy painted surfaces must be roughened. Nonferrous surfaces also frequently require some type of pretreatment. In the case of aluminum or galvanized steel, degreasing and the application of a wash primer are often employed to provide proper adhesion.

Methods of Surface Preparation

A variety of surface preparation methods are available, including:

- Solvent or chemical washing
- Steam cleaning
- Hand tool cleaning
- Power tool cleaning
- Water blasting
- Abrasive blast cleaning

Each of these is discussed below.

Solvent cleaning (covered in SSPC SP1) removes oil and grease and is usually used in conjunction with or before the mechanical methods of preparation. Because of rapid contamination, fresh solvent must be used continuously, and the rags or cloths must be turned and/or replaced frequently. If this is not done, the grease and oil will be spread across the surface rather than removed. The final wash should be made with clean solvent. The organic solvents used should not contact the eyes or skin and should not be used near sparks or open flames. The disadvantages of solvent cleaning are that it will have no effect on rust or mill scale, it is very slow and labor intensive, and the materials are rapidly used up and need constant replacement. In addition, many of the solvents used are highly flammable and toxic. Natural or mechanical exhaust ventilation for diluting the concentration of vapors in an enclosed working space should be employed during the entire work period.

Steam cleaning uses high-temperature high-velocity wet steam to remove heavy soil, oil, or grease. It does not remove rust or mill scale, nor does it etch or roughen the surface. Commercial detergents can be added to the steam to improve cleaning. On steel, steam cleaning is sometimes followed by spot blast cleaning or wire brushing on areas exhibiting coating failure or rusting.

Hand tool cleaning (SSPC SP2) is used only for removing loosely adherent paint, rust, or mill scale. Because this method is slow, it is primarily used for spot cleaning. Hand tools include scrapers, wire brushes, abrasive pads, chisels, knives, and chipping hammers. The disadvantages of using these tools, in addition to the lack of speed, are that they will not remove tightly adherent contaminants (for example, dirt trapped in crevices, or oil or grease) and that they may raise burrs or dent the surface, actually causing some damage to the surface. In addition, these tools will generally not provide a surface profile.

Power tool cleaning (SSPC SP3) is faster than hand tool cleaning, it removes loose paint, rust, and scale, and it is good for the preparation of welded surfaces. Power tool cleaning is also good for removing old paint that has been lifted by rust. It provides a duplication of hand tools in power-driven equipment (electric or pneumatic), such as sanders, wire brushes, grinders, clippers, needle guns, and rotary descalers. Generally, power tool cleaning is suitable only for small areas because it is relatively slow. Power tools do not leave as much residue or produce as much dust as abrasive blasting, and they are frequently used where blasting dust could damage sensitive surroundings. However, they may polish the surface if they are used at too high a speed or kept in one spot for too long.

Water blast cleaning (sometimes called hydroblasting) may be high or low pressure, hot or cold, and with or without a detergent, depending on the type of cleaning desired. This process removes loose, flaky rust, paint, and mill scale. It has gained wide acceptance where abrasive blast cleaning, dust, and contamination present a hazard to either personnel or machinery. Low-pressure washing (<14 MPa, or 2000 psi) is effective in removing dirt, mildew, and chalk from the coating surface, and it is generally safe on concrete or masonry surfaces. Low-pressure water blast units use the same components as high-pressure water blast equipment. Low-pressure cleaning is referred to as power washing, and it should be recognized as such. For cleaning steel, water pressures as high as 69 MPa (10,000 psi) or more and volumes from 30 to 38 L/min (8 to 10 gal./min) are used.

Water alone does not etch a metal surface or remove tight paint, rust, or mill scale. Therefore, abrasives can be injected into the water stream to remove tightly adhering materials, to hasten the cleaning, or to roughen the surface profile. Any type of abrasive that is commonly used with abrasive blast cleaning can be used in water blast cleaning. Because the abrasive is normally not dried, screened, and recycled, less expensive abrasives are commonly selected in this application. The abrasive is injected into the system after water is pressurized by means of a suction head to prevent pump damage. Injecting abrasives into the water eliminates the dust that normally accompanies dry use of such abrasives.

Flash rusting is a concern when using these methods. Flash rust is a light rust layer that forms on steel after cleaning, particularly after water or wet abrasive blasting, or in humid marine environments. To avoid flash rusting, rust inhibitors such as sodium and/or potassium dichromate or phosphate are often used during or after water blasting. These inhibitors may retard rusting for up to 7 days. The disadvantage of using these corrosion inhibitors is that the solutions, upon drying, leave salts that can produce adhesion problems for protective coatings. The primary consideration, therefore, should be to determine if the protective coating is compatible with the inhibitor that was used.

Abrasive blast cleaning is the preferred surface preparation method for paints and coatings that require an anchor pattern and a high degree of cleanliness. Blast cleaning is the only method that can completely remove intact mill scale and give an even roughness with a controlled anchor pattern. Abrasive blasting is the propelling, or shooting, of sand or other types of small, hard particles at a surface. In nozzle blasting, the force that propels the abrasive is compressed air. The abrasive strikes the surface at speeds of 320 to 640 km/h (200 to 400 mph), breaking and loosening the rust or scale.

The cleaning principle is the same in centrifugal wheel blasting. In this case, the spinning of large paddle wheels creates the force that throws the abrasive at the surface. This method is usually confined to shop use with units approximately the size of a large trailer, although smaller one-man units have been developed for preparing floors or ship hulls. In contrast with open blast cleaning, the abrasives used are recyclable steel grit or shot.

Vacuum blasting is another option for dust-free blast cleaning. With this technique, the blast nozzle is surrounded by a brush, and a vacuum is created within the annular space. The spent abrasive and removed paint, rust, and debris are contained by the brush, removed by the vacuum, and transported to a separator. The debris and fine particles are removed, and the abrasive is returned for reuse. This method is very slow, because the blast pattern is approximately 25 mm (1 in.) in diameter. However, for small areas or where dust cannot be tolerated, it may be the best alternative.

The grades of cleaning are identified as Brush-Off (SSPC SP7). Commercial (SSPC SP6). Near-White (SSPC SP10), and White (SSPC SP5). The specific definitions are provided later in this section. Abrasive blasting is ideally suited for high-production work because it rapidly cleans large areas. In spite of its efficiency and good results, some problems still occur, such as the accumulation of used abrasives in low-lying areas and the attendant difficulty in removing them. Airborne dust and abrasive can interfere with machinery and the work of persons nearby and can contaminate adjacent locations. Airborne dust can be a hostile environment for the blast operator, and an air-fed hood must be worn while operating the air blast cleaning equipment. In addition, open nozzle blast abrasives are expensive and are usually not recycled in the field.

Open nozzle blasting equipment has six basic components:

- Air compressor
- Air hose
- Blasting machine, with a safety valve
- Blast hose
- Nozzle
- Moisture and oil separator

The function of each part is described below.

The air compressor is the source of energy for the blasting job. The constant supply of a high-volume high-pressure air stream hour after hour is the most critical part of blast operations.

Work is done in direct proportion to the volume and pressure of air at the nozzle. The larger the compressor, the larger the nozzle it can operate. The larger the nozzle at the proper pressure, the faster the job can be completed.

The air hose connects the compressor to the blast pot. For efficient blasting, the air hose should have as large an inside diameter as practical in order to reduce friction and avoid air pressure loss (a minimum 32-mm, or 1 $\frac{1}{4}$-in., ID air hose is usually recommended). A 15% production loss can result from a 69-kPa (10-psi) drop in pressure. The air hose should also be as short as practical to reduce leakage and should contain as few couplings as possible.

The blasting machine or sandpot is a pressurized container that holds the abrasive. A valve at the bottom measures and controls the amount of abrasive fed into the blast hose. Efficient abrasive blast operations require the right size pot for the job, which enables very few refill stops, and the releasing of an even flow of abrasive with the air stream. A deadman control valve is a required safety feature for operation of the blast pot.

To start the machine, the operator presses down on the deadman valve with his hand: this allows the air inlet valve to open and the air outlet valve to close, at which time blasting begins. Should he want to stop the operation, the operator releases his hold on the deadman valve, thus closing the air inlet valve, shutting off any incoming air from the compressor to the machine, and instantly opening the bleed-off or depressurizing valve.

Consider the possibility of an operator who faints, collapses, or falls off the scaffold. He may be within the range of the nozzle, which in effect is an automatic shot gun. Many injuries have been caused by such incidents. With remote control deadman valves, the machine will shut off the moment the grip on the nozzle is relaxed.

The blast hose connects the blast pot and nozzle and carries both air and abrasive. It is treated to prevent electrical shock by the installation of a grounding line. Sturdily constructed, multiple-ply hose with a minimum inside diameter of 32 mm (1 $\frac{1}{4}$ in.) is required in most work. A short length of lighter, more flexible hose with a 25- or 32-mm (1- or 1 $\frac{1}{4}$-in.) inside diameter is sometimes joined in at the end. These sections called whips, are easier to handle and are effective for work in areas with many angles, pipes, and stiffeners. The use of whips will, however, effectively reduce the pressure at the nozzle and cancel the advantage gained by a large-diameter blast hose; therefore, their use should be discouraged except where necessary.

The nozzle is a major element in the blasting operation. Nozzle sizes are identified by the diameter of the orifice. Diameters are measured in sixteenths of an inch. A 4.8-mm ($\frac{3}{16}$-in.) diam orifice is designated No. 3; a 7.9-mm ($\frac{5}{16}$-in.) diam nozzle, No. 5; and so forth. Nozzles are commonly available up to 12.7 mm ($\frac{1}{2}$ in.) (No. 8) in diameter. The rate of surface cleaning is a function of the volume of air pushed through the nozzle at high pressure. For example, if a cleaning rate of 9 m^2/h (100 ft^2/h) can be attained with a 6.4-mm ($\frac{1}{4}$-in.) nozzle, a rate of 37 m^2/h (400 ft^2/h) can be attained with a 12.7-mm ($\frac{1}{2}$-in.) nozzle. However, the nozzle can be too large for the air volume. This will result in insufficient air

pressure, and production will drop. Therefore, nozzle size should be as large as permitted by the air supply to maintain air pressure of 620 to 690 kPa (90 to 100 psi) at the nozzle.

Nozzles should use the venturi design, have as long a nozzle length as practical, use a tungsten carbide or other wear-resistant lining, and have as large an orifice size as possible with a given compressor. For difficult-to-reach places, nozzles also come in shapes such that they can propel abrasives around corners, in a 360° arc, or even backwards.

Moisture and Oil Separators. The large consumption of compressed air in an abrasive blasting operation introduces the problem of contamination by moisture (especially in high-humidity areas) and oil mists from compressors. This is especially true of portable compressors. To combat this, an adequately sized moisture and oil separator should be installed at the blast machine (at the most distant point from the compressor). Separators are usually of the cyclone type and employ expansion chambers and small micron filters to eliminate up to 95% of moisture and contaminants. They require solvent cleaning to remove oil and regular replacement of filters.

Abrasives. The proper abrasive is the one that provides the necessary cleanliness and profile. The characteristics of such an abrasive related to performance include size, hardness, shape, and material.

Size. A large abrasive particle will cut deeper than a smaller particle of the same composition and shape and will therefore provide a deeper surface profile. However, the greatest cleaning rate is achieved with the smaller abrasive because of a larger number of impacts per unit area.

Hardness. Hard abrasives generally cut deeper and faster than softer or brittle abrasives. A hard but brittle abrasive will shatter upon impact; this reduces its cleaning power accordingly.

Shape. The shape and size of abrasive grains determine the type of surface profile achieved by blast cleaning. Steel shot, because it is round, peens the surface to give a wavy profile. Therefore, shot is particularly effective at removing brittle deposits, such as mill scale. Grit, on the other hand, is angular, and when blast cleaning produces a jagged finish that is generally preferred for coating adhesion. A wide variety of surface patterns are available from different grits. Use of sand and slag abrasives that are semiangular results in a pattern somewhat between that of shot and grit.

Materials. The abrasive should have a neutral pH, that is, between 6 and 8. It should not be washed with seawater or other contaminated water. Four types of abrasive materials are commonly used on a nonrecycled basis, as follows.

The first type is the natural oxides. Silica sand is the most widely used natural oxide because it is readily available, low in cost, and effective. The hazards of sand have recently been elucidated by the EPA and by the Occupational Safety and Health Administration, and the use of silica sand abrasives has been restricted in many areas. Another natural silica material has received attention in recent years. It consists of a blend of coarse and fine staurolite sands mined from certain mineral deposits in Florida. It is characterized as efficient cutting, and it has less dusting and a lower breakdown rate than silica sand.

The second type is the metallic abrasives. Steel shot and grit abrasives are efficient, hard, and dust free, but care must be taken in their storage to prevent rusting. Although their initial cost is higher, they may be recycled many times to make them cost effective. A mixture of both shot and grit abrasives in blasting may combine the advantages of both.

The third type is the slag abrasives. Copper and nickel abrasives are a by-product of the ore-smelting industry. Coal slags result from the burning of coal. These abrasives are fast cutting, but they have a high breakdown rate and are generally not recycled. Slag abrasives are most likely to exhibit an acidic pH.

The fourth type is the synthetic abrasives. Aluminum oxide and silicon carbide are nonmetallic abrasives that have cleaning properties similar to the metallics without the problem of rusting. They are very hard, fast cutting, and low dusting, but they are quite costly and must be recycled for economical use.

Coating Application

In a most basic sense, coating application can be described as getting the paint from the can to the surface being coated. There are a number of ways of accomplishing this, and often the type of paint material determines the selection of the most appropriate method. For example, zinc-rich coatings should always be sprayed (except for very small areas), and agitation must be used when spraying to keep the heavy pigment particles from settling. Vinyls and chlorinated rubbers

are not usually formulated for brush or roller application, and they too should be sprayed. On the other hand, alkyds and oil-base coatings are often applied by brush or roller, but can be readily sprayed as well. For most corrosion-protective coating systems, airless or conventional spraying is preferred; spraying deposits a more uniform film with greater thickness control and a better appearance. The rate of application is much faster with spraying, particularly airless spray, than with brush and roller application. The more common application techniques and equipment are described below.

Brushing

Brushing is an effective, relatively simple method of paint application, particularly with primers, because of the ability to work the paint into pores and surface irregularities. Because brushing is slow, it is used primarily for smaller jobs, surfaces with complex configurations (edges, corners, cuts, and so on), or where overspray may constitute a serious problem. The other disadvantage of brushing is that it does not produce a very uniform film thickness. Natural brush bristles of good quality are preferred, but synthetic bristles resistant to strong paint solvents can also be used. Bristles that are naturally or artificially flagged, that is, with split tips, are preferred because they hold more paint. Nylon and polyester bristles are more water resistant than natural fibers and are preferred for latex paints.

Paint Mitts. A paint mitt can hold more paint than a brush and is faster, but it produces a very nonuniform thickness. Therefore, paint mitts are generally used only for hard-to-reach areas or oddly shaped objects, such as small pipes and railings.

Rolling

Rollers are best used on large, flat areas that do not require the surface smoothness or uniformity achievable by spraying. Rollers are also used in interior areas where overspray presents a cleaning and masking problem. However, the brush is preferred over a roller for applying primers because of the difficulties in penetrating pores, cracks, and other surface irregularities. In rolling, air mixes with the paint and leaves points for moisture to penetrate the cured film. Rolling is generally more suitable for topcoating a primer that has been applied by some other method.

The nap (fiber length) of a roller normally varies from 6.4 to 19 mm ($\frac{1}{4}$ to $\frac{3}{4}$ in.). A longer nap holds more paint, but does not give a smooth finish; therefore, it is used on rough surfaces. Rollers with extra-long naps (32 mm. or 1 $\frac{1}{4}$ in.) are used for chain-link fencing. Handle extensions up to 3 m (10 ft) in length or longer allow a painter to reach otherwise inaccessible areas, but the net effect is usually a reduction in the quality of the application. High-performance coatings for immersion service are seldom applied by roller because of nonuniform thickness, wicking caused by roller residue, and the rapid drying properties of some coatings, such as vinyls.

Spray Painting

Spray painting of coatings results in a smoother, more uniform surface than that obtained by brushing or rolling, because these application methods tend to leave brush or stipple marks and irregular thicknesses. The most common methods of spray painting are conventional and airless.

The conventional spray method of spraying relies on air for paint atomization. Jets of compressed air introduced into the stream of paint at the nozzle break the stream into tiny droplets that are carried to the surface by the current of air.

Because large amounts of air are mixed with the paint during conventional spray application, paint losses from bounce back or overspray can be high. Such losses have been estimated to be as much as 30 to 40%, depending on the configuration of the substrate. However, the ability to vary fluid and air independently gives conventional spray the versatility to provide a wide choice of pattern shapes and coating wetness by infinitely varying the atomization at the gun. Spray gun triggering is more easily controlled for precise spraying of irregular shapes, corners, and pipes than with airless spray. Conventional spraying provides a finer degree of atomization and a higher quality surface finish than airless spray.

However, some of the disadvantages of conventional air spray application are:

- It is slower than airless application

- More overspray results than with other methods
- It is hard to coat corners, crevices, and so on, because of blowback

Nonetheless, conventional spray is still one of the most frequently used application methods. The equipment required for conventional spray application of coatings is discussed below.

Air compressors can be of various types, with the size usually dependent on the amount of air required to operate the spray gun. Hoses must be properly sized to deliver the proper amount of air volume and pressure to the gun. It takes approximately 276 to 414 kPa (40 to 60 psi) and 0.25 m^3/min (8.5 ft^3/min) to operate most production spray guns with medium-viscosity paint.

An oil and moisture separator should be set up between the air compressor and the paint pot to prevent moisture and oil from getting into the paint and ruining the quality of the finish. This component of the conventional spray set-up should be considered as a standard item that cannot be omitted, because of potential paint contamination and equipment damage.

Pressure Feed Tanks (Paint Pots). The amount of fluid material delivered to the spray gun is regulated by the pressure set by the fluid pressure regulator of the feed tank pressure pot. The pressure pot should contain 19 to 38 L (5 to 10 gal.) of paint for most jobs. Pressures of 55 to 83 kPa (8 to 12 psi) at the gun are commonly used; excessive fluid pressure can cause the fluid stream to exit the fluid nozzle at too high a velocity for the air jets in the nozzle to atomize the fluid stream properly.

Connecting Hoses. Two hoses are used in conventional air spray painting: the air hose and the fluid hose. Air hoses supply air from the compressor to the paint pot and should be at least 12.7 mm ($\frac{1}{2}$ in.) in inside diameter. The air hose from the paint pot to the spray gun should be 6.4 to 7.9 mm ($\frac{1}{4}$ to $\frac{5}{16}$ in.) in inside diameter and as short as possible.

The fluid hose usually has a solvent-resistant liner. It should have a 7.9- to 9.5-mm ($\frac{5}{16}$- to $\frac{3}{8}$-in.) inside diameter for medium-viscosity materials and should be as short as possible. Hoses with inside diameters up to 12.7 mm ($\frac{1}{2}$ in.) are commonly used. Excessive hose length allows the solids to settle in the line before reaching the spray gun. This leads to clogging and the application of a nonhomogeneous film.

The spray gun is used to atomize the paint by mixing it with air under pressure in order to apply the coating material to the surface. Various spray patterns can be obtained by changing the volume of both air and fluid. The selection of the fluid nozzle and the needle size is another way to regulate the amount of paint exiting the fluid nozzle. If it is found that excessive amounts of paint are flowing through the fluid nozzle at low pressures (55 to 83 kPa, or 8 to 12 psi), the fluid-adjusting knob can be used to reduce the flow, or a smaller fluid nozzle/needle combination may be needed. Paint manufacturers normally recommend at least one set of sizes known to work for their product.

Airless spray provides a rapid film build, greater paint flow into surface irregularities, and rapid coverage. In airless spraying, paint is forced through a very small nozzle opening at very high pressures to break the existing paint stream into tiny particles (similar to water exiting a garden hose). Because of the high fluid pressure of airless spray, paint can be applied more rapidly and at greater film builds than in conventional spraying. The high-pressure paint stream generated by airless spray penetrates cavities and corners with little surface rebound. If airless spray is used, proper spraying technique is essential for quality paint films. Poor technique can result in variations in paint thickness, holidays, and a host of other film defects in addition to wasted time and materials.

Some of the advantages of airless spray as compared to conventional spray include:

- Higher film builds are possible (heavier coatings)
- Less fog or rebound

- Easier to use by the operator, because there is only one hose
- Higher viscosity paints can be applied
- Easier clean up

The disadvantages of the airless spray process include:

- Relies on dangerous high pressure
- Fan pattern is not adjustable
- Many more working parts that can cause difficulty
- Higher initial cost than other forms of spraying
- Requires special care to avoid excessive buildup of paint that causes solvent entrapment, pinholes, runs, sags, and wrinkles

The equipment and materials for airless spraying are discussed below.

Power Source. An electric motor can be used instead of an air compressor to drive the fluid pump. The electric airless is a self-contained spray outfit mounted on wheels and designed to use commercial 115-V electrical power.

An air compressor, usually with a 1-hp, 690-kPa (100-psi) electric motor or a 1 $\frac{1}{2}$-hp gasoline engine, is required to operate one gun with a 0.46-mm (0.018-in.) tip. For two or more guns or heavy materials, a greater capacity is needed.

Air Hose and Siphon Hose. A 12.7-mm ($\frac{1}{2}$-in.) ID hose is generally used to deliver air from the compressor to the pump. The most common hose length is 15 m (50 ft). However, as hose length and pump size increase, the inside diameter of the hose must be increased as well.

A siphon hose is required, and it must have an inside diameter of 12.7 to 19 mm ($\frac{1}{2}$ to $\frac{3}{4}$ in.) to provide adequate fluid delivery. Also, the hose material must be resistant to the fluid solvent and other materials. A paint filter should be used to prevent dirt from clogging the fluid hose and tip. This hose is often eliminated, and the pump is immersed directly into the paint.

High-Pressure Fluid Pump. The fluid pump is the most important part of the hydraulic airless system; it multiplies the air input pressure to deliver material at pressures up to 31 MPa (4500 psi). Pumps are offered with delivery ranges from 0.8 L/min (28 oz/min) (one gun) up to 11.4 L/min (3 gal./min) (three to four guns). The pump used for many airless outfits will convert 0.45 kg (1 lb) of air input into 13.5 kg (30 lb) of fluid pressure. This is referred to as a 30:1 ratio. Pump ratios as high as 45:1 are common.

Some airless spray units use an electric-hydraulic power pack. These units can supply two guns with airless spray tips of up to 0.53 mm (0.021 in.) and long spray lines, or one gun for high-volume delivery with an airless tip of up to a 0.79-mm (0.031-in.) orifice. These electric units are wheel mounted and use a long-stroke slow-speed pump. The unit is equipped with an explosion-proof motor and can deliver as much as 3.8 L/min (1 gal./min) at pressures up to 21 MPa (3000 psi).

A paint filter should be attached to the pump at the fluid hose connection. The filter prevents dirt and particles from clogging the gun and being sprayed onto the work surface.

The fluid hose is made to withstand high operating pressures. It is made of vinyl-covered, reinforced nylon braid and can handle about 2040 kg (4500 lb) of pressure. The hose is designed to resist the solvent action of the various coatings being sprayed. A wire is often molded into the hose assembly to prevent any possible static electrical charge. The hose

inside diameter should be at least 6.4 mm ($\frac{1}{4}$ in.), and the length should not be longer than necessary to do the work (ideally, 15 to 30 m, or 50 to 100 ft). Fluid hose diameters up to 12.7 mm ($\frac{1}{2}$ in.) are commonly used.

The airless spray gun is designed for use with high fluid pressures. It is similar in appearance to the conventional gun, but has a single hose for the fluid. The hose may be attached to the front of the gun or to the handle. Atomization occurs when fluid is forced through the small orifice in the spray tip at high pressures.

A variety of spray tips are available to suit the type of material being sprayed and the size of spray pattern desired. The orifice, or hole, in the tip and the fan angle control the pattern size and fluid flow. There are no controls on the gun itself. Tip orifices vary to fit the viscosity of the paint being applied; fan angles range from 10 to 95°.

Quality Assurance

To obtain the desired protection of a metal substrate from a coating system, it is important not only to choose the proper coating materials but also to ensure that they are properly applied. On most jobs, such assurance is provided by a reputable paint force, or contractor, but on many other jobs, surveillance by plant personnel or thorough inspection by independent third-party organizations is done. In all cases, the rudiments of quality are the same:

- Proper masking and protection of surfaces not to be blast cleaned or painted
- Removal of rust and contaminants and suitable roughening of the surface
- Application of the specified coating system to the proper thickness
- Observation of application parameters, such as minimum and maximum temperatures, interval between coats, and induction times
- Verification of proper hardening or cure of the coating
- Testing to ensure that defects such as pinholes, skips, or holdings are minimized or avoided.
- Tests for adhesion, color, gloss, and other parameters that may affect appearance or protective capability of the coating

Coating inspection requires training, experience, and familiarity with the instrumentation the inspector must use. Inspector training courses are available, and certification of inspectors is available from some training organizations. For example, NACE and the National Institute of Accreditation and Certification both certify coating inspectors. A brief overview of some of the more common coating inspections and inspection equipment is presented below.

Inspection Sequence

Inspection often begins with a pre-job conference at which the ground rules are set, but when the work begins, the inspector is responsible for witnessing, verifying, inspecting, and documenting the work at various inspection points. The inspector should be aware of the following inspection points and should witness or conduct the operation if feasible:

- Pre-surface preparation inspection
- Measurement of ambient conditions
- Evaluation of compressed air cleanliness and surface preparation equipment
- Determination of surface preparation, cleanliness and profile
- Witnessing coating mixing and thinning
- Inspection of application equipment
- Inspection of coating application
- Determination of wet-film thickness
- Determination of dry-film thickness
- Evaluating cleanliness between coats
- Pinhole and holiday testing

- Evaluation of adhesion and cure

Pre-Surface Preparation Inspection. Prior to the start of surface preparation and other coating activities, it is necessary to inspect in order to determine if the work is ready to be prepared and painted. Heavy deposits of grease, oil, dust, dirt, and other contaminants must be removed. Removal of this miscellaneous debris before blast cleaning ensures that these materials are not redeposited onto the freshly blast-cleaned surfaces.

In addition, the specifications may require that weld spatter be ground or otherwise removed and that sharp edges be rounded (customarily to a 3.2-mm. or $\frac{1}{8}$-in., radius). Unusual pitting in the steel substrate should be examined; the pits will either be accepted as they are or will be ground or filled. Areas that do not need to be cleaned or coated should be masked to protect them from the cleaning and coating operations.

Measurement of Ambient Conditions. Before final blast cleaning and before any paint is applied, the inspector or painter should check the ambient or surrounding weather conditions. This is especially important in the early morning when the weather is changing or during seasonal changes when condensation is common. The presence of a thin film of condensed moisture on the surface may be visually imperceptible, but a quick check of the dew point and the surface temperature will determine if such a condition exists.

Dew point is calculated by using temperature readings from a psychrometer and the appropriate psychometric tables. A psychrometer is an instrument used for determining relative humidity and dew point. The temperature of the surface to be coated should be at least 3 °C (5 °F) higher than the dew point.

Evaluation of Compressed Air Cleanliness and Surface Preparation Equipment. The air supply should be tested for cleanliness at frequent intervals during the day. This is done by holding a blotter or cheesecloth in the air stream for a minimum of 2 min. The blotter or cheesecloth should be held at a distance of 0.5 to 0.6 m (18 to 24 in.) from the source of the air stream being tested. The test material should be examined immediately after the test is complete for evidence of contamination by oil or moisture. Examination should be made visually as well as by touching and smelling the test material. If there is no discoloration on the blotter, the air quality is excellent, while moisture and oil on the blotter indicate unsatisfactory air.

Determination of Surface Preparation, Cleanliness, and Profile. Surface preparation is believed to be the most important factor affecting the performance of the coating. Any compromise in surface preparation usually reduces the performance of the applied material as well. The primary goals of surface preparation are, first, to provide a satisfactory, clean surface free of detrimental contaminants and, second, to provide an anchor pattern and to increase the steel surface area to improve bonding of the applied coating or lining to the steel surface.

Surface cleanliness should be visually inspected to verify that it is in conformance with the specified cleanliness standard. Surface profile can be determined by using any of several instruments, including surface profile comparators, which give a visual and tactile comparison to a known profile; replica tape with a spring micrometer, in which a tape is pressed into the valleys of a profile and the profile height measured with a micrometer; and dial surface profile gages, where the base of a depth micrometer rests on the profile peaks while a needle penetrates into the valleys.

Witnessing Coating Mixing and Thinning. Before a coating can be applied to a substrate, it must be suitably mixed to ensure that the material is homogeneous. During storage, most coatings tend to show some separation of the lighter and heavier components. Heavier pigments settle to the bottom of the can and sometimes appear as a hard cake, while other materials settle as a soft sludge. Some binders and some paints curdle or gel when stored for too long a period. Stirring may reconstitute the paint to a homogeneous liquid; if not, then the paint must be discarded.

Inspection of Application Equipment and Techniques. A lack of cleanliness is the predominant failure associated with spray guns and spray pumps. Paint chips or residues of previous coating materials can lodge in the pump, lines, or guns and cause clogging. Cleanliness of mixing equipment, lines, spray pots, guns, tips, and other application equipment is important and necessary.

During application, the safety and respiration equipment of the operator should be verified to be in working order, and the spray technique should be reviewed. For example, is the spray gun the proper distance from the work? Is there pattern overlap, uniform speed, and triggering before and after each stroke? Is the gun perpendicular to the surface?

Wet-film thickness readings are used as an aid to the painter in determining how much material to apply to the surface in order to achieve the specified dry film. Wet-film thickness gages are of value only if one knows how heavy a wet film to apply. The wet-film thickness/dry-film thickness ratio is based on knowing the percent solids by volume of the specific coating material:

$$\text{Wet-film thickness} = \frac{\text{Desired dry-film thickness}}{\text{\% solids by volume}}$$

If the paint is thinned at the time of use:

$$\text{Wet-film thickness} = \frac{\text{Desired dry-film thickness}}{\left(\dfrac{\text{\% solids by volume}}{100\% + \text{\% thinner added}}\right)}$$

Dry-film thickness measurements are made after complete drying of the coating. They are used to determine if the desired coating thickness is obtained. Dry-film thickness gages for steel surfaces are almost always of the magnetic type. If properly calibrated and operated, they have an error of only approximately 5 to 15% at normal temperatures (-18 to 100 °C, or 0 to 212 °F). Dry-film thickness instruments fall into four basic categories, as follows.

Magnetic pull-off instruments rely on the attraction of a magnet to an underlying steel surface. The stronger the attraction, the greater the force necessary to pull off the magnet. This pulling force can be calibrated to indicate coating thickness.

Magnetic fixed probe instruments measure the strength of the magnetic flux in a steel substrate exerted by a permanent magnet. Thickness can be measured by nulling the wheatstone bridge circuitry at various known thicknesses.

In eddy current inspection, a fluctuating electrical current induces residual eddy currents in an underlying metallic (aluminum, copper, stainless steel, and so on) substrate. The strength of the induced currents is a function of the distance of the induction probe from the substrate, that is, separation by paint thickness. The strength of the induced eddy current is measured and converted into paint thickness.

Destructive Inspection. The most common instrument for destructive coating thickness measurement cuts a small "V" into the paint at a known angle. By measuring the width of the slope of the "V" incision, a measurement of coating thickness can be obtained. The advantage is that each coat of a multiple-coat system can be measured and that thickness measurement is independent of substrate (steel, concrete, wood, and so on).

Evaluating Cleanliness Between Coats. When a multiple-coat system is to be applied, the surface between coats should be examined to ensure that all grease, oil, dirt, bird droppings, pebbles, sand from abrasives, dry spray, and the like have been removed before the application of the next layer of coating.

Pinhole and Holiday Testing. Many coating systems, particularly those for immersion or splash zone service, require additional testing with holiday detectors after the coating has dried. Pinhole and holiday detectors are of two basic types: low-voltage wet sponges and dc high voltage. The basic function of a holiday tester is to detect minute pinholes, holidays, skips, or misses in coating systems, all of which can cause premature coating failure.

The low-voltage (30 and 67.5 V are common) wet-sponge holiday detectors are used for locating discontinuities in nonconductive coatings applied to metal bases. The low-voltage detector is suitable for use on coatings up to 0.5 mm (20 mils) in thickness. The basic unit consists of the detector, a ground cable, and a sponge electrode. The ground cable is firmly attached to the bare substrate, and the sponge electrode is saturated with tap water. The electrode is moved across

the entire surface at a speed of approximately 4.5 to 6 m/min (15 to 20 ft/min); the water permits at small current to flow through the pinholes down to the substrate. Once the current reaches the substrate, the circuit is completed to the detector unit, and an audible signal indicates that a pinhole or discontinuity has been found.

High-voltage holiday detectors basically function on the same operating principle as the low-voltage instruments described above except that a sponge is not used. The instrument consists of a testing unit that can produce various voltage outputs, a ground cable, and an electrode made of conductive neoprene, brass, or steel. High-voltage units are available up to 20,000 V and more. The rule of thumb for high-voltage detectors is to apply approximately 100 V per mil of dry-film thickness. High-voltage detectors are used for nonconductive coatings applied to conductive substrates. The ground wire should be firmly attached to a section of the bare substrate and the electrode passed over the entire surface. A spark will jump from the electrode through the air gap down to the substrate at pinholes, holidays, and so on, simultaneously activating a signaling device in the unit.

Adhesion Testing. Occasionally, there is a need to test the adhesion of the coatings after application in the field. Different types of adhesion-testing methods are used, ranging from the simple penknife to the more elaborate tensile-testing units. The use of a penknife generally requires a subjective evaluation of the coating adhesion based on some previous experience. Generally, one cuts through the coating and probes at it with the knife blade, trying to lift it from the surface to ascertain whether or not the adhesion is adequate.

A modified version of this type of testing is the cross-out test. The cross-cut test consists of cutting an X, or a number of small squares or diamonds, through the coating down to the substrate. Tape is then rubbed vigorously onto the scribed marks and removed briskly. The cross-hatch pattern is evaluated according to the percentage of squares delaminated or remaining intact. A cross-cut guide can be used to cut a precision crosshatch pattern.

Another technique involves adhering a small dolly to the coated surface, scoring around the dolly periphery, and using a tensile-pulling device to pull it from the surface. The tensile pressure required to disbond, as well as the nature of the disbondment, is used to characterize adhesion.

Tests for Cure. The rate of cure of organic coating materials is affected by surface temperature, ambient conditions, coating formulation, and film thickness. Laboratory testing of paint chips is the only true means for verifying cure. Field techniques include the following.

Solvent Rub. On thermosetting cross-linked coatings, a clean cloth saturated with a strong solvent such as methyl ethyl ketone (MEK) or methyl isobutyl ketone (MIBK) can be used to rub the surface of the coating. If the materials is properly mixed and cured, no color will be transferred to the cloth. If the coating is improperly mixed or cured, it may partially redissolve, and the color will be seen on the cloth. Of course, the solvent rub test cannot be used on certain solvent-sensitive coatings, such as alkyds, vinyls, and chlorinated rubbers.

Sandpaper Test. When a properly cured film is abraded with fine sandpaper, a fine powdery residue is observed. Coating material that remains on the face of the sandpaper may indicate an uncured, slightly tacky coating.

Hardness Tests. A penetrating needle hardness tester or pencil hardness tester can be used to check film cure. The use of such instruments entails exerting a light perpendicular pressure on an instrument, which holds a hardened steel indenter ground to microscopic accuracy. The penetration of the spring-loaded indenter, which indicates hardness, is read directly from a scale dial. Pencil hardness is established by the lead hardness that will just scratch the paint surface.

Electroplated Coatings

Joseph Mazia, Mazia Tech-Com Services, Inc.; David S. Lashmore, National Bureau of Standards

Introduction

ELECTROPLATED COATINGS can be very effective in reducing the annual $167 billion (as of 1985) cost of corrosion. Even when metallic coatings are applied to a substrate to provide decorative effects or to enhance material properties, such as wear or electrical contact resistance, the corrosion performance of the coating-substrate system must be carefully considered to avoid future degradation. Metallic coatings can be very useful in providing the optimum properties for a part not obtainable if it were fabricated from a single material.

The overall properties of coated parts are determined by the properties of the coating itself and by defects in the coating. The understanding of how defects in a coating affect the corrosion performance is critical in designing an effective coating system.

Electroplating is the electrodeposition of an adherent metallic coating upon an electrode for the purpose of securing a surface with properties or dimensions different from those of the basis metal (Ref 1). Electrodeposits are applied to metal substrates for decoration, protection, corrosion resistance, chemical inertness, wear resistance, buildup of substrate dimensions, electrical properties, magnetic properties, solderability, reflectance, and reduction of friction (Ref 2). Electrodeposited coatings are sometimes applied for two or more reasons. For example, decorative and protective plating and combined in such applications as steel automobile bumpers, trim items made of zinc die castings or steel, trim items on large and small appliances, costume jewelry, electronic circuits, piano strings, construction and architectural hardware, plumbing fittings, electrical contacts, plastic items, and magnetic memory devices (Ref 2).

This ability to be decorative as well as protective to substrates distinguishes electrodeposited coatings from metallic coatings applied by hot dipping or spraying. Metallic luster, achieved by bright plating or by polishing after plating, lends a distinctive appearance not provided by other types of coatings. However, corrosion resistance is the primary reason for the use of electrodeposited coatings. Electrodeposited coatings are also applied to protect substrate metals. Examples of this application include:

- Tin, as well as chromium, plating of steel strip for food packaging and other container uses
- Electrogalvanizing, or zinc plating, of steel strip, sheet, stampings, forgings, wire, and screw machine products
- Zinc and cadmium plating of fasteners and other hardware items
- Chromium plating of gun bores

Electrodeposits are used to enhance properties other than corrosion protection. For example, many fasteners are coated with a bright cadmium or zinc deposit supplemented with a clear or colored chromate conversion film. This results in coatings that are both protective and decorative. In addition, chromium is applied to the interior of gun barrels to provide lubricity and erosion resistance as well as corrosion protection.

This article will discuss the various factors that affect the corrosion performance of electroplated coatings, the effects of environment and the deposition process on substrate coatings, and the electrochemical techniques capable of predicting the corrosion performance of a plated part. Because the practical aspects of electroplating are covered in such publications as Volume 5 of the *ASM Handbook* and Ref 3, 4, 5, and 6, this article will be primarily concerned with the corrosion resistance of electrodeposited coatings. An exception will be the discussion of mill-applied finishes, about which the open literature is sparse and limited in scope. Special attention will be given to the design of coating systems for optimum protection of the substrate. An ideal electroplated coating system will be defined. Finally, attention will be given to controlled weathering tests and accelerated tests used to predict and determine the relative durability of the coating.

Idealized Coating

Coatings are either anodic or cathodic to the substrate. Only a very rough idea of which situation applies can be obtained from the electromotive force (emf) series (Table 1). Coatings that are anodic to a substrate in one environment may be cathodic to the same substrate in a second environment. The environment itself may change from the surface of the coating to one that exists within any defects, such as scratches, cracks, or corrosion pits. These defects are particularly important if the coating is cathodic to the substrate; in this case, if the substrate becomes exposed, rapid corrosion of the substrate may occur as it attempts to protect the coating. If the coating is anodic to the substrate, defects are somewhat less important, although they still must be considered. Thus, if the substrate becomes exposed, it will be protected by the corrosion of the coating. However, if the corrosion should proceed to such an extent that a large area of the substrate is exposed, the coating will lose its effectiveness, because the electrical resistance of the substrate limits the area that the coating can protect.

Table 1 Electromotive force series of metals and alloys

Solution concentration: 1 *N*; temperature: 25 °C (75 °F)

Metal	**Ion**	Standard potential (E_0), V
Calcium	Ca^{2+}	**-2.87**
Sodium	Na^{+}	**-2.71**
Magnesium	Mg^{2+}	**-2.37**
Aluminum	Al^{3+}	**-1.66**
Zinc	Zn^{2+}	**-0.763**
Chromium	Cr^{3+}	**-0.71**
	Cr^{6+}	**-0.56**
Iron	Fe^{2+}	**-0.44**

Cadmium	Cd^{2+}	**-0.40**
Nickel	Ni^{2+}	**-0.25**
Tin	Sn^{2+}	**-0.136**
Lead	Pb^{2+}	**-0.126**
Hydrogen	H^{+}	**0**
Copper	Cu^{2+}	**0.337**
	Cu^{+}	**0.521**
Silver	Ag^{+}	**0.799**
Platinum	Pt^{4+}	**0.90**
Gold	**Au^{+}**	**1.68**

Source: Ref 2

The nature of any corrosion products formed also must be taken into account. For example, in industrial environments, zinc is more protective of steel than cadmium is because the zinc sulfate ($ZnSO_4$) corrosion product formed has a lower solubility than cadmium sulfate ($CdSO_4$); $ZnSO_4$ thus provides a blocking action to reduce subsequent corrosion. This situation is reversed in marine environments, in which the corrosion products are more likely to be carbonates and chlorides. Zinc produces more soluble corrosion products than cadmium does in this environment. The most desirable situation is to have the coating anodic to the material beneath it and at the same time to have a very low corrosion rate.

This general rule has been exploited to a high degree of sophistication by the automotive industry. Chromium-plated exterior steel parts have a coating system consisting of several layers of metals, each of which is anodic to the layer beneath it. In fact, there are accurate lifetime predictions based on the electrochemical potential differences and the thicknesses of the layers. Also, multilayer corrosion standards are available from the National Bureau of Standards that ensure that the coatings meet specifications. Even the chromium layer has been designed to be microcracked or microporous to spread the corrosion reactions over a large area. Corrosion is then distributed over a large area, and localized pitting is minimized. This will be discussed in more detail in the section "Applications for Electrodeposited Coatings" in this article.

Substrates

The emf series is a table that lists in order the standard electrode potentials of specified electrochemical reactions (Ref 1). The potentials are measured against a standard reference electrode when the metal is immersed in a solution of its own ions at unit activity (Table 1).

Similarly, the galvanic series is a list of metals and alloys arranged according to their relative potentials in a given environment (Ref 1). Figure 1 shows a galvanic series of commercially used metals and alloys in seawater. The positions of metals and alloys in a galvanic series--and the corrosion behavior of metals and alloys--depend on the specific environment to which the materials are exposed. Therefore, there are as many galvanic series as there are aqueous

environments. Generally, the relative positions, of metals and alloys in both emf and galvanic series are the same. An exception is the position of cadmium with respect to iron and its alloys. In the emf series, cadmium is cathodic to iron, but in the galvanic series (at least in seawater) cadmium is anodic to iron. Thus, if only the emf series were used to predict the behavior of a ferrous metal system, cadmium would not be chosen as a sacrificial protective coating, yet this is the principal use for cadmium plating on steel.

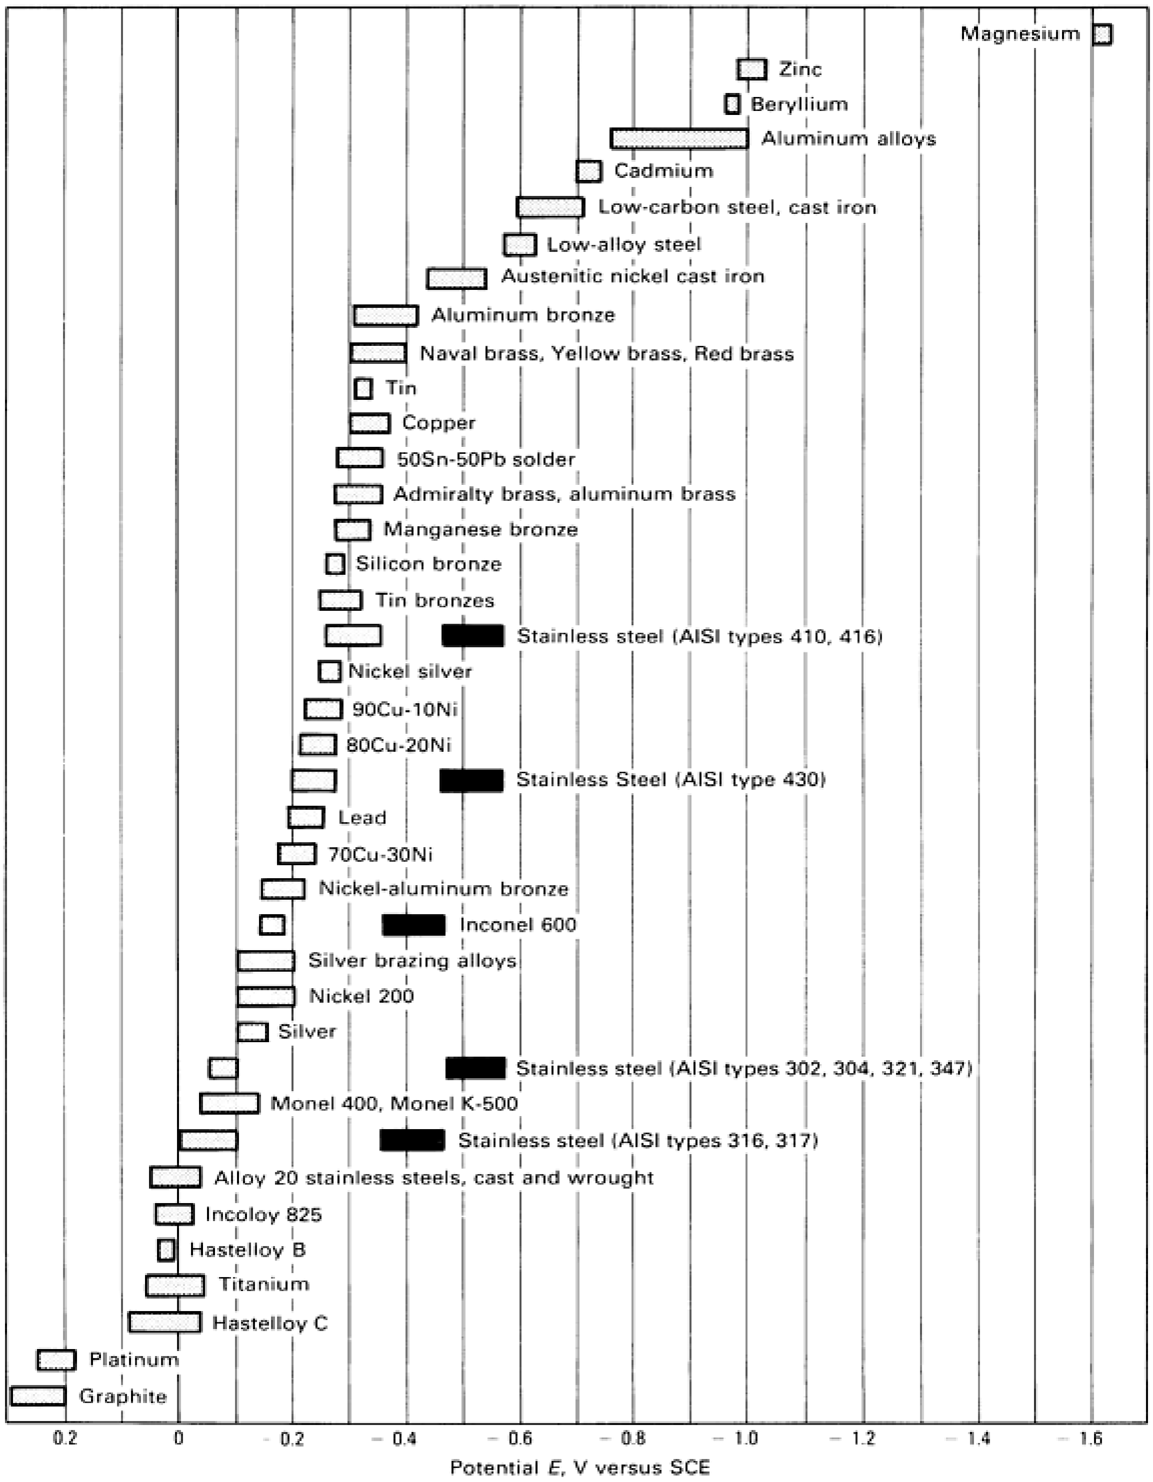

Fig. 1 Galvanic series of metals and alloys in seawater. Alloys are listed in order of the potential they exhibit in flowing seawater; those indicated by the black rectangle were tested in low-velocity or poorly aerated water and at shielded areas may become active and exhibit a potential near -0.5 V. Source: Ref 7

The importance of knowing the position of substrates in the emf and a specific galvanic series is frequently overlooked. The sole consideration is often the position of the protective coating in these series. It is prudent, however, to select a coating as close as possible in potential to the substrate in moist environments, because few coatings are completely free of pores, cracks and other defects. Even if a coating does start out defect free, scratching, normal wear, or gouging can change this condition. Accordingly, in a corrosive environment, plated components present at least two (not one) metal to the hostile galvanic-corrosion forces (see the section "Electrochemical Predictions of Corrosion Performance" in this article).

Cleanliness of the Substrate

Regardless of the composition and metallurgical condition of a substrate, its surface must be free from soils and oxides before being plated. The ASTM International Committee on Selection of Cleaning Processes classifies soil into six groups: pigmented drawing compounds, unpigmented oil and grease, chips and cutting fluids, polishing and buffing compounds, rust and scale, and miscellaneous surface contaminants, such as lapping compounds and residue from magnetic-particle inspection. Cleaning methods are discussed in Ref 2, 3, 4, 5, and 6. Although these methods are beyond the scope of this article, the point is made that unclean substrates often defeat the purpose of electrodeposited or other plated coatings.

Freedom from water break after the activating rinse and before immersion of a part in the plating tank is an essential prerequisite for satisfactory plating. Water break is defined as the appearance of a discontinuous film of water on a surface, signifying nonuniform wetting and usually associated with surface contaminations (Ref 1). A false reading of freedom from water break often occurs if the inspection is made after the rinse following a surfactant-laden alkaline cleaner. This misleading conclusion is nullified by inspection after acid dipping and rinsing.

Knowledge of the Nature of Substrates

Before designing or applying a protective coating to a metal, the plater must know the nature and essential properties of the substrate. Generally, a substrate is known to be ferrous or nonferrous, but these generic terms are inadequate. For example, there are thousands of ferrous metals and alloys, ranging from cast iron (high carbon) to ingot iron (very low carbon) and the entire range of carbon and alloy steels. Also, the microstructure, hardness, yield and tensile strengths, and internal stress of the substrate have major influences on the protective quality and durability of plated coatings. High-strength, high-carbon, high-hardness steels are susceptible to hydrogen embrittlement when subjected to alkalies, acids, and plating processes. Aluminum and zinc alloys and, to a lesser extent, chromium are amphoteric (soluble in both acidic and alkaline solutions). Accordingly, these metals must be treated with inhibited solutions to prevent chemical attack. Methods of determining the nature and condition of the substrates are described in the following sections.

Information on the Substrate. A design engineer, draftsman, engineer, or project manager in an organization with in-house plating facilities should have detailed information on the analysis, microstructure, and mechanical properties of the substrate. In a plating job shop, the customer should have someone informed on the subject. The plater is advised to ask these potential sources for as much information about the substrate as can be obtained.

Engineering Drawings and Associated Lists. Study of engineering drawings, parts lists, bills of materials, and pertinent manuals will usually clear up questions concerning the substrate submitted for plating. The bill of material, for example, may simply specify 1095 steel. This informs the plater that he is dealing with a high-carbon (0.95% C) and steel that can be heat treated to a high degree of hardness (for example, 50 to 60 HRC). This alerts the plater to be concerned with hydrogen embrittlement. As another example, if a drawing or associated list specifies Aluminum Alloy 6061T, the plater can deduce that the substrate is heat treatable by precipitation hardening to various tempers (degrees of hardness). Such an alloy is subject to developing a smut or to leaving a heavy oxide layer after being alkaline etched or cleaned. An experienced plater will recognize this and will know to treat the cleaned and etched part in a desmutter/deoxidizer in the treating sequence before anodizing or chemically converting the surface.

Chemical Spot Tests. A simple chemical spot reaction test is documented in Ref 6 and 7. This method is based on the use of a magnet and five chemicals. Three of the chemicals are different concentrations of nitric acid (HNO_3), another is concentrated hydrochloric acid (HCl), and the fifth is a 10% solution of potassium ferricyanide ($K_3Fe(CN)_6$). Although it tests for only one element at a time, this simple test distinguishes among the a large number of commonly used steels and nickel alloys.

Electrolytic Spot Test Method. This is a commercially available method, complete with chemicals, a power source, and instructions. The operation is divided into four steps. First, a test paper moistened with a conductive solution is placed in contact with the unknown metal. Second, using a dc power source with the unknown metal connected to the anode terminal (+) and a metal probe to the cathode terminal (-), a small amount of the unknown meal is dissolved into the test paper. Dissolution is brought about by electrolytic action when the dc current is switched on. Third, a few drops of a specific color developer are added to the wet spot on the paper. The developer reacts chemically with a characteristic component of the dissolved metal. Fourth, almost immediately, a color appears on the paper if a specific suspected alloying element is present in the unknown. This method is semiquantitative because the relative color intensity is proportional to the amount of alloying element or major metallic constituent. By comparing the results of the unknown with those of standard alloy samples, the nature of the unknown substrate can be adequately identified.

Electronic Alloy Identification. This method is quite rapid and depends on the Peltier Effect (also the basis of the thermocouple). If a current of electricity is sent through a circuit containing two dissimilar metals, heat is emitted at one junction and absorbed at the other junction. A characteristic voltage (potential) is generated at the thermocouple junction that causes an electrical current to flow. This voltage varies with the metals that constitute the couple. The electronic alloy identification meter operates on this principle. It measures the voltage generated by the action of a file of known composition scratched along the surface of an unknown alloy. The file acts as the positive meter input probe, with a clip-on providing negative reference. In a commercially available apparatus, the thermocouple voltage is shown on a battery-powered digital display. This voltage is characteristic of specific alloys or classes of alloys. Again, the instrument can be calibrated against known alloy specimens that are sold as standards.

Physical and Mechanical Properties of Substrates

The susceptibility to corrosion of a plated substrate depends on physical properties and mechanical condition. For example, surface profile (roughness, presence of scratches, pits, lapped metal, and so on) can profoundly affect the durability of plated ware. Some of the harmful effect can be avoided by mechanical or electropolishings, polishing and buffing, shot peening, or glass beading. Internal stresses can also be harmful. These may dictate heating for stress relief, or shot peening or glass beading to convert surface tensile stresses to compression. The physical properties of a substrate, particularly at the surface, are often as important to the metal finisher as its composition. Porosity, hardness, melting point, coefficient of thermal expansion, and permeability to hydrogen (nascent, or atomic, and gas) are vital to many operations. Porosity of substrates, particularly in castings and sintered powder metal compacts, causes many problems because of the difficulty of rinsing processing solutions. Capillary action tends to hold solutions with forces that defy normal rinsing efforts. This results in spotting out of corrosive liquids, which appear as stains and corrosion products on the plated surface. It also causes contamination of processing baths.

Some surface irregularities of substrate can be compensated for by the leaving properties of specially formulated plating solutions. Leveling action is the ability of a plating solution to produce a surface smoother than that of the substrate. The property of the plating solutions that produces leveling is also referred to as micro-throwing power.

Another property of substrates that can cause difficulties is susceptibility to hydrogen absorption. High-carbon and, particularly, hardened steels and titanium are susceptible to embrittlement when processed by methods that subject them to atomic or gaseous hydrogen. Recognizing this weakness of such substrates, the designer or specifier of plating sequences must select alkaline cleaning and oxide removal (pickling agents, activators) procedures that lessen or avoid hydrogen evolution. Mechanical cleaning and mechanical plating (also known as peen plating) are examples of the methods used to avoid hydrogen embrittlement. Because total avoidance of hydrogen evolution is often not possible, a step or steps must be added to the plating sequence to remove hydrogen. This usually consists or baking plated parts at low temperatures (205 °C, or 400 °F) to release absorbed hydrogen. Time and temperature is also an important variable in ensuring the release of hydrogen and restoration of the mechanical properties of the plated substrate.

Substrate metals that have been heavily worked by such operations as deep drawing, swaging, polishing and buffing, grinding, machining, forging, and die drawing often come to the plating shop with a damaged layer on the surface. This heavily worked layer is termed a Beilby Layer in honor of Sir George T. Beilby, who stated that this layer was amorphous or vitreous rather than crystalline. He compared this weak, somewhat brittle layer to substances that resemble the glass-like form assumed by the silicates when they are solidified from the molten state (Ref 8). X-ray analyses in later years proved that severe cold working causes fragmentation of crystals into particles of different orientations but that the surface metal is not vitreous or amorphous. However, this smeared, shattered layer is inherently low in ductility and fatigue strength and is therefore a weak foundation for plated coatings. This is particularly true of metal objects that require a surface of substantial corrosion resistance and high mechanical properties as well as metal objects that will be

further formed or distorted in service. To avoid the weakness introduced by such layers, abrasive cleaning, machining, or electrolytic polishing are required to remove them before plating.

Stresses in Substrates

Substrates with locked-in stress reduce the corrosion resistance of electroplated coatings relative to the same coating on an annealed substrate. Stressed metal is anodic to annealed or lesser stressed metals and is therefore more prone to corrosion in unfavorable service conditions. Substrates with flaws on the surface, stress-raising or stress-localizing scratches, or abrupt changes in section are less resistant to corrosion than smooth, streamlined parts. The coefficients of thermal expansion of the coating and substrate should also be matched as closely as possible to minimize stresses caused by differential expansion during temperature cycling.

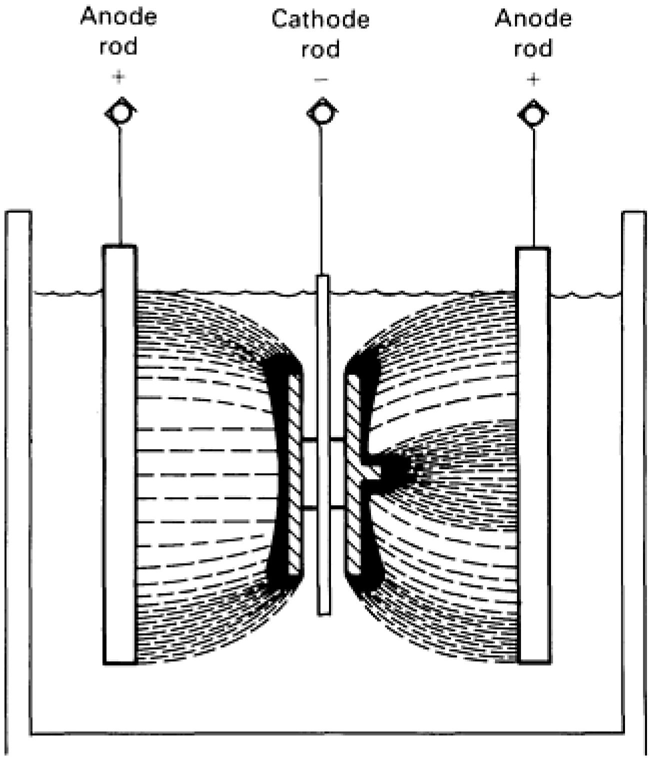
Stress-Corrosion Cracking of Substrates

Stress-corrosion cracking (SCC) is a cracking process that requires the simultaneous action of a corrodent and sustained tensile stress. Certain alloys are susceptible to SCC when subjected to certain corrosive environments. Examples are copper alloys, such as Cu-30Zn (cartridge brass), and nickel-chromium alloys. Ammoniacal materials, such as aqueous ammonia (NH_4) and amines, produce such failures in stressed copper alloys. Halides, such as chlorides and bromides, attack certain nickel chromium alloys with this type of corrosion.

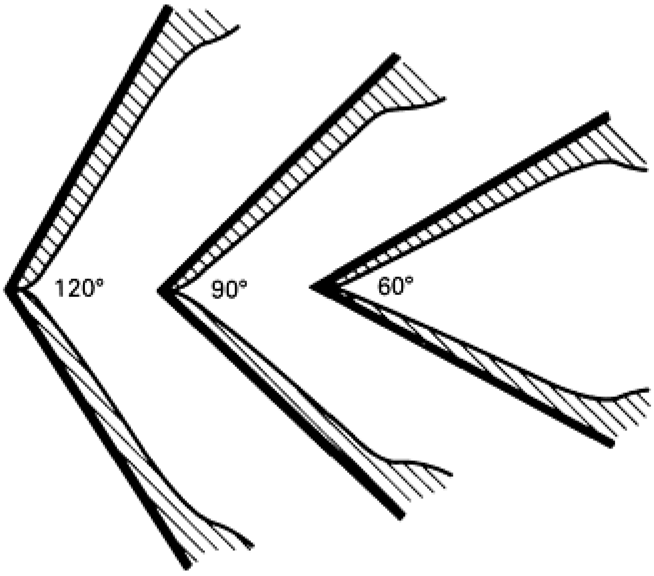
The basic characteristics of SCC are summarized in Ref 9. There is no available evidence that plated coatings on substrates susceptible to SCC will prevent its occurrence. Stress relief of susceptible alloys is often adequate for avoiding SCC. For example, brass cartridge cases, which are made by a deep-drawing process (leaving high residual stress), are stress relieved in a temperature range that produces recovery without recrystallization. Stress relieving at a higher temperature would produce recrystallization and an unacceptable reduction in mechanical properties. Avoidance of the use of SCC-susceptible alloys in known hostile environments is another approach to avoiding this mode of failure, but this is not always feasible. For example, for the brass cartridge case cited above, amine stabilizers in the smokeless powder propellant obviated control of the environment; therefore, stress relief was required. However, use of SCC-susceptible metals in corrosion cracking environments should be avoided whenever possible.

Design for Plating

Much can be done at the design stage to improve the plateability of metal stampings, castings, forgings, and extruded shapes. In doing so, the corrosion protection afforded by the plating can be enhanced. Corrosion resistance of a plated object depends on coating thickness and distribution, and these factors depend largely on the design of the parts. The ASTM standard B 507 (Ref 10) covers practices for the design of articles to be electroplated on racks with nickel, but its significance goes beyond nickel plating. It also applies in most respects to all rack-plated coatings. The general principles of design are discussed in Ref 10, which states that the electrodeposition of one metal onto another follows a pattern that can be illustrated by a sketch showing current distribution and the distribution of the resultant electrodeposit (Fig. 2).



(a)



(b)

Fig. 2 Current distribution (a) and effect of substrate geometry (b) on thickness of electroplated nickel deposits. For the 120° substrate in (b), the ratio of average coating thickness to minimum coating thickness is 1.9; for the 90° substrate, 2.7; and for the 60° substrate, 3.3. Source: Ref 10

Distribution of the deposit will vary slightly as a function of bath type, additives, current density, and temperature. The coating is preferentially deposited at protuberances, sharp corners, edges, fins, and ribs on the component being plated; to avoid coating buildup, these areas should be rounded with a minimum radius of 0.4 mm (0.015 in.). A 0.8-mm (0.03-in.) radius is preferable. Conversely, the base of any cavity, recess, or depression in the component being plated will be

deficient in plate thickness; these features should be designed to avoid sharp fillets. In general, such features should be designed so that the ratio of width to depth of the depression is held to a minimum of 3, and the minimum radius at the edge and base of an indentation should be one-fourth of the depth of the indentation. When sharp angles are required for functional purposes, the electroplater cannot be expected to meet minimum coating thickness requirements in these areas and corrosion resistance may be inadequate.

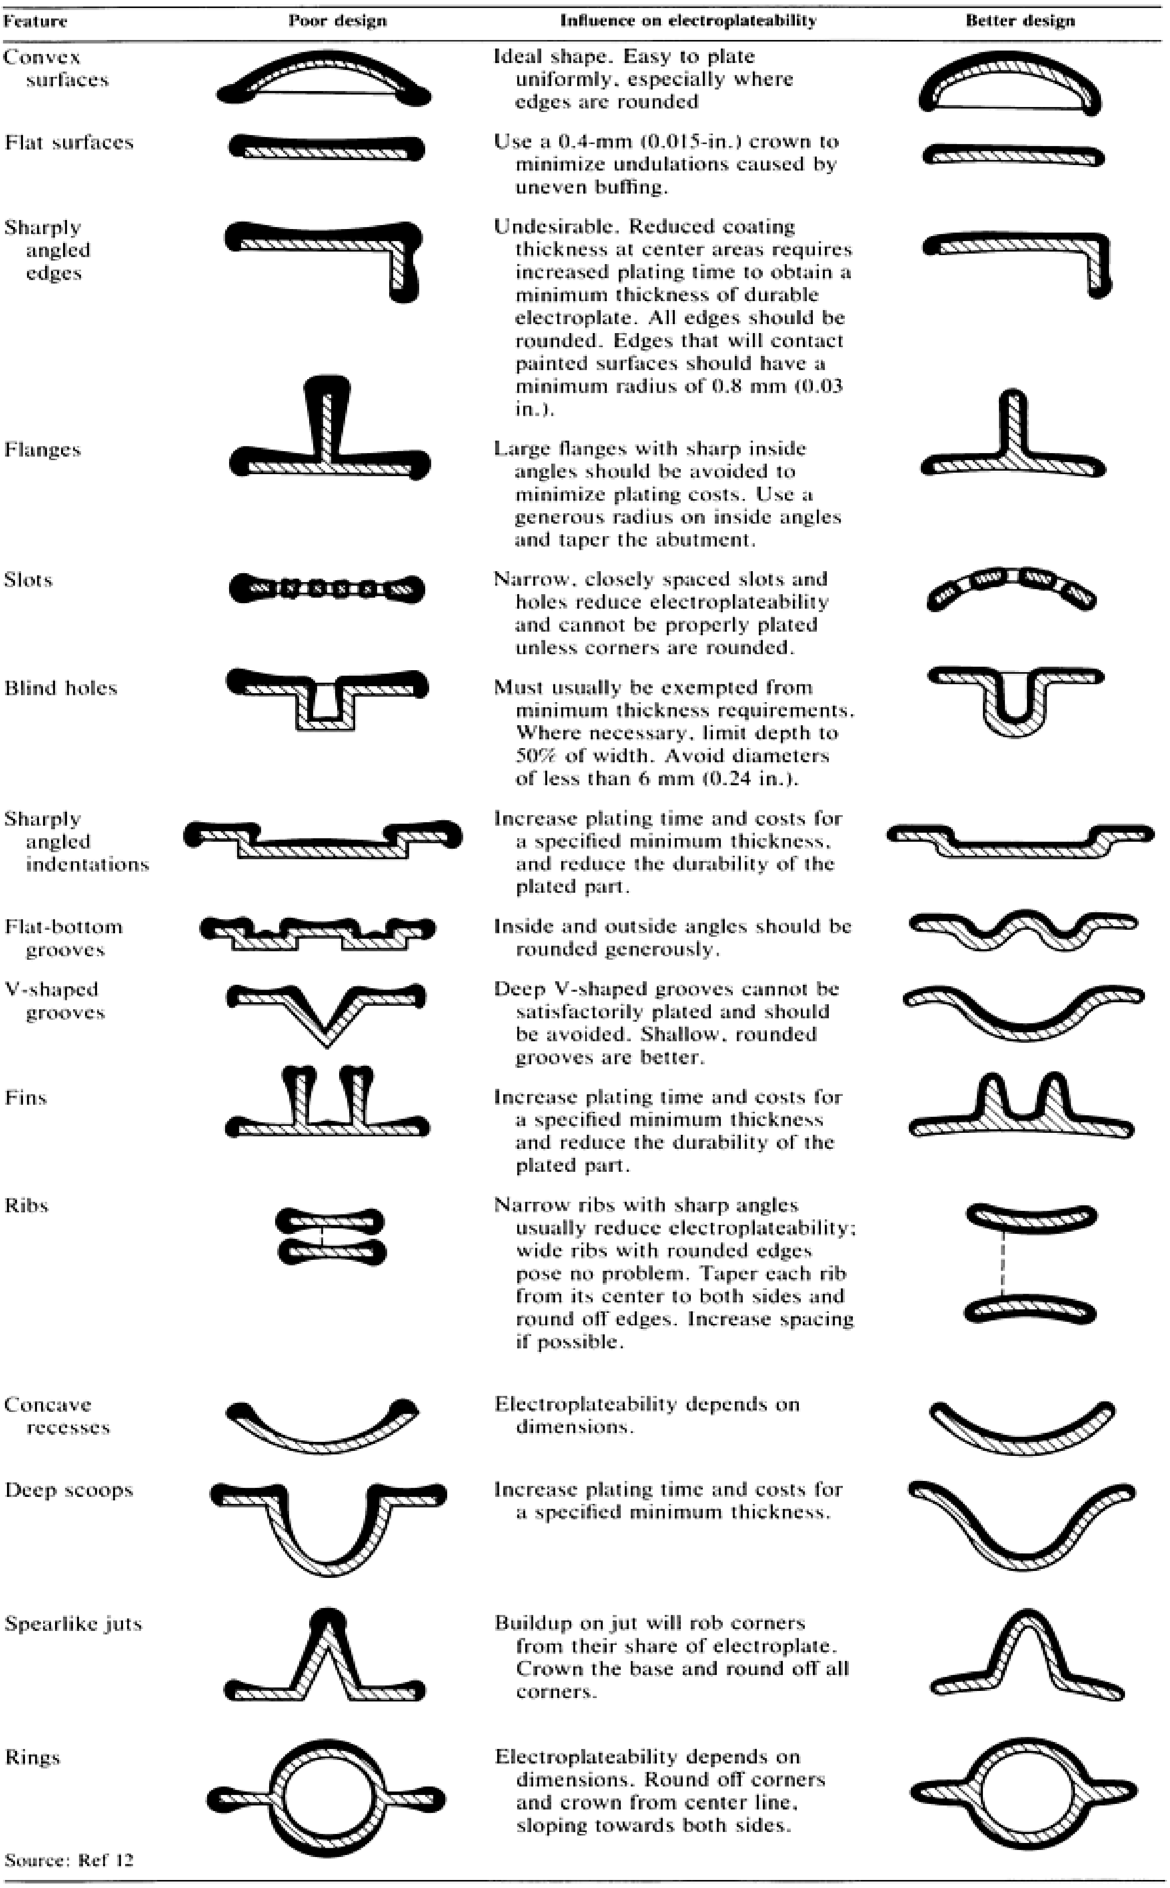
When designs cannot be changed, electroplaters resort to one or more of the following methods to overcome the aforementioned difficulties: provision of inside anodes, use of thieves or robbers (nonconductive shields that slow or prevent deposition) to lower the catholic current density at protuberances, bipolar electrodes, changing electroplating baths to ones with greater covering power, and switching from electroplating to autocatalytic (electroless) plating. This last method is widely used on parts that cannot be properly plated by electrodeposition. The limitation is that the most prevalent coating applied autocatalytically--electroless nickel--deposits an alloy of nickel and phosphorus (phosphorus content varies with the solution used and the deposition condition), not unalloyed nickel. There is also an economic disadvantage in switching to these processes. However, in most cases in which electroless processes have been adopted, they have been specified for reasons other than merely to compensate for part designs that cannot be readily electroplated with uniform coatings.

An article should not be designed for plating, but rather to perform its intended function (Ref 11). If the part is successfully designed, provision will have been made for corrosion resistance, hardness, lubricity, decorative appeal, or whichever required property the finish process is to supply. Function, fit, form, and aesthetics--the major dictates of design criteria--often take precedence over the practicality of corrosion prevention by plated coatings; this need not be the case. Design manuals must be instructional with regard to the effects of geometry on function, and designers should be taught these principles.

Additional information on design for electroplating is available in Ref 12. Table 2 lists proper and improper designs for various features of electroplated components. Plating of relatively small parts in rotating containers is termed barrel plating. This differentiates it from rack plating, in which individual parts are held in a rack or fixture during plating. Fastening hardware, such as nuts, bolts, washers, screws, and studs, are barrel plated, as are numerous critical electrical and electronic components. Many of these parts are as important from the corrosion resistance standpoint as rack-plated parts are--perhaps more so because such parts as fasteners and connectors are used in, and therefore coupled to, other materials. This raises the problem of galvanic corrosion.

Table 2 Influence of substrate design features on electroplateability

Source: Ref 12



Feature	Poor design	Influence on electroplateability	Better design
Convex surfaces		Ideal shape. Easy to plate uniformly, especially where edges are rounded	
Flat surfaces		Use a 0.4-mm (0.015-in.) crown to minimize undulations caused by uneven buffing.	
Sharply angled edges		Undesirable. Reduced coating thickness at center areas requires increased plating time to obtain a minimum thickness of durable electroplate. All edges should be rounded. Edges that will contact painted surfaces should have a minimum radius of 0.8 mm (0.03 in.).	
Flanges		Large flanges with sharp inside angles should be avoided to minimize plating costs. Use a generous radius on inside angles and taper the abutment.	
Slots		Narrow, closely spaced slots and holes reduce electroplateability and cannot be properly plated unless corners are rounded.	
Blind holes		Must usually be exempted from minimum thickness requirements. Where necessary, limit depth to 50% of width. Avoid diameters of less than 6 mm (0.24 in.).	
Sharply angled indentations		Increase plating time and costs for a specified minimum thickness, and reduce the durability of the plated part.	
Flat-bottom grooves		Inside and outside angles should be rounded generously.	
V-shaped grooves		Deep V-shaped grooves cannot be satisfactorily plated and should be avoided. Shallow, rounded grooves are better.	
Fins		Increase plating time and costs for a specified minimum thickness and reduce the durability of the plated part.	
Ribs		Narrow ribs with sharp angles usually reduce electroplateability; wide ribs with rounded edges pose no problem. Taper each rib from its center to both sides and round off edges. Increase spacing if possible.	
Concave recesses		Electroplateability depends on dimensions.	
Deep scoops		Increase plating time and costs for a specified minimum thickness.	
Spearlike juts		Buildup on jut will rob corners from their share of electroplate. Crown the base and round off all corners.	
Rings		Electroplateability depends on dimensions. Round off corners and crown from center line, sloping towards both sides.	

Source: Ref 12

Bulk parts in a plating barrel are subject to a greater variation in cathodic current density than parts plated on racks. Cathode contact is made by danglers, chains, buttons, or studs near the bottom of the load, while the plating occurs only at the surface of the load. This produces a large statistical variation in thickness of the electrodeposits on barrel-plated parts; this is not the case for rack-plated parts. Corrosion of a plated part is often controlled by the minimum thickness of protective coating; therefore, if parts are to be barrel plated, special design practices should be observed, including (Ref 12):

- Avoid blind holes, recesses, and joint crevices that can retain tumbling compounds and metal debris from previous operations
- Avoid intricate surface patterns that will be blurred by barrel finishing
- Design parts to withstand the multiple impacts of barrel rotation
- Design small, flat parts with ridges or dimples to prevent nesting
- Design for good entry and drainage of solutions during rotation by using simple shapes
- Design surfaces to be plated so that they undergo proper mechanical preparation and cleaning and to ensure that they receive their share of metal deposit. They should be convex, if possible, rather than recessed

In a larger sense, the design of parts for plating parallels good design practice for corrosion resistance. Avoidance of sharp edges, burrs, or other areas of high free energy, avoidance of abrupt changes in section, recesses, and other traps for moisture, and avoidance of scratches, notches and other anodic-site producers are common design criteria for parts in general as well as for plated parts. More information on designing to minimize corrosion is available in the article "Design Details to Minimize Corrosion" in this Volume.

Advantages and Disadvantages of Electroplated Coatings

Alternatives to electroplating for the protection of metal surfaces against corrosion include organic finishing, hot-dip coating, metal spraying, chemical vapor deposition (CVD) and physical vapor deposition (PVD), vacuum deposition by sputtering and ion implantation, and ceramic coating (see the articles "Organic Coatings and Linings," "Hot Dip Coatings," "Thermal Spray Coatings," "CVD/PVD Coatings," "Surface Modification," and "Chemical-Setting Ceramic Linings," respectively, in this Volume). The decision to use one or more of these methods must consider at least the following factors:

- Applicability to the substrate in question (for example, zinc plating is applicable as a protective coating to steel, but not cast iron)
- Purposes of the finish (Is color a requirement? Will the object to be finished fit into available plating equipment?)
- Cost of suitable electroplating versus alternative methods of coating the part (What finish will be functionally adequate and applicable at the least cost?)
- Anticipated service conditions and length of service desired under these conditions (SC5, extended very severe; SC4, very severe; SC3, severe; SC2, moderate; SCI, mild) (Ref 13)

Advantages of Electroplating

Variety of Coatings. The principal metals that are widely plated are cadmium, zinc and its alloys, chromium, copper, gold, nickel, tin, and silver. Other metals that are plated by in-house shops and some job platers are cobalt, indium, iron, lead, palladium, platinum, rhenium, and rhodium. Plateable alloys add versatility to the catalog of plated coatings. The commonly plated alloys are brass, bronze, copper-cadmium, tin-lead (solder), tin-zinc, gold alloyed with many metals, and nickel alloys with iron and cobalt. Ternary alloys, such as karat gold alloys and copper-tin-zinc, are also available. Nickel-phosphorus and nickel-boron are readily plated by the autocatalytic (electroless) process. Nickel-phosphorus can also be electrodeposited. Coatings of many types can be codeposited with occluded particles by elctrodeposition or electroless deposition to modify friction and wear properties. Particles used for these applications range from such deposited or occluded abrasives as diamond, silicon carbide (SiC), and such lubricous materials as polytetrafluoroethylene (PTFE).

Versatility of Application. Plated coatings can be applied to racked parts, in barrels (both by immersion in tanks and manually), semiautomatically, or on microprocessor-controlled fully automatic machines. Local, selective application of a coating, if necessary can be accomplished by such methods as brush plating (also known as electrochemical metallizing and tampon plating). Similarly, precious metals, such as gold and palladium, have been conserved in electronics applications by selective plating on continuous strips. This is referred to as reel-to-reel plating. The adaptability of plating methods to the job at hand is limited only by the imagination and skill of the plater.

Availability of Applicators. Plating job shops and in-house applicators are plentiful in the United States and throughout the world. The technology is popularized and nurtured by such technical societies and trade associations as the American Electroplaters and Surface Finishers Society, the National Association of Metal Finishers, the Metal Finishing Suppliers' Association, and at the Society of Automotive Engineers Airline Plating Forum.

The electrical conductivity of electrodeposited and other metallic coatings gives them an advantage over most organic and ceramic-base coatings in applications that require this characteristic. Applications in which electrical conductivity is necessary include the welding, electrical bonding, or grounding of objects as well as electrical and electronic circuitry.

Galvanic Protection of Substrates. Zinc and cadmium deposits protect steel substrates by sacrificial action in many wet environments. In aircraft and other aerospace applications, cadmium plating is used on steel components in contact with aluminum alloys because cadmium is closer in potential to aluminum than steel is (Fig. 1). On coil-coating lines for prepainted steel sheet and strip, elctrogalvanizing stages are provided in the wet section to protect the substrate at points of failure of the organic overcoating. Electrogalvanized steel, often further treated with chromate conversion coatings, is used for various purposes because of the sacrificial protective value of the zinc coating. Duplex or triplex coatings of nickel, often with a final thin coating of chromium, are another example of a more complex galvanic protective system (see the section "Nickel-Chromium Coatings" in this article).

Weldability and Solderability. Metal deposits are amenable to welding and soldering--an advantage over most organic coatings and porcelain enamel. Certain coatings are more weldable and solderable than others, which leads to the application of special types of plating to facilitate a specific type of joining or fabricating method.

Colored Anodic Coatings on Aluminum. Anodic oxidation of aluminum provides a protective coating that can be colored. The coating is integral to the substrate and can be colored by dyeing, integral color anodizing, or electrolytic coloring (Ref 6, 14). These coatings are highly resistant to abrasion and corrosion and are widely used on architectural forms. More information on these types of coatings is available in the article "Aluminum Anodizing" in this Volume.

Control of Thickness. Unlike hot-dip coating, electrodeposition affords a means of predicting and controlling the amount of metal deposited. This is possible through the validity and knowledge of Faraday's laws, which are as follows (Ref 2):

- The quantity of any element discharged at an electrode is proportional to the quantity of electricity that is passed
- The quantities of different ions of elements discharged by a given amount of electricity are proportional to the electrochemical equivalents of those elements

The quantity of electricity is measured by the coulomb (C; equivalent to one A · s), and the electrochemical equivalent of an element is its atomic weight divided by its valence. It is known that the 96,480 C, or 1 Faraday will deposit 1 gram equivalent weight of any element at 100% electrode efficiency. Electrode efficiencies are a function of plating electrolytes and conditions. They can be determined by coulometric measurement and are published for most plating processes. Because most plants control plating by measuring ampere hours, the amount in grams of metal plated, M_d, is calculated by the relationship:

$$M_d = \frac{A \cdot h}{26.8} EE_M \, CE_M$$

where EE_M is the electrochemical equivalent of metal M (atomic weight of M divided by valence of M), and CE_M is the cathode efficiency of the plating bath and conditions.

Ductility and Formability. Substrate metals coated by electrodeposition can be formed more readily than some metals coated by hot dipping or certain organic coatings. They do not result in intermetallic alloy layers of the type common to ordinary hot-dip galvanizing, for example. Diffusion of some electrodeposits into substrates, and vice versa, occurs after plating as a function of temperature, time, and the diffusion tendencies of the metals involved. These diffused layers are normally thin require protracted periods of time to develop, usually after the component has been formed to a desired shape.

Electroless Plating. The coating of the interiors of tubes or other recessed areas uniformly and with controlled thickness is the special province of autocatalytic, or electroless, plating.

Mechanical Plating. Mechanical, or peen, plating is a method of coating substrates, principally steel, with malleable metals, such as zinc, cadmium, tin, or their alloys. In mechanical plating, hard, small, spherical objects, such as glass shot, are tumbled against the parts to be plated in the presence of finely divided metal powder, such as zinc dust, and appropriate chemicals. Special advantages of this method over electroplating are the relative absence of problems with hydrogen embrittlement, the simplicity of operation with small parts in a single rotating container, and the ability to deposit desirable alloys that cannot be electroplated. As an example of the latter, tin and cadmium alloys have been found to provide excellent protection of steel against corrosion in marine environments.

Disadvantages of Electroplating

Color Limitations. The colors of electrodeposited coatings are limited to copper, silver metallic, brass, bronze, and gold and its alloys; black, iridescent, of olive drab chromate conversion coatings; and patinas formed on copper and its alloys by chemical and electrochemical treatments.

Inhospitable Substrates. Some substrates, such as cast iron, and certain substrate conditions, such as porosity, require special plating procedures. Unimpregnated powder-metal compacts and porous castings that can be plated are subject to spotting out, or bleeding, because of retention in pores of cleaning and plating alkalies, acids, and salts.

Limitations of Design. Parts are designed to function in the most economical manner. This is not always compatible with plating. Where the geometry of a part is such that cathodic current distribution will be unfavorable to uniform coatings, it is sometimes wise to seek an alternative protective coating. The criteria here are that the coating must achieve the required minimum thickness on significant surfaces, must meet all functional and dimensional requirements, and must accomplish these objectives at a reasonable cost.

Size Limitations. Large metal structures are often beyond the capabilities of electrodeposition. The limitation lies in the capacity of tanks to contain the electrolyte. Exceptions are certain architectural structures and statuary, which may be brush plated. Such coatings are almost always on copper or bronze and consist of nickel topped with gold electrodeposits. Steel structures, such as bridges, dams, and building elements, are more advantageously hot-dip galvanized and painted, or painted without zinc but with specially designed organic coating systems.

Effects of Deposition Parameters

The process used to apply the coating may have an important effect on the properties of the entire coating system. One of the more important considerations is the effect of hydrogen formation during electroplating. Hydrogen may embrittle the substrate. This is particularly important when cadmium, chromium, or zinc is used as a coating over high-strength steel. Atomic hydrogen can combine to form high-pressure hydrogen gas at defects or regions of poor adhesion, causing blisters in the coating. Appropriate standards have been developed to cover relief from hydrogen embrittlement in high-strength steels (Ref 15). Hydrogen can also be introduced into the coating system during one of the cleaning steps conducted before electroplating.

Mechanisms of Corrosion Prevention of Plated Coatings

Coatings applied by electrodeposition or electroless plating protect substrate metals in three ways. The first is cathodic protection of the substrate by sacrificial corrosion of the coating--for example, zinc and cadmium coatings on steel. Second is barrier action, that is, interposing a more corrosion-resistant coating between the environment and a less

corrosion-resistant substrate. Examples of this are copper-nickel-chromium and nickel-chromium coating systems over steel and zinc alloy automotive parts. Third is environmental modification or control in combination with a nonimpervious barrier coating. An example of this type of protection is the electrolytic tinplate used in food packaging.

Anodic Coatings. Zinc and cadmium deposits will protect steel at pores and other discontinuities by cathodic protection. Observation of the emf series (Table 1) shows that zinc is electronegative to steel in potential when these metals are immersed in solutions of their own ions. Under the same conditions, cadmium is more noble than iron, but in actual service under several environmental influences, cadmium is anodic to iron and is therefore sacrificially protective. Figure 3 shows the galvanic protection offered by a zinc coating to a steel substrate. This mechanism of galvanic protection gave rise to the term galvanized steel, which refers only to zinc-coated steel. This old, but commonly used term is modified to electrogalvanizing when referring to electrodeposited zinc in order to differentiate it from hot-dip galvanizing.

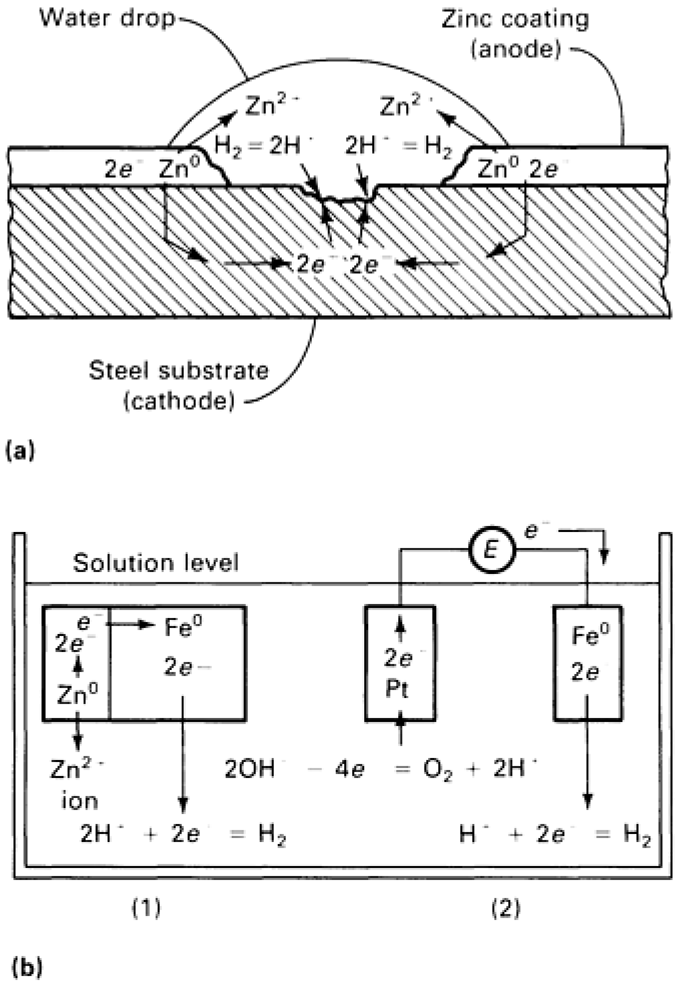


Fig. 3 Principles and mechanism of galvanic protection of a substrate by a coating. (a) Galvanic protection of a steel substrate at a void in a zinc coating. Corrosion of the substrate is light and occurs at some distance from the zinc. (b) Galvanic protection of a steel member (1) by a zinc member and by an impressed electric current flowing from an external dc power source (E) using an insoluble platinum electrode (2). Source: Ref 2

Cathodic Coatings. With reference to Table 1, it is apparent that the metals commonly plated, other than zinc (and cadmium, despite the inversion mentioned above), are electropositive to iron. This is also evidenced by Fig. 1. Such coatings on steel are therefore expected to act strictly as barriers to prevent corrosion of the steel substrate. For this to be successful, the coatings must be pore free and flaw free. It is very difficult to obtain impervious coatings of more noble metals on steel or zinc alloys. Substantial metal thicknesses, usually 25 μm (1 mil) or more, are required. With some of

these metallic deposits, particularly the noble metals, thinner coatings applied by pulse plating are more impervious than conventional plated metals, but this is the exception.

Generally, electroplated or hot-dipped coatings that are completely free of pores and other discontinuities are not commercially feasible (Ref 2). Pits eventually form a coating flaws, and the coating is penetrated. The substrate exposed at the bottom of the resulting pit corrodes rapidly (Fig. 4). A crater forms in the substrate, and because of the large area ratio between the more noble coating and the anodic crater, the crater becomes anodic at high current density. Electrons flow from the substrate to the coating as the steel dissolves. Hydrogen ions (H^+) in the moisture accept the electrons and, with dissolved oxygen, form water at the noble metal surface near the void. Use of an intermediate coating that is less noble than a surface coating but more noble than the basis metal may result in the mode of corrosion shown in Fig. 5. This would be typical of a costume jewelry item with the substrate being brass, the intermediate coating nickel, and the topcoat tarnish-resistant gold. It is also exemplified by nickel-chromium coating systems.

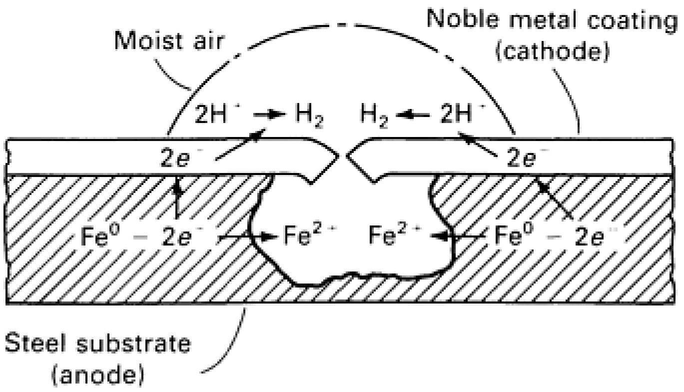

Fig. 4 Crater formation in a steel substrate beneath a void in a noble metal coating, for example, passive chromium or copper. Corrosion proceeds under the noble metal, the edges of which collapse into the corrosion pit. Source: Ref 2

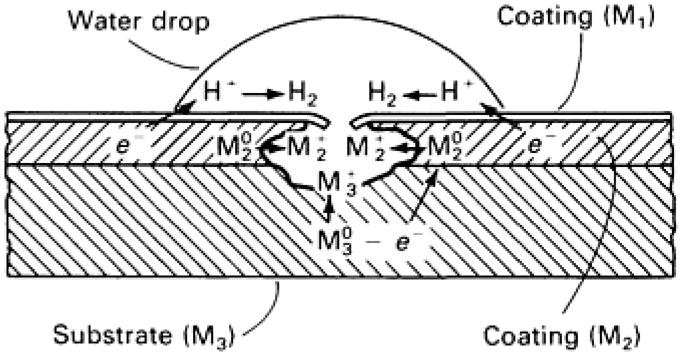

Fig. 5 Corrosion pit formation in a substrate beneath a void in a duplex noble metal coating. The top coating layer (M_1) is cathodic to the coating underlayer (M_2), which is in turn cathodic to the substrate (M_3). As in Fig. 4, the coating tends to collapse into the pit. Source: Ref 2

Exceptions. The durability of a plated coating system cannot always be accurately predicted by conventional analysis of the potentials shown in the emf or galvanic series. Much depends on environmental exposure and the oxidized films formed in pores and discontinuities of plated coatings.

For example, several corrosion specialists predicted that copper-plated zinc one-cent pieces would be unsuitable coinage because of rapid corrosion. The coating is barrel-plated copper on a zinc-rich alloy, with the coating thickness varying from 4 to 8 μm (0.15 to 0.3 mil). In this thickness range, the coating is far from impervious, or pore free. In the 1970s, before the minting of these coins, pictures were published showing exfoliated, voluminous zinc corrosion products on

sample pennies after exposure to the ASTM B 117 neutral salt spray test (Ref 16). The predicted result did not occur after more than 10 years of service. This indicates that the conditions to which these coins have been subjected are more forgiving than a salt spray test.

Another example of an apparent exception is the case of lead-plated steel, which is quite durable despite the fact that lead is more noble than iron. This is the case because a lead corrosion product develops in the pores (most likely lead sulfate $PbSO_4$ and arrests the progress of corrosion.

Importance of Thickness of Plated Coatings. In general, the thicker a metallic coating is, the less porous it is and the better serves as a barrier against corrosion. Therefore, the measurement of thickness is a most important feature of testing electrodeposited and electroless coatings. Table 3 indicates the applicability of coating thickness measuring methods. American Society for Testing and Materials (ASTM) and International Standards Organization (ISO) standards covering thickness measurement methods are given in Ref 17.

Porosity is another coating property that is very sensitive to deposition parameters and to substrate preparation. For very thin gold coatings (less than about 1 mm, or 0.04 mil), substrate texture controls coating porosity. At greater thicknesses, porosity is controlled by the coating properties. The variation in porosity with coating thickness is illustrated in Fig. 6, which shows three district phases: substrate dominated, transition, and coating dominated. Porosity can also be controlled to a large extent through deposition parameters, and this effect is attributed to a reduction in deposit grain size. The effects of porosity with thickness for pulsed-plated gold are shown in Fig. 7; again, the same three phases are apparent, although they are displaced downward.

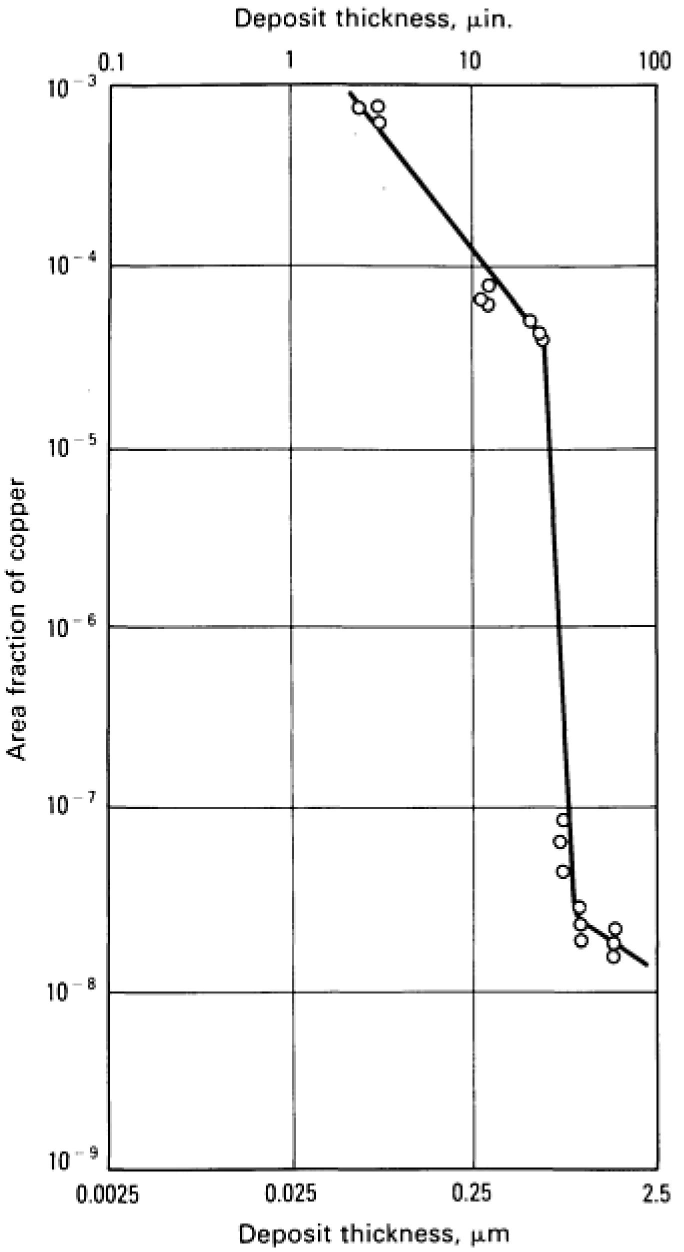

Fig. 6 Porosity versus deposit thickness for electrodeposited, unbrightened gold on a copper substrate. Compare with Fig. 7.

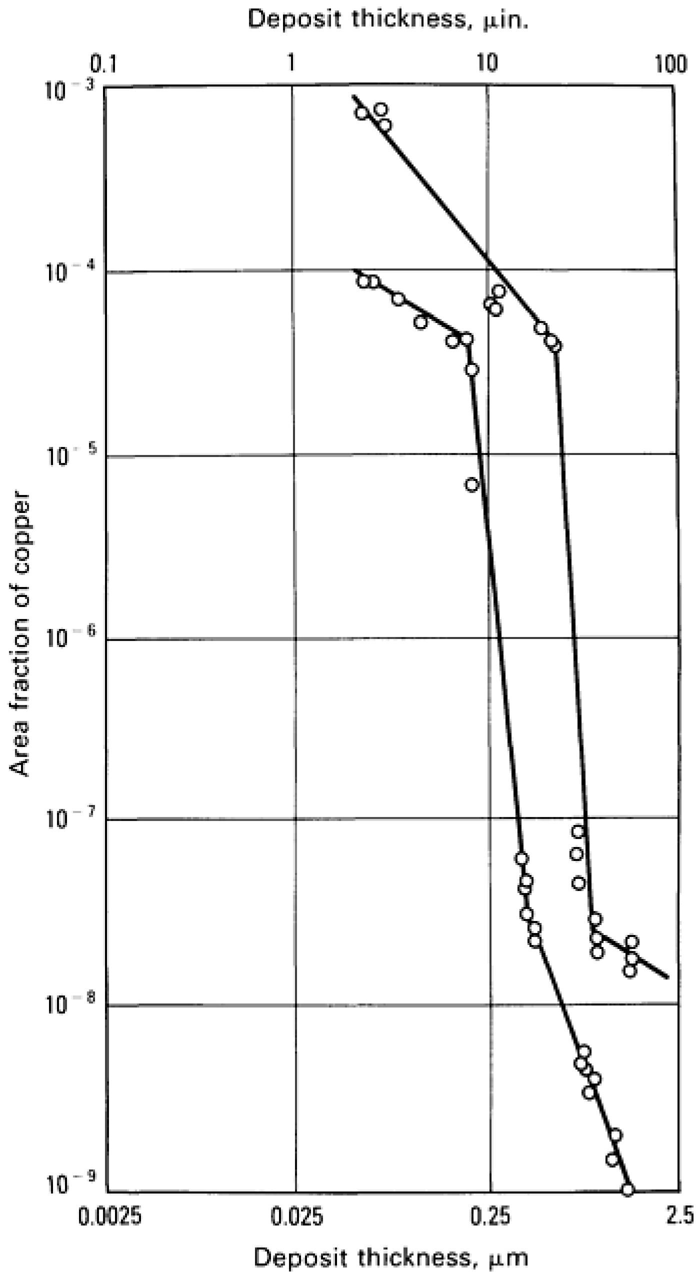

Fig. 7 Porosity versus deposit thickness for pulse-plated gold on a copper substrate. The curve for an unbrightened gold deposit on a copper substrate (top) is shown for comparison (see also Fig. 6).

Electrodeposited coatings applied to thicknesses of less than about 25 μm (1 mil) are porous. Porosity decreases with thicknesses, but it is present even at greater thicknesses. One of the reasons for this is the codeposition of hydrogen at cathodes, owing to the fact that most plating processes operate at less than 100% cathode efficiency. With sacrificially protective coatings, such as zinc and cadmium on steel, porosity is of little significance. Within limits, substrate steel exposed in the pores will be cathodic to the zinc or cadmium coating. Thus, the coatings will corrode under adverse conditions are protect the exposed cathodic steel, at least until the coating has been consumed by conversion to corrosion products. With the exception of chromium, coatings that are cathodic to the substrate depend on freedom from porosity for protection of the less noble substrate. Accordingly, such coatings must be tested for porosity as well as for thickness. Examples of ASTM standards for porosity testing are given in Ref 16 and 18, 19, 20, 21.

Adhesion is very important in the electro-deposition of a metallic coating, as implied in the definition of electroplating given earlier in this article. Therefore, it is logical for many end product specifications for plated components to contain adhesion tests for verification of this requirement. The ASTM standard B 571 (Ref 22) covers the following adhesion

tests for metallic coatings: the burnishing tests, the chisel-knife test, the draw test, the file test, the grind-saw test, and the heat-quench test.

Corrosion. Testing for corrosion resistance is an important part of evaluating electroplated coatings and allied finishing techniques. Standard methods of corrosion testing are given in Ref 16 and 23, 24, 25, 26, and 27. Accelerated tests of corrosion resistance of electroplated coatings can often lead to misleading conclusions. Claims that a certain number of hours in a particular test is equivalent to so many months or years of actual service should be viewed with suspicion.

Applications for Electrodeposited Coatings

Nickel is widely used as a corrosion-resistant coating and as an undercoat for subsequent coatings. It is not resistant to HNO_3 or to environments containing chloride ions (Cl^-). However, it corrodes slowly in environments that do not contain Cl^- ions. Nickel is widely used by the automotive industry as an underlayer for microcracked chromium to protect steel. As previously discussed, nickel is usually plated as part of a multilayer coating system in which the electrode potential of each layer is different from those of other layers. The outer layer in such systems is often 130 mV (versus the silver-silver chloride, Hg-$HgCl_2$, electrode) more anodic than the layer beneath it. Nickel is also used over copper as an underlayer for gold to prevent rapid diffusion of the gold into the copper substrate. Nickel and its reaction products are toxic. Nickel with organic additives to produce a very bright finish is widely used, although these coatings are much more brittle than the semibright nickel.

Nickel-phosphorus can be electrolessly or electrolytically deposited as a metallic coatings. In general, its corrosion performance exceeds that of nickel in all environments. If the phosphorus content is above about 10 wt%, the coating is amorphous and therefore lacks grain boundaries or other crystalline defects at which corrosion can be initiated. Electroless nickel has some advantage over electrolytic nickel in that its thickness and phosphorous content are uniform over the substrate and independent or substrate geometry. Electroless nickel is not resistant to hot caustic solutions. Heat treating nickel-phosphorus coatings above 350 to 400 °C (660 to 750 °F) results in recrystallization and loss of some corrosion resistance even though other properties, such as wear or hardness, may be enhanced.

Cadmium and zinc were compared earlier in this article. Cadmium is generally preferred for the protection of steel in marine environments and zinc is preferred in industrial environments. Cadmium tends to embrittle high-strength steel somewhat less than zinc does (being process related, new deposition processes may change this). The coefficient of friction of cadmium is less than that of zinc; therefore, cadmium is preferred for fastening hardware and connectors that have to be taken on and off-repeatedly. Cadmium is much more toxic than zinc, and applications in which its corrosion products may get into the environment should be avoided. The corrosion performance of both zinc and cadmium is greatly enhanced by chromate conversion coatings (see the article "Chromate Conversion Coatings" in this Volume).

Chromium is very resistant to atmospheric corrosion, but is soluble in HCl or in alkaline (caustic) solutions. Its resistance to corrosion is thought to be due to the formation of an amorphous chromium oxide that acts as a passive film to protect the metal. Chromium is deliberately deposited for decorative and wear applications as a microcracked coating over nickel so that corrosion currents are uniformly distributed over a large area. Chromium may be deposited as a noncracked coating both from hexavalent chromium (Cr^{6+}) and from trivalent chromium (Cr^{3+}) electrolytes. More information on corrosion of chromium plating is available in the article "Corrosion of Electroplated Hard Chromium" in this Volume.

Tin is widely used as a barrier and as an anodic coating for steel and copper. Because it is readily solderable and its oxide is conducting, if finds application in electrical conductors and contacts. Its corrosion products are not toxic; therefore, tinned containers are widely used in the food industry. Recommended thicknesses for application over copper components are given in Table 4 and over ferrous components in Table 5. More information on corrosion of tin and tinplate is available in the article "Corrosion of Tin and Tin Alloys" in this Volume.

Table 4 Suggested thicknesses for electrodeposited tin coatings on copper alloys (50% Cu min)

Purpose of coating	Minimum local thickness	
	µm	mils
Contact with food or water where a complete cover of tin must be maintained against corrosion and abrasion	30	**1.2**
Protection in atmosphere and in less aggressive immersion conditions	15	**0.6**
To provide solderability and protection in mild atmospheric conditions	5[(a)]	**0.2[(a)]**
Coatings flow brightened by fusion (solderability and protection in mild atmospheres)	**2.5-8[(a)]**	**0.1-0.3[(a)]**

Source: Ref 28

(a) On brass, an undercoat of 2.5-µm (0.1-mil) thick, copper, nickel, or bronze is required.

Table 5 Suggested thicknesses for electrodeposited tin coatings on ferrous components

Purpose of coating	Minimum local thickness

Lead is stable in most atmospheres and in both chromic (H_2CrO_4) and sulfuric acid (H_2SO_4) electrolytes; however, it is affected by chlorides. Lead electrodeposits form very inert passive films that tend to reduce the effects of galvanic corrosion.

Copper is not particularly corrosion resistant in the atmosphere, and it tarnishes rapidly. When used alone, it should be protected by an appropriate corrosion inhibitor, such as benzotriazote. On the other hand, copper is often present in a coating system because bright copper is leveling, and its small grain size tends to reduce the porosity and thus improve the corrosion resistance of subsequent coatings.

Gold is often used decoratively and for electrical contact applications. Gold that is plated directly over copper will increase the corrosion rate of the copper through the unavoidable porosity of the gold deposit. Gold will also rapidly diffuse into copper. Therefore, electroplated nickel or cobalt barrier coatings are normally plated underneath the gold coating. For wear applications, alloys with nickel or cobalt are preferred; however, pure gold has a lower contact resistance. Pulse plating will reduce porosity and increase the hardness of electrodeposited gold.

Selection of Coatings

Tables 6 and 7 represent current practice in guiding designers and platers to minimum thickness of the two principal classes of protective and decorative/protective coatings used in product finishing; zinc and cadmium coatings and bright nickel-chromium. Specification guides for these coatings are given in Ref 1 and are also contained in Federal and Military Specifications (Ref 6, 29). Frequently cited specifications in these documents are:

Specification	Title
ASTM A 165	**Standard Specification for Electrodeposited Coatings of Cadmium on Steel**
MIL-QQ-P-416	**Plating, Cadmium Electrodeposited**
ASTM B 633, MIL-QQ-P-416	**Standard Specification for Electrodeposited Coatings of Zinc on Iron and Steel**
ASTM B 456	**Standard Specification for Electrodeposited Coatings of Copper plus Nickel plus Chromium and Nickel plus Chromium**
MIL-QQ-C-320	**Chromium Plating (Electrodeposited)**
MIL-A-8625	**Anodic Coatings for Aluminum and Aluminum Alloys**

International Standards Organization standards often govern international transactions involving the buying and selling of plated parts. These standards are available from the American National Standards Institute or from the International Standards Organization.

(a) Nickel classifications: b, fully bright; p, dull or semibright; d, double layer or triple layer nickel coating, with the bottom layer containing less than 0.005% S and the top layer more than 0.04% S. If there are three layers, the middle layer should contain more sulfur than the top layer. Chromium classifications: r, regular (conventional) chromium; mc, microcracked chromium having more than 750 cracks/in.; mp, microporous chromium containing a minimum of 64,500 pores/in.^{2} that are visible to the unaided eye.

Nickel-Chromium Coatings. Because of their importance in the automotive industry, nickel-chromium (with or without a copper underlayer) coatings have been subjected to many changes and exhaustive testing over a long span of years. Results of extensive field experience and testing of variations dating from the days of buffed nickel coatings (1870 to 1924) are reported in Ref 30. Figure 8 shows a history of the development and use of nickel-chromium coatings. Significant developments in this history were the determination that the basic corrosion resistance of these systems is controlled by the thickness and composition of the nickel layer, the invention of the leveling copper and nickel plating processes, the development of semibright and bright nickel plating, the emergence of crack-free and microcraked chromium, and the evolution of duplex and triplex (multilayer) nickel-chromium systems.

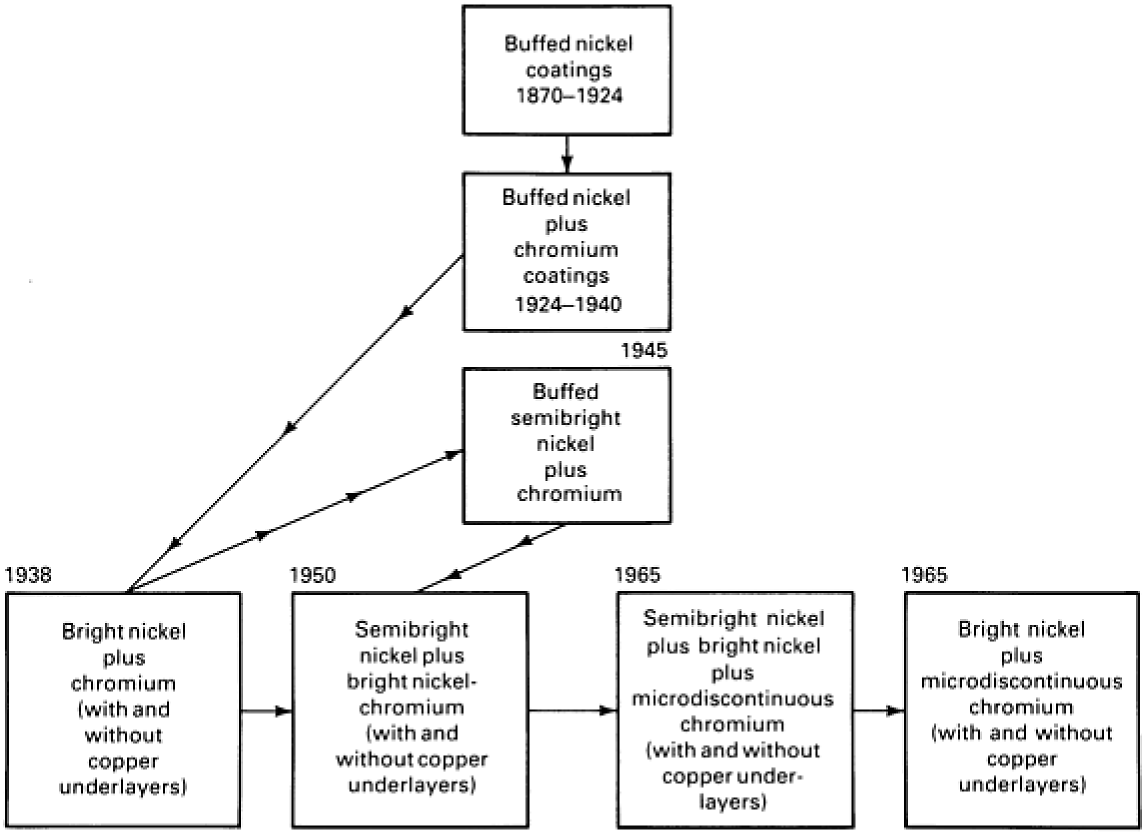

Fig. 8 History of the development of nickel and nickel-chromium coatings showing time of introduction and periods of use. Source: Ref 30

Reference 30 also discusses the application of these coatings on steel, zinc, plastics, and aluminum. In these systems, the chromium layer is very thin--of the order of only 0.25 μm (0.01 mils). However, the corrosion resistance of chromium plate depends not so much on its thickness as on its physical state. Crack-free, or nonporous, chromium is excellent, but does not remain crack-free in service. A small number of cracks are detrimental, but the presence of many fine microcracks may be beneficial (Ref 2). Microcraked chromium deposits cause the galvanic-corrosion action to be spread over a very wide area and therefore do not suffer from localized corrosion. Microcraked chromium, in combination with duplex or triplex nickel, is the most durable of these coatings. The results of marine exposure for 36 months on variations

of these coatings on steel are shown in Fig. 9. Figure 10 shows results of a similar program for nickel-chromium and copper-nickel-chromium coatings on zinc.

Plating of Mill Products

A trend toward applying tin and zinc coatings by electrodeposited to sheet and strip in tandem with continuous pickling and cold-rolling lines developed just before and during World War II. Much earlier, processes were developed in Germany and the United States to electrogalvanize wire. Advantages claimed over hot-dip galvanizing were control of thickness, the fact that the substrate is not affected by heat, and that the ductility and formability of the substrate is not limited by the iron-zinc intermetallic compound layer formed on hot-dip galvanized steel. Another advantage claimed for electrogalvanizing is that the thickness can be controlled, whereas in hot-dip galvanizing, the edges, especially of strip steel, tend to destroy wipes. Therefore, special care is required to secure a uniform smooth coating (Ref 31).

Electrolytic tinning was commercially introduced in 1927 (Ref 31). Before that time, all of the tinplate on the market was manufactured by hot-dip processes. Again, because of the amenability of electrodeposited to close thickness control and the development of highly efficient pretreating and plating processes, electrotinning has captured practically all of the food pack business. Various electrolytic processes have been used for producing tinplate, including the acid processes--sulfate, fluoborate, phenolsulfonic, and halide (fluoride-chloride)--and the alkaline sodium stannate bath.

In addition to electrogalvanizing and electrotinning, continuous plating or cold-rolled sheet and strip is performed by integrated steel mills as well as specially continuous strip producers and coil coaters. The specialty houses continuously plate nickel on steel for the battery (mostly alkaline dry cell) industry. They also plate alloy coatings such as nickel-zinc for protective/decorative uses and copper- and copper alloy-plated steel for post-fabrication of decorative items. Copper-nickel-chromium on nonferrous metals and wide-strip steel is also available. Reference 32 lists typical examples of

decorative/protective applications of continuously plated copper-nickel-chromium plated steel strip. Among these are various components for household appliances, dispensers, handles, lamps, cover plates for switches and outlet boxes, and furniture trim. Functional applications for copper-plated strip include flashlight shells and alligator clips for jumper cables. Nickel-plated strip is used in battery cans and caps and for paint brush ferrules. There are few companies in the continuous strip plating field because of the high initial investment required and the specialized knowledge needed to operate this process successfully.

Coil coaters, the name given to manufacturers of prepainted sheet and strip (mostly steel and aluminum substrates), apply thin zinc coatings plus chemical conversion coatings before applying organic coatings. Products of this segment of the industry are used in postforming operations.

Excellent control of plating conditions and the absence of complex substrate geometries provide a high degree of uniformity in coatings on preplated strip. This is reflected in predictable corrosion resistance because uniform thickness leads to uniform corrosion resistance.

Chromium plating has also penetrated the tin mill product field in such applications as food can ends. Thin coatings of tin and chromium act as a base for can varnishes and lacquers and for pigmented outer coatings. On the interior of cans, tin or chromium coatings are claimed to prevent filiform corrosion under the clear organic coatings--an insidious type of underfilm corrosion characteristic of clear and sparsely pigmented organic coatings. Information on equipment and processing is available in Ref 4, 31, and 33; Ref 33 also discusses corrosion of tinplate.

Immersion Plating

Immersion, or chemical, deposition has a long history of limited industrial use--for example, tin immersion deposits on mill wire products (called liquor finishing), immersion nickel plating of steel before porcelain enameling and many types of ceramic coatings, and the immersion copper plating of wire to be used in inert-gas shielded arc welding. In the last application mentioned, pure copper and copper-tin (gold colored) coatings have both been used as aids to wet-drawing of the wire to finished size and to furnish a highly conductive surface in the welding gun. Both tin and copper have been used in wire mills for the wire used for such products as paper clips and staples. According to the corrosion theory, these coatings, which are much more noble than the substrate, would be expected to hasten corrosion of the substrate. However, this is not the case, probably because the porosity is so widely distributed that whatever current is available for corrosion is so spread out as to be ineffective. This is similar to the effect of microdiscontinuous chromium (MDC).

Electrochemical Predictions of Corrosion Performance

Accelerated tests used for the prediction of corrosion performance for a particular application of a coating system have a certain risk associated with them. It is very difficult to design a test environment to simulate the actual environment, but there is often no alternative. A number of accelerated electrochemical tests are given in Ref 34, 35, 36, 37.

Sample Preparation. The preparation of the sample to be tested requires a great deal of care for a number of reasons. On an actual part, the geometry is rarely designed so that the current density is uniform over the entire part. Because such coating properties as grain size and porosity are critically affected by local current density, the ability of a coating to protect the part would be expected to vary from one point on the part to another. When conducting accelerated tests on flat samples (usually required by the tests listed in Ref 34, 35, 36, 37), the current density used to apply the coating(s) must be typical of that used on the real part. Equally important, the surface finish of the specimen substrate should be comparable to that of the actual substrate. The above tests usually require that the surface finish be produced by wet grinding on 600-grit SiC paper. Electrodeposited coatings are sometimes used without additional surface finishing. Grinding or certainly electropolishing will affect tests results.

Test Selection. Very high localized currents can exist during these tests and may result in rapid removal of the coating. The desired information is usually the corrosion current i_{corr}, which can be correlated with actual weight loss. The polarization resistance measurement (Ref 34) is probably the safest of these tests for this determination. The suitability of the test should be determined by correlating actual performance with test results whenever possible. Crevice corrosion under the gaskets used may affect results and should be considered.

Hot Dip Coatings

Introduction

HOT DIP COATING is a process in which a protective coating is applied to a metal by immersing it in a molten bath of the coating metal. Although hot dip coatings can be used to protect a number of metals, this article will consider only those used to protect steel.

Hot dip coatings have a number of advantages, including the ability to coat recessed or difficult areas (such as corner and edges) with a standard minimum coating thickness, resistance to mechanical damage (because the coating is metallurgically bonded to the steel), and good resistance to corrosion in a number of environments. However, the process has two limiting factors. First, the coating must melt at a reasonably low temperature, and second, the steel base metal must not undergo undesirable property changes during the coating process.

Hot dip coatings may be applied by continuous or batch processes. Materials such as steel sheet and wire may be hot dipped by continuously passing the steel through the molten metal bath. Continuous processing is highly automated and mechanized and is often associated with steel mill operations. The section "Continuous Hot Dip Coating" in this article discusses the corrosion resistance of zinc, aluminum, and zinc-aluminum alloy hot dip coatings on steel. Materials that are batch processed are generally fabricated before hot dipping, and the process may be performed manually or semiautomatically. Articles that can be hot dipped by the batch process range in size from large steel structural members to such small items as fasteners. The section "Hot Dip Galvanizing by the Bath Process" in this article provides details on the use of hot dip zinc coatings to protect steel. Other articles in this Volume that contain information on the use of hot dip coatings for corrosion prevention include "Corrosion of Zinc," "Corrosion in the Automotive Industry," and "Corrosion in Structures."

Steel sheet and wire are coated by a continuous hot dip process; that is, they enter the coating bath in an unending strip. In theory, all continuous hot dip processes are similar in that the steel sheet or wire is subjected to successive cleaning, coating, and postcoating steps.

Typical cleaning steps may include alkaline cleaning or acid pickling (both of which may be electrolytic), oxidation (usually gaseous for sheet, but often in molten lead for wire), and reduction (gaseous). If a gaseous reduction is the final cleaning step, the steel must enter the molten coating bath directly without being exposed to air. When the final cleaning step is an acid pickle (this is usually the case for wire), the steel is then immersed in a liquid flux, which dissolves any

remaining oxides, before entering the molten bath. Similarly, gaseous reduction can also be considered a flux treatment. All-gaseous cleaning is used on about 60% of the sheet-coating lines. The remaining 40% is approximately half liquid cleaning/flux and half liquid cleaning/gaseous cleaning. Most wire-coating lines use the liquid/ flux technique.

The clean steel is then immersed in the molten coating bath long enough to allow the coating metal to wet and react with the steel surface. As the coated sheet or wire emerges from the molten bath, it pulls coating metal up from the surface, which can then be smoothed or wiped to the desired thickness by a variety of methods. Most sheet-coating lines use a gas-wiping technique in which a jet of steam, air, or gas (such as nitrogen) is directed against the emerging sheet. Wire galvanizers either contact the wire with solid devices lined with asbestos or similar materials to produce thin coatings or use floating mounds of charcoal for heavier coatings, although other techniques are also used.

The coated steel can be given any number of subsequent mechanical, thermal, or chemical posttreatments designed to impart specific properties. Typically, a coated sheet might be oiled or coated with a chromate solution to inhibit staining or superficial corrosion during storage and transit (see the article "Chromate Conversion Coatings" in this Volume). Waxing would serve the same purpose on wire and would facilitate handling during subsequent processing.

Zinc-Coated (Galvanized) Steel

Galvanized steel has been in use for over 100 years. Continuous galvanizing of sheet steel was introduced into the United States in 1936. In 1985, an estimated 5.9×10^6 Mg (6.5×10^6 tons) of galvanized sheet steel were produced. Because of its long history of use, galvanized steel has been exposed to, and studied in, a wide range of corrosive environments. An excellent summary of the behavior of galvanized steel is provided in Ref 1.

Microstructure of Galvanized Coatings

A hot dip zinc coating consists of a series of layers. Starting at the steel surface, each layer is an iron-zinc alloy with successively lower iron content until the outer layer of pure zinc is reached. In continuous galvanizing, however, it is typical to add about 0.1 to 0.2% Al, which suppresses the formation of the alloy layers so that the coating is mostly pure zinc (Fig. 1). Other alloying elements, in addition to aluminum, can influence appearance, mechanical properties, and durability. Additional information is available in Ref 2. Zinc coatings are sometimes given an additional in-line heat treatment to produce a fully alloyed structure; this is often desirable if paint adhesion is important.

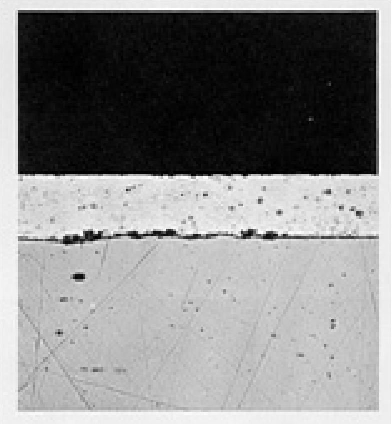

Fig. 1 Microstructure of continuously galvanized steel. In continuous hot dip galvanizing, the formation of various iron-zinc alloy layers is suppressed by the addition of 0.1 to 0.2% Al.

Protection by Galvanized Coatings

Zinc coatings protect steel from corrosion by two methods. First, in many environments, zinc corrodes much more slowly than steel; thus, the zinc coating essentially forms a barrier between the steel and the corrosive environment. Second, zinc protects steel electrochemically. When zinc is coupled to steel, the steel is polarized to such a potential that it becomes the cathode of the steel-zinc couple and is immune to further corrosion for the life of the zinc. In practice, this means that steel exposed at a coating defect or at a cut edge will not rust until the nearby zinc is consumed.

Atmospheric Corrosion Resistance

The atmospheric corrosion resistance of galvanized steel has been monitored for many years in numerous environments. Zinc corrosion has been found to be approximately linear with time. Examples of such behavior are shown in Fig. 2, in which the years to initial rust are plotted against the average coating weight for galvanized sheet in three different atmospheres. Similar behavior is observed on wire (Fig. 3).

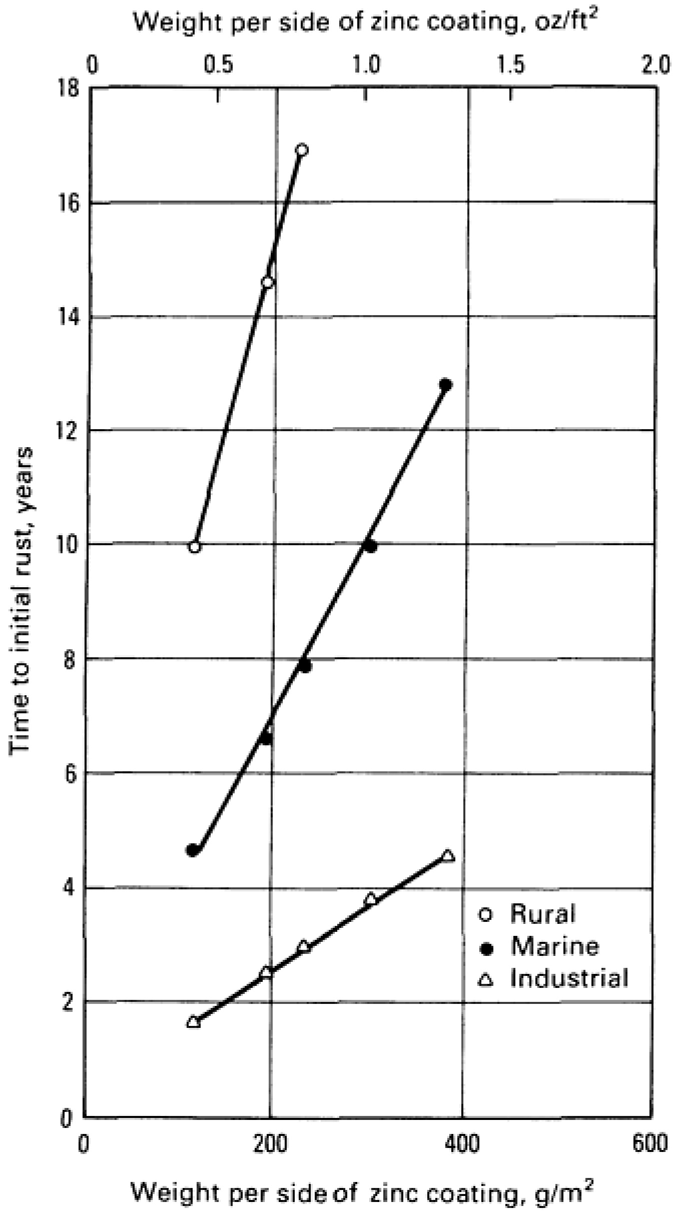

Fig. 2 Corrosion of galvanized steel in rural (State College, PA), marine (Sandy Hook, NJ), and industrial (Altoona, PA) atmospheres. Source: Ref 3

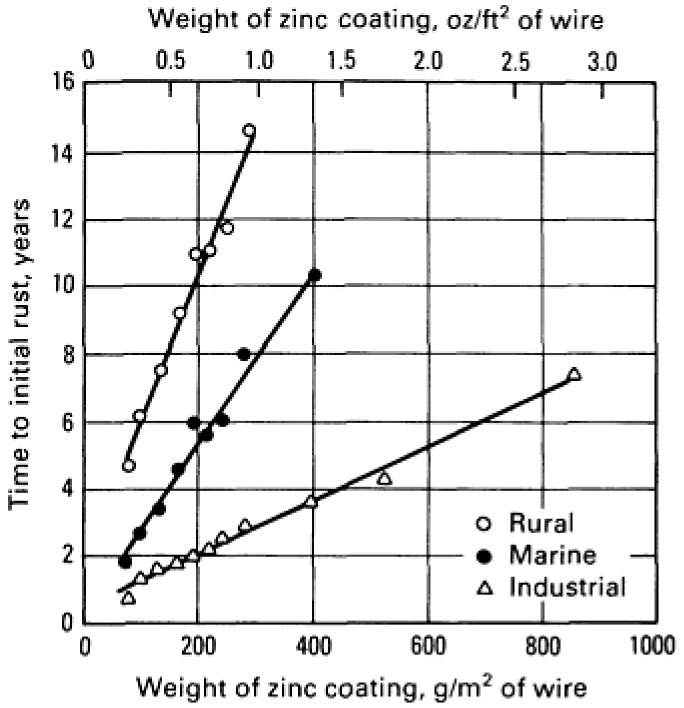

Fig. 3 Corrosion of galvanized wire in rural (State College, PA), marine (Sandy Hook, NJ), and industrial (Pittsburgh, PA) atmospheres. Source: Ref 4

Effects of Alloy Additions. There is good evidence that small amounts of alloying elements can affect the corrosion resistance of galvanized coatings. The mechanisms for these effects are complex and not fully understood, but current literature suggests that alloying elements segregate to grain boundaries, where they can accelerate or retard intergranular attack (Ref 5). Considering the Zn/0.1-0.2Al alloy typically used for continuous hot dip galvanizing, magnesium and copper tend to reduce intergranular corrosion, but bismuth, cadmium, lead, and tin increase attack. There is also some evidence that chromium, nickel, and titanium are beneficial.

Effect of Heat Treatment. Heating (galvannealing) a galvanized coating to produce an all iron-zinc alloy coating appears to be beneficial for corrosion resistance. Various investigators have reported increased atmospheric corrosion resistance of zinc coatings heat treated to give 10 to 15% Fe in the coating, but have not agreed on whether the effect was due to greater coating thickness resulting from zinc-iron diffusion or an inherent increase in corrosion resistance (Ref 6, 7).

Corrosion Mechanism. In dry air, zinc is oxidized to zinc oxide (ZnO). In the presence of moisture, ZnO reacts further to form zinc hydroxide ($Zn(OH)_2$). Neither of these corrosion products is very protective to the underlying zinc. However, $Zn(OH)_2$ can react further with carbon dioxide (CO_2) from the atmosphere to produce a basic zinc carbonate ($ZnCO_3$), which is protective.

In recent work, corrosion products identified on zinc coatings in industrial and marine atmospheres were mostly hydrozincite ($Zn_5(CO_3)_2(OH)_6$) (Ref 8). Zinc oxide was also present, as was a chloride in the marine environment. Surprisingly, zinc sulfate ($ZnSO_4$) was also found, even in the marine environment, indicating a definite role for sulfur dioxide (SO_2) in corrosion. Other investigations obtained a good correlation between the amount of SO_2 reacting with zinc and weight loss (Ref 9).

Aqueous Corrosion Resistance

Aqueous corrosion of galvanized coatings is largely determined by the impurities in the water. Water is usually classified into two major types: natural water and seawater.

The term natural water is used to describe groundwater surface water, and rainwater. Groundwater, by definition, flows from subsurface sources--springs and wells, for example. It often contains dissolved minerals, such as iron and manganese, salts of calcium and magnesium, and dissolved CO_2. Surface water refers to creeks and rivers (freshwater) and to runoff occurring after storms. It usually carries suspended organic and inorganic matter and many dissolved minerals picked up from soils. Even rainwater is not pure because the water droplets are often formed around dust and other particles suspended in the air. These droplets can absorb additional particles and dissolve atmospheric gases, such as oxygen, nitrogen, and CO_2, while falling to earth.

Seawater is of course characterized by its high sodium chloride (NaCl) content. It also contains many other salts.

Aqueous Corrosion Mechanism. Zinc corrodes in distilled water by the reaction:

$$Zn + 2H_2O \rightarrow Zn(OH)_2 + H_2$$

If oxygen is present, it combines with the evolved hydrogen to form water. This depolarizes and accelerates the corrosion reaction so that the corrosion rate in an oxygen-saturated solution depends on the diffusion of oxygen.

Corrosion in Natural Waters. Natural waters contain many impurities, and the reaction of zinc with these impurities largely controls the corrosion rate. The lowest corrosion rates are observed in hard waters in which calcium and magnesium salts can act as cathodic inhibitors. Their nearly insoluble hydroxides precipitate on cathodic regions, and this retards oxygen reduction. Also, the CO_2 in the water reacts with $Zn(OH)_2$ to form $ZnCO_3$. All of these corrosion products mix to form a very protective scale on the zinc surface. A typical corrosion rate in hard water is 0.25 $mg/dm^2/d$, but in a soft water with no protective scale, zinc may corrode ten times as fast.

Carbon dioxide generally has an accelerating effect on corrosion in both hard and soft waters (much more so in soft water). Table 1 illustrates the result of increasing the CO_2 content on the corrosion rate of galvanized steel. Also shown are the results when the zinc overlay is removed and the underlying alloy layers are exposed directly. Although the corrosion rates of the alloy layers are not much different from the corrosion rate of pure zinc, the layers did not provide the same degree of galvanic protection to exposed steel.

Table 1 Corrosion of galvanized steel in water with varying CO_2 contents

CO_2 content, ppm	Corrosion rate, $mg/dm^2/d$		
	Zinc overlay	**Zn-4.8Fe layer**	Zn-7.6Fe layer
0	1.0	. . .	**1.1**
5	2.3	2.6	**2.6**
18	3.3	7.0	**5.4**
37	**4.2**	**11.3**	**9.1**

Source: Ref 10

Both pH and temperature also affect the corrosion of galvanized coatings in natural waters. Both effects are thought to result from changes in the protective scales that occur as these variables change. Generally, corrosion will be lowest in the pH range of 6 to 12.5 and will increase with temperature to a maximum near 70 °C (160 °F). The potential of the zinc electrode changes with increasing temperature; therefore, it may no longer provide galvanic protection to steel at higher temperatures.

Corrugated Steel Pipe. Perhaps the most extensive effort to quantify the effect of natural waters on the corrosion to galvanized steel was carried out to predict the durability of corrugated steel drainage pipe (Ref 11). Based on a survey of thousands of culverts in California, the time to perforation of 16-gage corrugated steel pipe was related to water pH and resistivity. An abbreviated diagram of the results is shown in Fig. 4, which also gives correction factors for steel thickness. Although the time to perforation includes the steel thickness as well as the galvanized thickness, the variation in corrosion rate with pH and resistivity is mostly due to zinc. A note of caution: The fact that this method seems to work in the geographic area from which the data were derived does not guarantee similar results in other areas. There are numerous instances in the literature in which the predictions from this diagram were not borne out by service records.

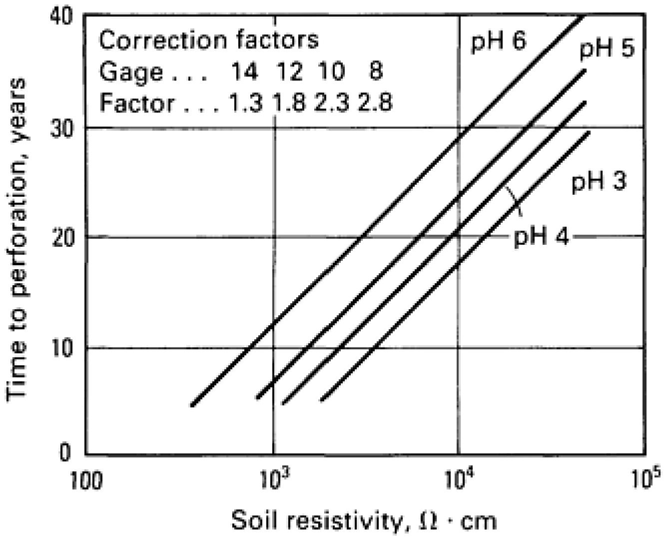

Fig. 4 Corrosion of 16-gage galvanized, corrugated steel pipe in soils of varying pH and resistivity. Correction factor for different steel thicknesses are also given. Source: Ref 11

Corrosion in Seawater. Limited data have been generated on the resistance of galvanized coatings to seawater. It was quickly evident that zinc coatings are inadequate by themselves for long-term protection. The high chloride content of seawater suggests a much higher corrosion rate than freshwater, but this higher rate is not obtained. Magnesium and calcium salts often inhibit corrosion sufficiently through scale formation to make seawater less corrosive than soft freshwater. Typical corrosion rates are 5 to 10 mg/dm^2/d.

Corrosion in Soils

Soil corrosion is complex and not well understood. The physical and chemical characteristics of soils are important in determining corrosiveness. Coarse, sandy soils tend to permit easy access for air and water, but clay or silt show poor aeration and drainage. Considering the soluble chemicals that may be present, soil corrosivity can range from equivalent to atmospheric or aqueous media to virtually inert. Similarly, if conditions favor the formation of insoluble, protective films on the galvanized surface, a longer service life can be obtained.

The National Bureau of Standards studies initiated in the 1920s remain the primary source for underground corrosion data (Ref 12). A simplified summary for galvanized coatings is given in Table 2.

Table 2 Corrosion of galvanized steel in various soils

Coating weight: 300 g/m^2 (1 oz/ft^2)

Soil description	**Soil corrosivity**	Coating life, years
Poor drainage, low resistivity	High	**1-2**
Poor drainage, high salt content	Moderate	**4-6**
Good drainage, high resistivity, low salt content	**Low**	**18-25**

Aluminum-Coated (Aluminized) Steel

The desirability of combining the properties of aluminum and steel through coatings has been recognized since before the turn of the century. Because of the higher temperature and aggressiveness of molten aluminum and its tenacious oxide, hot dip aluminum coating of steel was much more difficult to put into practice than hot dip galvanizing. Although aluminizing remains a more demanding process than galvanizing, aluminum-coated steel is readily available throughout the world, with an estimated sheet production capacity of over 363,000 mg/yr (400,000 tons/yr) in the United States alone. Major uses include roofing panels, automotive exhaust components, and chain link fence.

Microstructure of Aluminum Coatings

Two types of aluminum coatings are commercially significant. Type 2 uses commercially pure aluminum for the coating, and Type 1 uses an aluminum alloy containing 5 to 11% Si. The microstructure of the Type 2 coating shows a layer of aluminum, often with scattered iron-aluminum intermetallic particles, bonded to the steel substrate by an iron-aluminum intermetallic layer (Fig. 5). This intermetallic layer forms a distinctive serrated boundary with the steel and is generally identified as Fe_2Al_5, although some investigations have found additional iron-aluminum compounds (Ref 14).

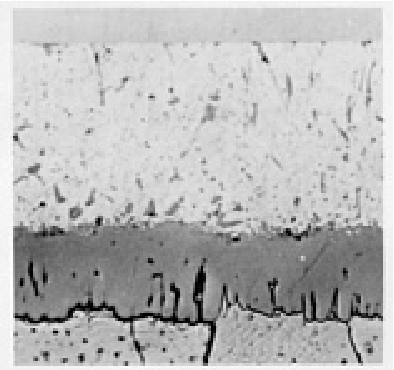

Fig. 5 Microstructure of type 2 aluminum coating on steel. This coating forms a layer of essentially pure aluminum (top) with scattered gray particles of aluminum-iron; the light gray center layer is aluminum-iron, and the bottom layer is the base steel. 1000×

When silicon is added to form a Type 1 coating, a different microstructure results. The intermetallic layer becomes narrower and smoother (Fig. 6), resulting in increased coating ductility relative to the Type 2 coating. With increasing silicon additions, the coating bath temperature can also be lowered, and the growth of the intermetallic layer is further inhibited.

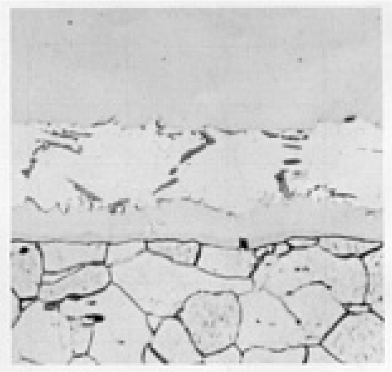

Fig. 6 Microstructure of type 1 aluminum coating on steel. From top: a nickel filler, aluminum-silicon alloy, aluminum-silicon-iron alloy, and steel base metal. 1000×

Effect of Alloy Additions. Beryllium, copper, and some other elements have also been found to retard the growth of the intermetallic layer. Additions of these and other elements to the steel itself can also retard the growth of the alloy layer. The way in which these elements reduce the growth is not understood, although silicon appears to act after being incorporated into the intermetallic layer itself (Ref 15).

Protection by Aluminum Coatings

Aluminum coatings protect steel from attack by forming a very resistant barrier between the corrosive atmosphere and the steel. The aluminum oxide that forms on the aluminum surface is highly resistant to a wide range of environments.

In some aggressive environments containing chlorides, in which the aluminum oxide barrier is breached, the aluminum, like zinc, can also electrochemically protect steel from rusting. Because of this limited ability to protect steel galvanically, aluminum coatings are usually not used at very low thicknesses when the likelihood of coating defects is increased.

Atmospheric Corrosion Resistance

Numerous tests have shown that Type 1 and Type 2 aluminum coatings provide excellent atmospheric corrosion protection for steel. The major difference between the two coatings is the darkening and pinpoint rust formation that occur very early on Type 1 coatings. Weight loss measurements show that overall corrosion losses are nearly identical for both coatings (Ref 16). However, because of this appearance factor, the major use for Type 1 coatings is for high-temperature resistance, especially in automotive exhaust components. Typical atmospheric corrosion data for Type 2 aluminum-coated steel are given in Table 3. Galvanized steel data are included for comparison purposes. On the basis of this and similar investigations, a Type 2 aluminum coating will provide substantially longer life than a galvanized coating of equivalent thickness.

Table 3 Coating thickness losses for galvanized steel and type 2 aluminized steel in atmospheric exposure

Year exposed	Coating thickness loss

Source: Ref 16

(a) G90 galvanized steel has a coating weight of 0.90 oz/ft^2 (270 g/m^2).

In 1961, the American Society for Testing and Materials (ASTM) exposed aluminum-coated wire (all hot dip coated wire is made with a Type 1 coating) and galvanized wire at marine, industrial, and rural atmosphere test sites. Results from unfabricated wire show that (Ref 17):

- Aluminum coatings are rust free 1.3 to 2.2 times longer than zinc coatings of the same thickness (43 µm) in industrial and marine atmospheres
- Zinc coatings are rust free longer at the rural test site, an unexpected result that is possibly explained by the nonuniformity of the aluminum coating. Fabricated wire products made from precoated wire showed virtually no difference between aluminum and zinc coatings

Corrosion Mechanism. Because contact with oxygen results in the formation of a protective aluminum oxide layer, other components of the atmosphere must be responsible for the corrosion of the aluminum coating. Careful analysis of the corrosion products formed on aluminum coatings in industrial and marine atmospheres has shown that the predominant product is an amorphous, hydrated aluminum sulfate (Ref 8). This suggests that SO_2 is an important factor in atmospheric corrosion. This sulfate compound also appears to be more protective than the sulfates found on zinc coatings, which is consistent with observed corrosion behavior.

Aqueous Corrosion Resistance

Aluminum-coated steel has not generally been used in situations requiring aqueous corrosion resistance. There are no counterparts to galvanized water tanks, galvanized pipe, or galvanized pails. However, since 1979 the Type 2 aluminum coating has been used in the manufacture of corrugated steel pipe.

Corrosion in Natural Waters. Numerical data on the corrosion resistance of aluminum coatings are few because of the lack of use. Behavior is usually inferred from aluminum alloy data, but this could be inappropriate because of differences in structure and composition. Nonetheless, studies on aluminum alloys have shown that the air-formed aluminum oxide is destroyed after immersion (Ref 18). Corrosion resistance then depends on the oxide being re-formed from dissolved oxygen quicker than the aluminum is attacked by other ions, such as chlorides (Cl^-), nitrates (NO_3^-), or sulfates (SO_4^{2-}). With the protective aluminum oxide layer in place, the normal mode of failure is pitting, not general dissolution.

In general, soft waters are the least aggressive toward aluminum. The oxide is regarded as stable from pH 5 to 9. However, specific ions can change this range of stability. There is also some evidence that pitting may increase as the pH varies from neutral, but increasing the flow rate, especially at the more extreme pH values, can alleviate pitting. Small concentrations of copper and some other heavy metals can also lead to accelerated pitting. Pitting and corrosion have been observed in less than 3 years on aluminum-coated roofing panels exposed to stagnant water (Ref 19). On the other hand, when under a constant flow of relatively soft neutral pH water, corrugated steel pipe made from Type 2 aluminum-coated steel gives excellent service (Ref 20).

Corrosion in Seawater. Unlike aluminum alloys, aluminum-coated steel is not used in seawater. Corrosion rates are too high to provide economical use except as part of a more complex protection system. Typical thickness loss after 1 year of immersion in seawater has been reported to be 198 μm (7.8 mils) for Type 1 and 38 μm (1.5 mils) for Type 2 aluminum-coated sheets (Ref 16).

Corrosion in Soils

As with aqueous environments, aluminum-coated steel does not have a history of use in soils. Behavior would be expected to depend on pH, resistivity, and especially the chemistry of the soil. The mode of failure should be pitting. To date, no detrimental soil experience has been reported for the corrugated steel pipe use discussed previously.

Aluminum-Zinc Alloy Coated Steel

As discussed earlier, galvanized coatings provide an acceptable degree of resistance to atmospheric, aqueous, and soil corrosion. Because of galvanic protection, the rusting and staining of steel exposed at cut edges or coating defects are prevented until the nearby zinc is consumed. The major inadequacies of zinc coatings are the limited protection in the more severe environments and any significant high-temperature protection. Aluminum coatings have addressed these two factors. However, because they cannot provide cathodic protection to exposed steel in most environments, early rusting occurs at coating defects and cut edges. Even though this rusting seldom progresses, it precludes use where appearance is important. Aluminum coatings are also subject to crevice corrosion in marine environments.

Many attempts have been made to improve the corrosion resistance of both galvanized and aluminum coatings through alloying. Although combinations of these two elements with each other were known to provide an attractive degree of corrosion resistance, hot dip coatings did not become feasible until the discovery that silicon inhibits the rapid alloying reaction with steel (Ref 21). The 55Al-Zn (by weight, 55Al-43.4Zn-1.6Si) coating was first available commercially in 1972. This composition was selected from a systematic investigation of aluminum-zinc alloys, with up to 70% Al providing the best combination of galvanic protection and low corrosion rate. Current use varies from metal roofing, for which it is the major coated steel used, to automotive components, appliances, and, most recently, corrugated steel pipe. Production capacity of sheet in the United States in over 726,000 Mg (800,000 tons). The 55Al-Zn coating is now the fastest-growing hot dip coating worldwide in both production capacity and use.

Microstructure of 55Al-Zn Coating

The 55Al-Zn coating has a two-phase structure of cored aluminum-rich dendrites and a zinc-rich interdendritic constituent. This overlay is bonded to the steel substrate by a thin intermetallic layer whose composition is 48% Al, 24% Fe, 14% Zn, and 11% Si. X-ray diffraction suggests a structure similar to $Al_{13}Fe_4$. In addition, silicon particles are often found in the interdendritic region. By volume, the coating is approximately 80% Al + Si and 20% Zn. The effect of cooling rate during solidification is manifested in the spacing between the dendritic arms. Faster cooling (used commercially) results in finer spacing, which improves corrosion resistance.

Protection by Aluminum-Zinc Alloy Coatings

The 55Al-Zn coating provides both barrier and galvanic protection. Because the zinc-rich constituent is intimately distributed throughout the coating, it will be in contact with exposed steel at any break in the coating and at cut edges. Although less galvanic protection is available than with pure galvanized coatings, the alloy coating lasts longer because the overall corrosion rate is controlled by the aluminum-rich phase, which corrodes much more slowly than zinc.

Atmospheric Corrosion Resistance

Samples of 55Al-Zn-coated steel have been tested in atmospheric exposure for over 20 years. Figure 7 shows thickness loss with time for the first 13 years of exposure in four different atmospheres. Compared to galvanized panels exposed at the same time, the 55Al-Zn coating provides two to six times the corrosion resistance (based on equal coating thicknesses). Although these results were based on pilot line samples, subsequent testing of commercial 55Al-Zn sheet steel for 10 years shows a slightly greater advantage over galvanized steel (Ref 23).

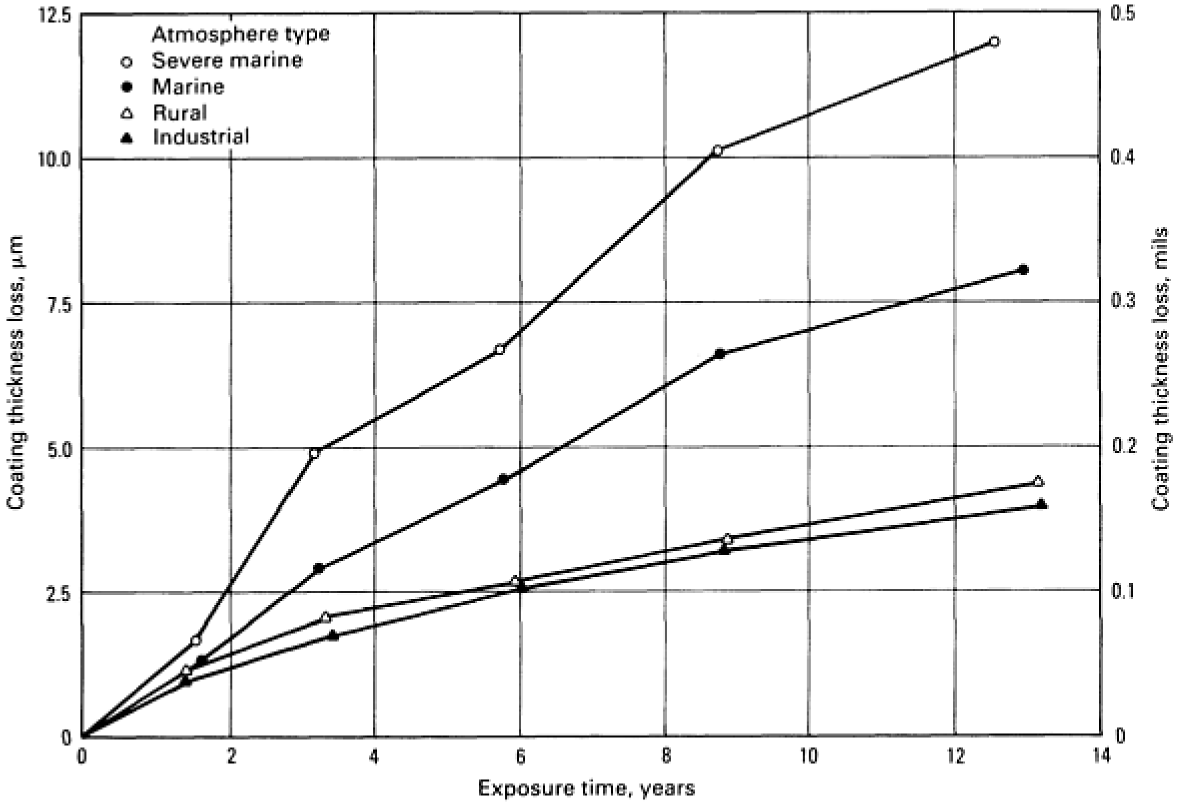

Fig. 7 Coating thickness loss of 55Al-Zn-coated steel in four atmospheres. Source: Ref 22

Corrosion Mechanism. The zinc-rich constituent of the coating has been observed to corrode preferentially. As these regions are removed, their space is taken by corrosion products that become mechanically locked into the interdendritic spaces. These corrosion products are mostly amorphous aluminum or hydrated aluminum-zinc sulfates--similar to the corrosion products found on the coating surface of aluminum and 55Al-Zn coatings. These sulfates are adherent and may help explain the improved durability of the aluminum-zinc coating. Support for this mechanism is also obtained from aqueous corrosion studies in which the corrosion potential is observed to change that of a galvanized coating upon immersion to a value approaching that of aluminum after subsequent corrosion (Ref 24).

Aqueous Corrosion Resistance

The 55Al-Zn coating is finding increased use in applications demanding resistance to aqueous corrosion, especially where wet/dry cycles are obtained.

Corrosion in Natural Waters. As with other coatings, the corrosion of 55Al-Zn coating would be expected to vary with the specific properties of the water. It is not known how water hardness will affect corrosion, but in distilled water

(very soft) and distilled water containing 85 mg/L of Cl^- ion, the 55Al-Zn coating is much more resistant than a galvanized coating (Table 4). In similar tests, 55Al-Zn and galvanized panels were immersed for 90 days in distilled water containing 45 ppm of SO_4^{2-} and 10 ppm of Cl^- at pH values from 3 to 11 (Ref 26). The pH was maintained through sulfuric acid (H_2SO_4) or sodium hydroxide (NaOH) additions. As Table 5 demonstrates, the 55Al-Zn retains more coating than the galvanized at all pH values, especially within the 5 to 9 range most characteristic of natural waters.

Table 4 Average coating thickness loss of galvanized and 55Al-Zn-coated steel after 56 days of immersion

Material	Thickness loss			
	Distilled water		85 mg/L NaCl	
	μm	**mils**	**μm**	mils
Galvanized	1.06	0.042	1.26	**0.049**

5	45	**2**
7	41	**4**
9	40	**8**
11	**33**	**26**

Source: Ref 26

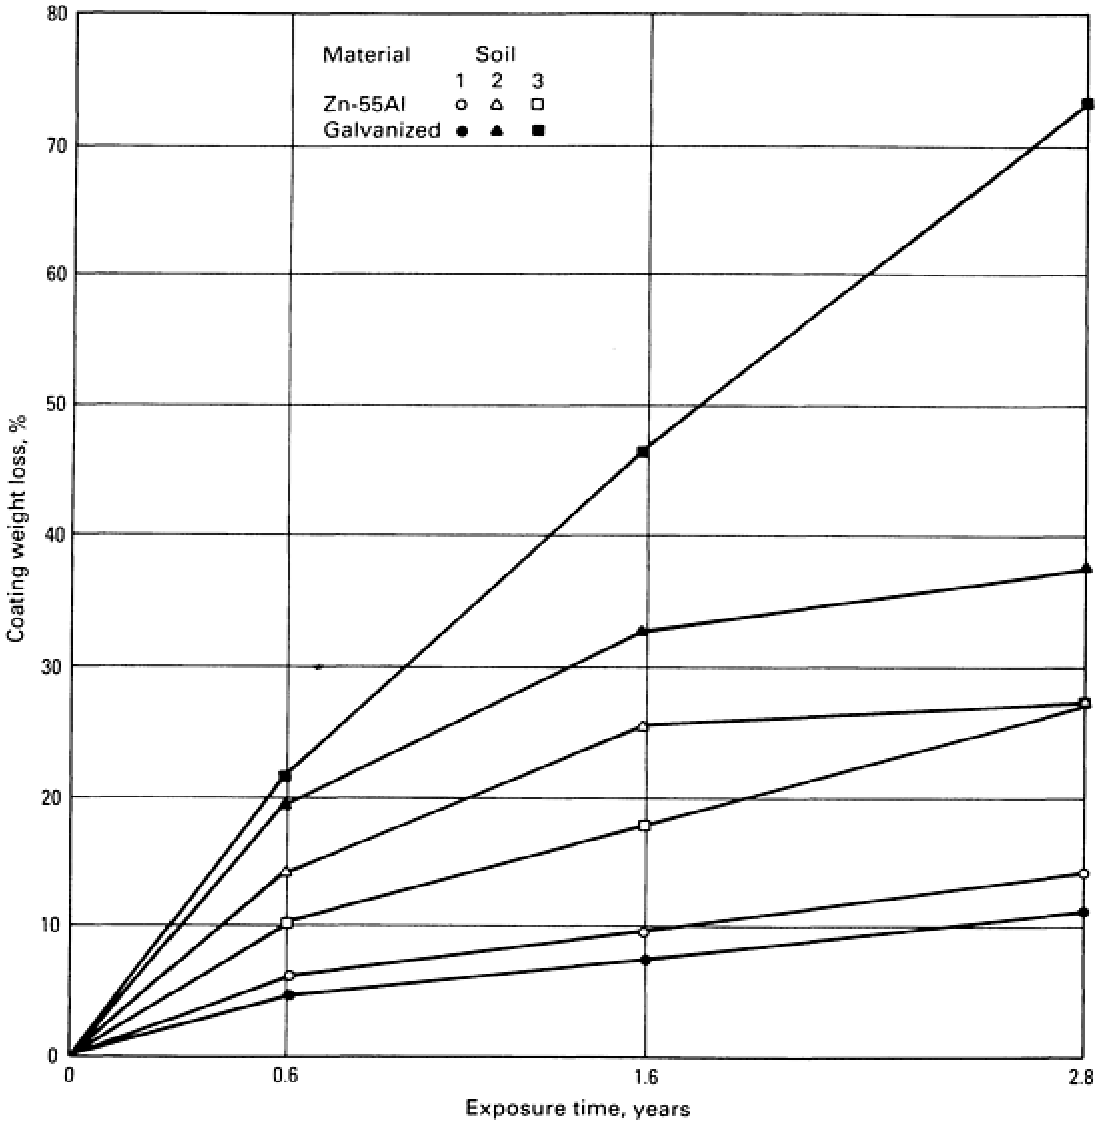
The longest service history of exposure to natural water for the 55Al-Zn coating is obtained from corrugated steel pipe installed between October, 1973, and October, 1974 (Ref 27). Water chemistry, pH, and resistivity varied widely from site to site and sometimes changed considerably with time. Erosion and abrasion caused additional wear factors.

Overall, 55Al-Zn applied at a coating weight of 180 g/m^2 provides greater durability than a 600-g/m^2 galvanized coating. Continued monitoring of these sites suggests an average of 10 years of additional life for the 55Al-Zn coating in the pipe inverts, the point of severest corrosion and wear.

Corrosion in Seawater. No results of seawater exposures have been published. It is unlikely that the 55Al-Zn coating would provide service that differs substantially from that of a galvanized or aluminum coating. Supplemental protection would be required for long-term use in seawater.

Corrosion in Soils

Again, there are few performance data for the 55Al-Zn coating in soil. The corrugated steel pipe exposures described previously provide the longest history of soil exposure, but because most culverts fail from the inside, exterior soil corrosion was not monitored closely in these tests. Some data are available from laboratory tests in which 16-gage coated steel panels were buried in test soils and monitored for coating loss (Ref 27). Figure 8 shows coating loss and the soil characteristics. These data suggest that the 55Al-Zn coating should provide corrosion resistance in soil similar to that of a galvanized coating.



Soil number	Description	pH	Resistivity, Ω· cm
1	Native shale, clay; wet to dry	4	**76,000**
2	Native shale with chloride and sulfate salts; wet and dry	5	**35,000**

Hot Dip Galvanizing by the Batch Process

J.W. Gambrell, American Hot Dip Galvanizers Association

The metallic coating produced by the hot dip galvanizing process is the result of a metallurgical reaction called diffusion. Diffusion occurs when the steel is immersed in the molten zinc. In this reaction, a series of intermetallic iron-zinc phases is formed as zinc diffuses inward and iron diffuses outward. The finished product consists of four layers on the steel; the outer layer is free zinc, and the inner three layers are separate intermetallic layers that are metallurgically bonded to each other and the steel. Thus, a galvanized coating has extremely high bond strength relative to other coatings, which rely on mechanical or weak electrical forces for bonding.

For the diffusion reaction to occur, the zinc must wet the steel surface. The presence on the steel surface of foreign materials, such as rust, scale, paints, or lubricants, can prevent the zinc from wetting and reacting with the steel surface; therefore, all contaminants must be removed before galvanizing.

The batch hot dip galvanizing process consists of two basic steps: surface preparation and immersion in the bath of molten zinc. Within each of these broad steps is a series of operations essential to the production of a quality galvanized coating.

Surface Preparation

Surface preparation essentially involves cleaning the steel. Dirt, oils, lubricants, greases, and other impurities, as well as normal oxidation products, such as mill scale or rust, may be deposited on the steel during fabrication, transportation, or storage. These impurities must be removed for the galvanizing reaction to occur.

Alkaline Degreasing. If required by the condition of the material, the first step in the process is treatment in an alkaline solution. Oils, greases, and other saponifiable compounds are removed in this step. Most of the various proprietary compounds available for this purpose consist of a mixture of basic sodium salts.

Acid Pickling. The steel article is usually rinsed after alkaline degreasing and before pickling to avoid neutralization and weakening of the pickle acid. The pickling process removes surface oxides and mill scale. The pickle acid is an aqueous solution of a mineral acid, usually hydrochloric acid (HCl) or sulfuric acid (H_2SO_4); acid concentrations and pickling temperatures vary from galvanizer to galvanizer, but are within a narrow range. An inhibitor is sometimes used to avoid attack of the base metal.

Abrasive Cleaning. As an alternative to alkaline degreasing and pickling, abrasive gritblasting may be used, followed by a flash pickle to remove any surface oxides that may develop between cleaning and further processing. Abrasive cleaning may not be practical for the galvanizer who handles a variety of sizes and shapes of material. Abrasive cleaning provides rapid and complete cleaning and is particularly effective in cleaning iron castings because casting sands are

easily removed and surface uniformity is promoted. The method is also useful for cleaning fabricated products composed of different ferrous materials that may pickle at different rates or for removing weld slags or other impurities that are difficult to remove chemically. Abrasive cleaning may result in increased coating thicknesses because of changes in the steel surface profile (increased effective surface area and roughness).

Fluxing is required to dissolve any oxide films formed on the steel after pickling but before galvanizing and to ensure that a clean metal surface contacts the molten zinc. The fluxing procedures used include the wet process and the dry process. In the wet process, steel is passed through a layer of molten flux floating on the surface of the molten zinc. The dry process (prefluxing), involves immersion of the steel in an aqueous flux solution and drying before galvanizing. In both cases, a flux composed of zinc ammonium chloride ($ZnCl_2 \cdot 2NH_4Cl$) is used. Because both processes have advantages, selection of a method is based on individual choice and the types of material to be processed.

Galvanizing

The molten zinc metal is contained in a kettle made of firebox-quality steel, although ceramic-lined kettles are increasing in use, particularly in Europe. The zinc is maintained at a temperature of 445 to 460 °C (830 to 860 °F). The kettle should be large enough to accommodate the material expected to be handled and should have sufficient heat content to prevent deep thermal cycling, with a resulting decrease in the kettle life.

The clean iron or steel is immersed (dipped) directly into the molten zinc or is passed through a molten flux blanket into the zinc. The material is immediately wetted, and as it reaches the temperature of the molten zinc, the diffusion reaction begins, resulting in the formation of a series of iron-zinc alloys. For most steels, the reaction is rapid at first, but it subsequently slows. The thickness of the coating does not increase substantially with longer immersion times.

The coating produced consists of a series of zinc-iron alloys, with increasing zinc content occurring toward the coating surface. When the material is withdrawn from the kettle, a thin layer of free zinc remains on the zinc-iron alloys, resulting in the characteristic bright, shiny, galvanized coating finish when allowed to cool quickly in air. The thickness of the free zinc layer varies with the speed of withdrawal from the molten bath.

Most galvanized articles are air cooled after coating, although centrifuged parts and smaller items are often water quenched. Water quenching halts the alloying reaction by diminishing the heat retained by the workpiece; this prevents the continued reaction that could convert the free zinc layer to iron-zinc alloy.

Coating Weight and Thickness

Galvanizing specifications in the United States require the coating to be measured in ounces per square foot. For wire, sheet, or small parts and fasteners, the procedure involves stripping the coating, determining the weight loss of the item, then calculating the coating weight. For large iron and steel structural materials, this may be impossible or impractical. The coating weight can be determined by measuring the coating thickness with a calibrated magnetic thickness gage. The thickness-to-weight conversion is 1 oz of zinc/ft^2 (305 g/m^2 of zinc) equals 1.7 mils (43 μm) of thickness.

Factors Affecting Coating Thickness and Structure

For most steels, the coating thickness and structure are relatively insensitive to variations in the galvanizing process. Variations in steel chemistry; zinc bath temperature; the physical condition of the steel surface (grain size, stresses, microstructure, roughness); zinc chemistry; the amount of wiping, shaking, or centrifuging; and the rate of cooling after galvanizing can effect the thickness, metallurgical characteristics, and the appearance of the coating.

Steel Chemistry. Although almost any steel can be galvanized, steel chemistry can have a marked effect on the thickness, structure, and appearance of the galvanized coating. Silicon, phosphorus, carbon, and manganese may be present in the steel and can influence the zinc-iron reaction mechanism, depending on their concentration.

The most influential steel constituent is silicon, which is added to steel as ferro-silicon to remove oxygen from the molten steel before casting. Figure 9 shows the effect of increasing silicon content in the steel versus time at two different galvanizing temperatures. In high-silicon (reactive) steels, the increase in coating thickness results from the accelerated growth of the zinc-iron alloy layers. This growth is due to the formation of loosely packed small grains or long-stem crystals in the outermost alloy layer of the coating, allowing zinc from the bath to penetrate to the steel surface, with

continuation of the reaction. In general, steels with the following maximum impurity levels are best suited to galvanizing: 0.05% Si, 0.05% P, 0.25% C, and 1.3% Mn.

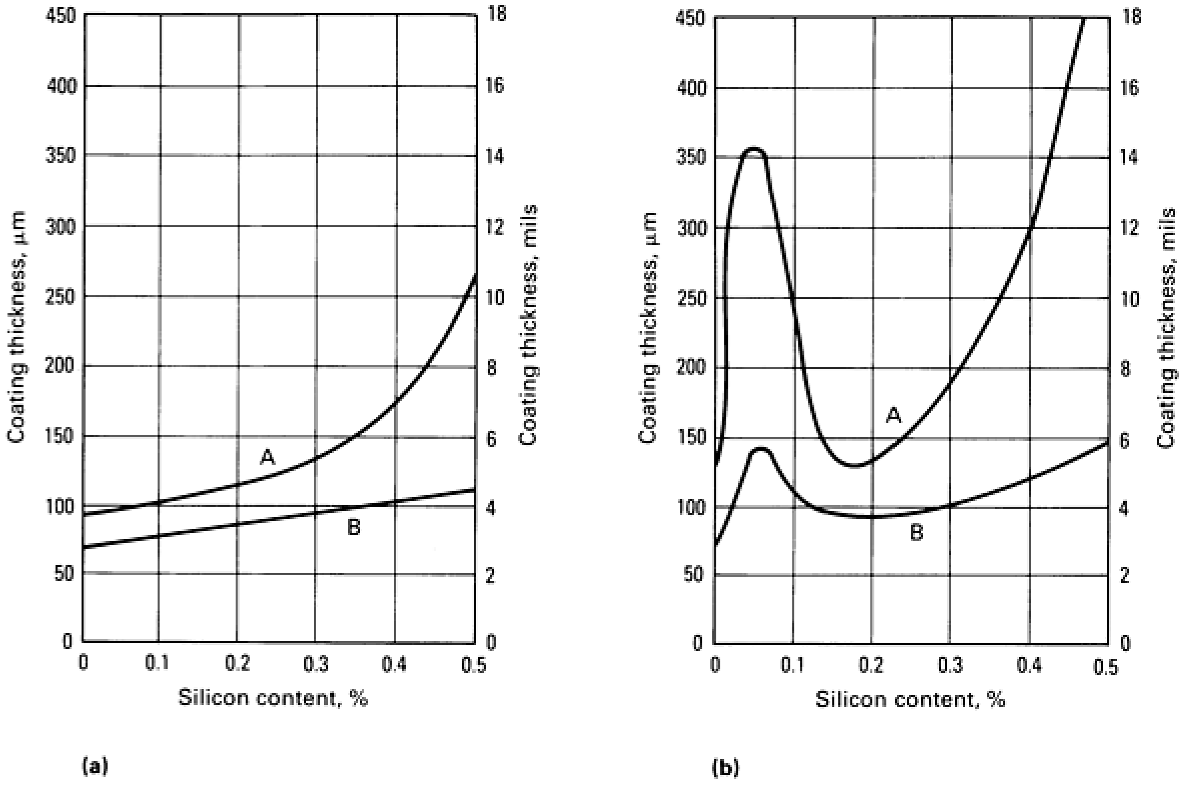

Fig. 9 Effect of silicon content of steel, immersion time, and galvanizing temperature on the thickness of hot dip galvanized coatings. Curves A and B are for 9-min and 3-min immersions, respectively. (a) Galvanizing temperature: 430 °C (805 °F). (b) Galvanizing temperature: 460 °C (860 °F). Source: Ref 28

Zinc Bath Temperature. For normal steels, an increase in the zinc bath temperature, if it does not exceed the normal operating range, results in reduced immersion time and improved drainage of free zinc from the coating. The coating thickness for silicon-containing steels is very temperature dependent (Fig. 9).

Steel Surface Condition. The condition of the steel surface with respect to roughness and microstructure can affect the thickness of the galvanized coating. Roughening of the surface increases the profile and thus the effective surface area of the material, resulting in increased coating thickness. Fine-grain microstructures can result in lower coating weights (Ref 29). Coating thickness specifications generally provide for lower coating thicknesses for thinner steel sections.

Zinc Chemistry. Trace elements in the molten zinc, either present as impurities or intentionally added to the zinc to achieve certain beneficial results, can affect the appearance of the galvanized coating. Prime Western zinc, the grade normally used for batch process galvanizing, can contain up to 1.4% Pb, 0.2% Cd, 0.05% Fe, and must contain a minimum of 98% Zn.

Although the lead content of Prime Western zinc can be as high as 1.4%, a typical galvanizing bath will contain 1% or less. Lead has no effect on the viscosity of molten zinc, but it does affect the surface tension; this results in better drainage of zinc from the galvanized product, an important consideration when galvanizing complex shapes or wire fabrics.

Aluminum is usually not found in the grades of zinc normally used for galvanizing, but is occasionally added to improve the finish of the work. Aluminum at a concentration of 0.005% in zinc will result in coatings with improved brightness and uniformity. It also retards the surface oxidation of the molten zinc, resulting in a smoother flow of zinc over the work and improved drainage characteristics.

The typical galvanizing zinc bath may contain other trace elements that were originally present in the zinc or that resulted from the chemistry of the steel processed. These trace elements, including cadmium and copper, are usually present at too low a concentration to affect the coating structure or appearance.

Degree of Wiping, Shaking, or Centrifuging. These techniques are used for the efficient removal of excess zinc after galvanizing and result in a coating with a very uniform surface appearance. These techniques are particularly important when galvanizing threaded materials.

Rate of Cooling. Silicon-containing steels that are allowed to cool slowly after galvanizing will continue to react until the temperature decreases to below about 300 °C (570 °F). This may result in the iron-zinc alloy layers extending to the coating surface and an almost total absence of the free zinc layer. The result is a gray coating instead of the normal bright finish. The service life of the coating is not adversely affected and may in fact be greater with these coatings because of their increased thicknesses.

If the material is not water quenched after galvanizing, then close stacking of material while still hot should be avoided because of heat retention, which could allow the zinc-iron alloying reaction to continue. Material should be well spaced with good air circulation for cooling efficiency.

Mechanical Properties of the Coating and Steel Substrate

Hardness and Abrasion Resistance. The layers that compose the galvanized coating, being discrete zinc-iron alloys, vary in hardness. The free zinc layer (η) is relatively soft, but the alloy layers are very hard, harder even than ordinary structural steels. Typical values for the microhardness and other properties of the various alloy layers are given in Table 6.

Table 6 Properties of alloy layers of hot dip galvanized steels

Layer	**Alloy**	**Iron, %**	**Melting point**		**Crystal structure**	**Diamond pyramid microhardness**	Alloy characteristics
			°C	**°F**			
Eta (η)	Zinc	0.03	419	787	Hexagonal	70-72	**Soft, ductile**
Zeta (ζ)	$FeZn_{13}$	5.7-6.3	530	986	Monoclinic	175-185	**Hard, brittle**
Delta (δ)	$FeZn_7$	7.0-11.0	530-670	986-1238	Hexagonal	240-300	**Ductile**
Gamma (γ)	Fe_3Zn_{10}	20.0-27.0	670-780	1238-1436	Cubic	. . .	**Thin, hard brittle**
Steel base metal	**Iron**	**. . .**	**1510**	**2750**	**Cubic**	**150-175**	**. . .**

The alloy layers are from four to six times more resistant to abrasion than pure zinc. Galvanized coatings exhibit better abrasion resistance compared to paints with the same coating thickness and can be effectively used where excessive abrasive wear is expected, for example, floor gratings, stairs, conveyors, and storage bins.

Adhesion and Impact Resistance. Unlike other coatings, which are mechanically or chemically bonded to the steel, the galvanized coating is metallurgically bonded to and integral with the steel, making conventional measures of bond strength inappropriate for this coating. As a result of the metallurgical bond, the galvanized coating is very adherent.

The structure of the galvanized coating, particularly the relative thicknesses of the δ and z layers (Table 2), is primarily influenced by the steel chemistry and, to a lesser extent, by the galvanizing temperature and the duration of immersion. Coating structure has the greatest effect on the impact resistance of the coating. A high relative proportion of z phase in the iron-zinc alloy may result in localized flaking if the coating is subjected to heavy impact or excessive twisting or bending. Semikilled steels with silicon contents of 0.05 to 0.12% are the most susceptible to coating brittleness and less adherent coatings.

Steel Strength and Ductility. The effects of hot dip galvanizing on the mechanical properties of steels have been thoroughly researched. This research has shown that galvanizing causes no significant alteration in the bend, tensile, and impact properties of the commonly galvanized steels produced throughout the world (Ref 30). Galvanizing reduces slightly the impact toughness of cold-rolled steels, but this reduction is generally not sufficient to affect the applicability of the steel.

Weld Stresses. Welded structures have higher strength in the galvanized condition than in the uncoated condition. Hot dip galvanizing reduces weld stresses by 50 to 60% (Ref 30).

Fatigue Strength. For most steels, little reduction in fatigue strength occurs as a result of galvanizing. Fatigue tests comparing hot dip galvanized steels with uncoated steels usually compare an uncoated steel with mill scale and the same steel after galvanizing. These tests do not consider that an uncoated steel exposed to an outside environment begins to rust immediately, with the resulting formation of pits that may be five to seven times deeper than the general corrosion and a rapid decrease in fatigue strength. The reduction in fatigue strength due to corrosion attack is much more significant than that due to galvanizing.

Embrittlement. It is relatively rare for a steel to be in the embrittled condition after hot dip galvanizing. The amount of cold working (plastic straining) of steels susceptible to strain aging is the single most important factor where strain-age embrittlement is of concern. The temperature of the galvanizing process accelerates the aging process; generally susceptible materials fail almost immediately after removal from the bath. Research has shown that a minimum cold bend radius of three times the section thickness will preclude sufficient cold working and prevent the embrittled condition from occurring (Ref 29, 30).

If possible, steel fabrications should use steels with a low susceptibility to strain-age embrittlement. When cold working is necessary, the guidelines and limitations contained in ASTM A 143 (Ref 31) should be observed.

Hydrogen embrittlement does not occur when ordinary carbon or low-alloy steels are galvanized. Hardened steels may become embrittled if the hydrogen picked up during pickling is not expelled during immersion in the molten zinc bath. Precautions should be taken with steels having an ultimate tensile strength exceeding 1034 MPa (150 ksi). Steels of medium-to-high strength that have been severely cold worked may have local areas that also approach this threshold limit for susceptibility to hydrogen embrittlement.

Fabrication Details for Galvanizing

The design fabrication of materials to be hot dip galvanized involve a few basic rules that are easy to apply and are necessary to the production of quality galvanized articles meeting intended functional requirements. Foremost among these rules is the interrelationship among the design engineer, fabricator, and galvanizer. Although this interrelationship becomes increasingly important with the complexity of the configuration of the material to be galvanized, most problems relating to design can be eliminated if it becomes an integral part of the design and fabrication program.

Steel Selection. As previously discussed, steel chemistry can affect the nature and extent of the zinc-iron alloys formed during galvanizing. Some steels that are commonly used for galvanized products are ASTM A36 (with <0.05% Si specified) for structural shapes, A120 for pipe, A569 for sheet, and A615 for reinforcing bar.

Combining Different Materials. Optimum galvanizing quality is seldom obtained when ferrous materials that have different chemistries, different surface conditions, or are constructed by different fabrication methods are combined. Different pickling and immersion times are required for different materials, and combinations may result in over- or undertreatment of the combined parts of the fabricated article. Different material types for which combinations should be avoided include excessively rusted items, material with machined or pitted surfaces, cast iron and steel, malleable iron, hot-rolled steel, cold-rolled steel, and reactive steels.

Castings. The cleaning of castings requires special attention. Burned-on sand from the casting process is difficult to remove by conventional HCl or H_2SO_4 pickling methods, and the use of hydrofluoric acid (HF), although effective, can be extremely dangerous to personnel. Castings should be shot- or gritblasted before delivery to the galvanizer.

Castings that consist of two or more different metals may pickle and galvanize differently. The designer and fabricator should be aware of this; abrasive cleaning may moderate these effects and provide for a more uniform coating appearance. Alternatively, the materials may be galvanized separately and assembled after galvanizing.

Surface contaminants resulting from fabrication should be removed before delivery of the material to the galvanizer, unless special arrangements have been made. Typical contaminants include welding slag and paints or other labeling compounds. Welding slag results from the use of coated welding rod. Weld slags are not removed by pickling, and if the use of uncoated rod is not possible, slags should be removed by mechanical methods. Paints or other labeling compounds, often used to identify the work, are sometimes difficult or impossible to remove by alkaline cleaning methods. Permanent markings for identification, if needed, should be punched or embossed in the steel, applied to the part as weld metal, or punched into 12-gage or thicker steel tags and wired securely to the part with heavy-gage steel wire.

Size of Material. The size of material to be galvanized is limited by the size of the galvanizing kettle and the capacity of the lifting equipment. If the material is too long or too deep to be completely immersed in the molten zinc in one dip, it may still be possible to galvanize by immersing one-half of the article in the kettle, withdrawing, then immersing the other half. By using this procedure, known as double end dipping, materials up to 75% longer than the kettle may be successfully galvanized, depending on the depth of the item and other kettle dimensions. Although double end dipping is an accepted galvanizing practice, special attention to galvanizing details and proper inspection are essential to its use on tubular items.

Threaded and Movable Parts. For threaded parts, such as nut and bolt assemblies, it is advisable to retap the nut after galvanizing to ensure a proper fit. For movable parts, such as shackles or shafts, a radial clearance of 1.6 mm ($\frac{1}{16}$ in.) is usually sufficient to allow free movement after galvanizing.

Drainage. When designing for hod dip galvanizing, consideration must be given by the designer and fabricator to providing a way for cleaning solutions and zinc to flow into, through, and out of the item so that all surfaces can be properly galvanized.

Venting of hollow objects is necessary for proper treatment of exterior and interior surfaces. More important, venting is essential for avoiding the extreme explosion hazard that can result from heating a closed or improperly vented hollow object to the galvanizing temperature. Discussions of proper venting techniques become very complex when intricate configurations are under consideration. Venting practices for various configurations, as well as additional fabrication techniques, are discussed in Ref 32, 33, 34.

Overlapping or contacting surfaces. When designing parts that are to be hot dip galvanized, it is best to avoid narrow gaps between plates, overlapping surfaces, and back-to-back angles and channels. When overlapping or contacting surfaces cannot be avoided, the edges should be completely sealed by welding; otherwise, pickling can enter and result in conditions that would permit the generation of high pressures and steam, delayed weeping, or improperly cleaned and galvanized areas.

Welding for Hot Dip Galvanizing. When materials are welded before hot dip galvanizing, the cleanliness of the weld area and the composition of the weld metal can affect the quality and appearance of the galvanized coating. Specific welding information can be obtained from the American Welding Society (Ref 35) or welding suppliers. Several welding techniques have been found to be satisfactory for materials to be galvanized:

- An uncoated electrode should be used to prevent flux deposits
- If a coated electrode is used, all flux residues must be removed, because they are chemically inert to pickling acids
- A welding process, such as metal inert gas, tungsten inert gas, or CO_2 shielded arc, should be used because virtually no slag is produced
- In the case of heavy weldments, a submerged are method is recommended
- If none of the above is available, a coated rod specifically designed for self-slagging, as recommended

by welding equipment distributors, should be selected

- A welding rod that will provide a deposited weld composition as close as possible to the parent steel should be chosen. This will prevent differential reaction rates during cleaning
- High-silicon welding rods may cause excessively high coating weights or darkened coatings

Galvanized Coatings in Corrosion Service

Protection Mechanism. Galvanized coatings protect steel in corrosion service in two ways: barrier protection and cathodic protection. Barrier protection is provided by the galvanized coating and is further enhanced by the formation of a thin, tightly adherent layer of zinc corrosion products on the coating surface. Upon initial weathering of a freshly galvanized surface, ZnO in formed, and it is converted to $ZnOH_2$ in the presence of moisture. Further reaction with CO_2 in the air results in the formation of basic $ZnCO_3$, which is relatively insoluble and impedes further corrosion. The gray patina normally associated with weathered galvanized coatings is the result of this thin layer of basic $ZnCO_3$.

Cathodic protection is provided to the steel by the fact that zinc is anodic to steel in most environments. Minor discontinuities or small areas of exposed steel resulting from drilled holes or cut edges are protected from corrosion by the sacrificial protection afforded by zinc. The corrosion products that result from this action provide further protection.

Atmospheric Exposure. Zinc, steel, and hot dip galvanized coatings have been the subject of long-term atmospheric studies conducted throughout the world (Ref 36, 37). From these studies, the behavior of these materials in a specific atmospheric environment can be reasonably estimated. An exact determination of corrosion behavior is complicated by several factors: the frequency and duration of exposure to moisture (rain, sleet, snow, and dew), the type and concentration of corrosive pollutants, the prevailing wind direction and velocity, and exposure to sea spray or windborne abrasives. All atmospheres contain some type of corrosive agent, and the concentration of these agents, as well as the frequency and duration of moisture contact, determines the corrosion rate of galvanized coatings.

Figure 10 shows the results of outdoor atmospheric-exposure tests designed to measure the protective life of galvanized coatings in various atmospheric environments. The sites were selected as representative of various broad environmental classifications: heavy industrial, moderate industrial (urban), suburban, rural, and marine. Within these broad classifications, the following factors are most significant in influencing the rate of corrosion of the galvanized coating.

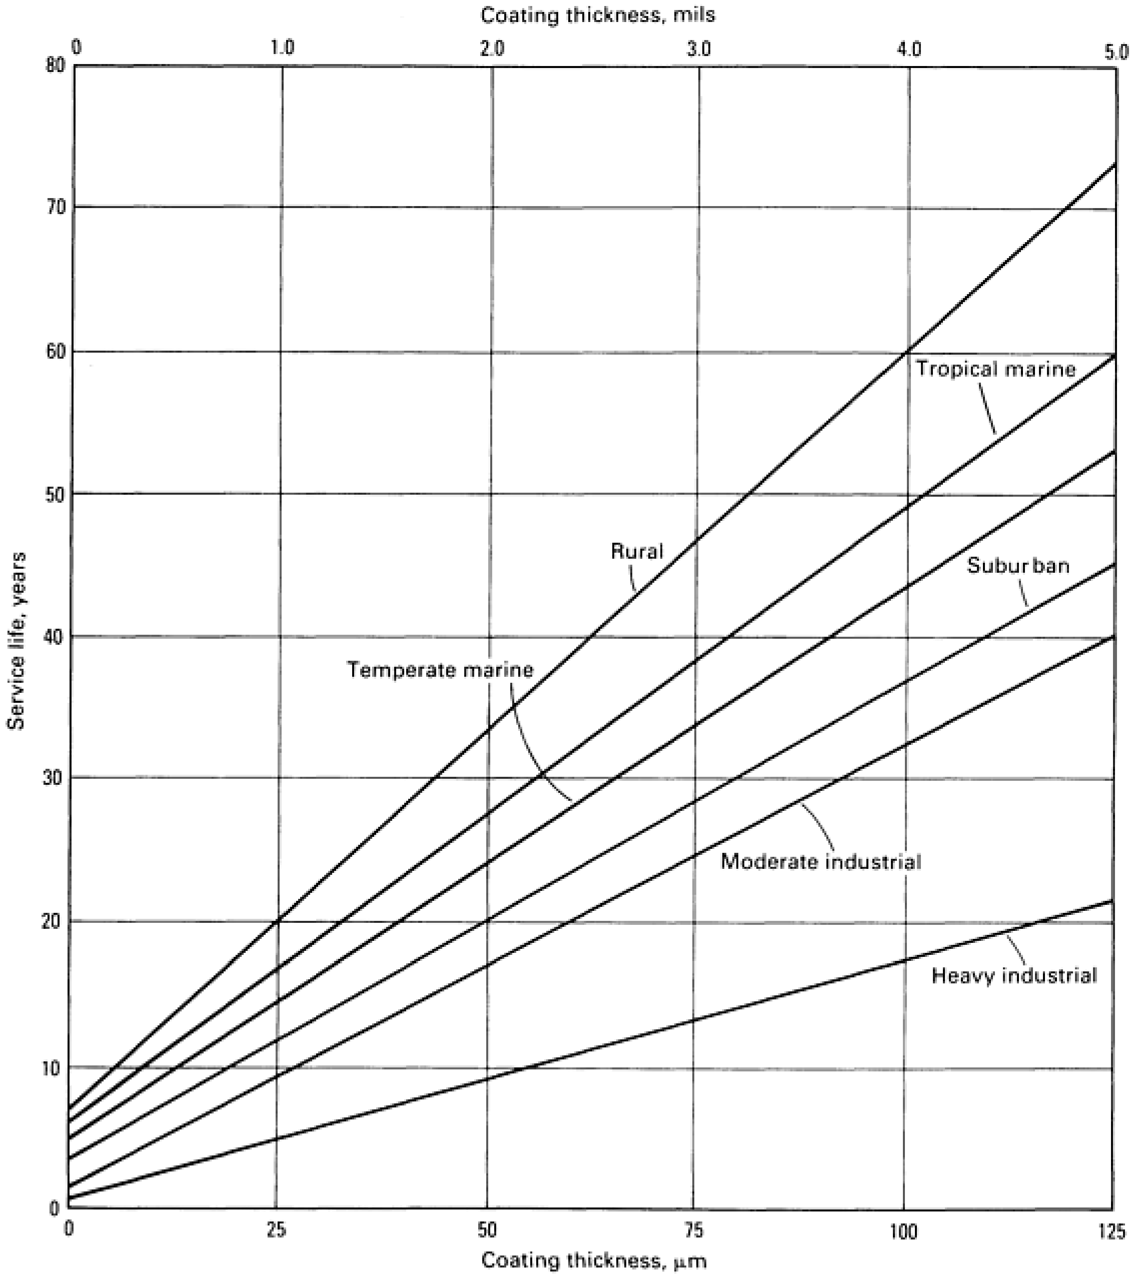

Fig. 10 Service life versus coating thickness for hot dip galvanized steel in various atmospheres. Source: Ref 36

Industrial and Urban Environments. Corrosive conditions are most pronounced in areas with highly developed industrial complexes that release sulfurous gases and corrosive fumes and mists to the atmosphere. These corrodents react with the normally impervious basic $ZnCO_3$ film to produce $ZnSO_4$ and other soluble zinc salts that, in the presence of moisture, are washed from the surface. This exposes fresh zinc to the atmospheres, and another corrosion cycle begins.

Rural and Suburban. The corrosion rate of zinc in these areas is relatively slow compared to that in industrial settings. Once the original weathering occurs, there is little in the atmosphere to convert the basic zinc salts to water-soluble compounds.

Marine Atmospheres. The corrosion rate of zinc and galvanized steel in marine atmospheres is influenced by several factors. Zinc forms a soluble corrosion product, zinc chloride ($ZnCl_2$), in marine atmospheres; therefore, the corrosion rate is influenced by salt spray, sea breezes, topography, and proximity to the coastline. For example, one investigation found

that the corrosion rate for zinc exposed 24.4 m (80 ft) from the ocean was three times that for zinc exposed 244 m (800 ft) from the ocean (Ref 37).

The corrosion product formed in a given type of atmosphere (industrial, marine, and so on) determines the corrosion rate of zinc in that atmosphere. Results from exposures in a variety of atmospheres show that zinc is 20 to 30 times more resistant to corrosion than steel is (Table 7).

Table 7 Weight losses of steel and zinc in various locations

Results are from 2-year atmospheric exposures.

Seawater and Salt Spray Performance. Table 8 gives the approximate corrosion rates of zinc in various waters, and Fig. 11 illustrates the expected service life of galvanized coatings in areas exposed to salt spray influences. Sea salts are mainly NaCl, with small amounts of calcium, magnesium, and manganese salts. Typical pH is about 8. Compared to other metals and alloys, galvanized coatings provide considerably more protection to steel than many other metals and alloys, even though the anticipated coating life is shorter in seawater and salt spray exposures than a number of others.

Table 8 Corrosion of zinc in various waters

Water type	Approximate material loss	
	µm/yr	mils/yr
Seawater		
Global oceans, average	15-25	**0.6-1.0**
North Sea	12	**0.5**
Baltic Sea and Gulf of Bothnia	10	**0.4**

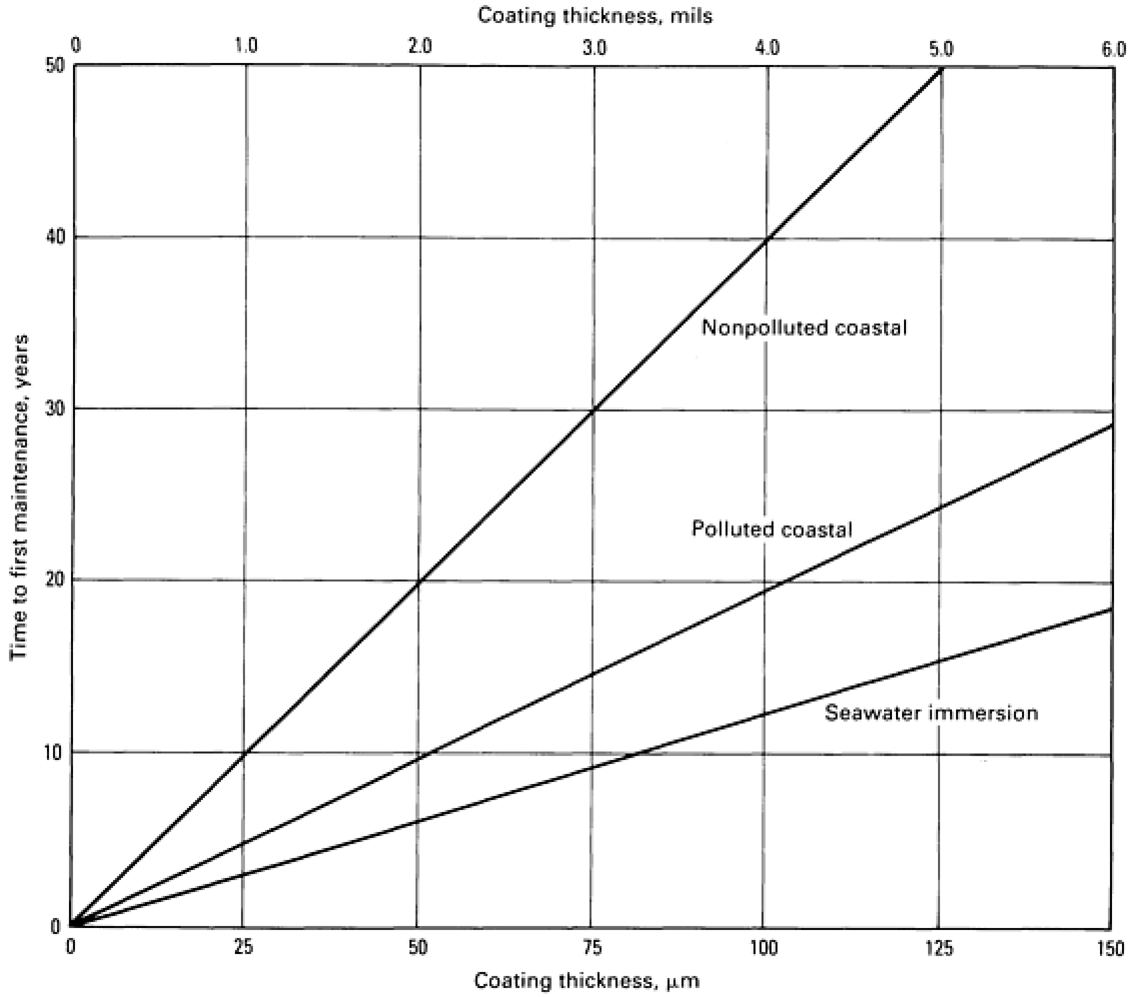

Fig. 11 Time to first maintenance versus coating thickness for hot dip galvanized coatings in seawater immersion and sea spray exposures. Source: Ref 39

Freshwater Performance. The corrosion protection mechanism of zinc in freshwater is similar to that in atmospheric exposures. The corrosion rate depends on the ability of the coating to develop a protective layer of adherent basic zinc salts. This layer denies access to the coating by oxygen and slows the rate of attack. The ability of the water to form scale depends on a number of variables, such as the pH of the water, hardness, total alkalinity, and total dissolved solids. Table 9 demonstrates the effects of various water chemistries on the relative corrosion rates of zinc.

Table 9 Corrosion of zinc in different types of water

Water type	Attacking substances	Passivating substances	Properties of corrosion products		Relative corrosion rate
			Solubility	**Adhesion**	
Hard water	Oxygen, CO_2	Calcium, magnesium	Very low	Very good	**Very low**
Seawater	Oxygen, CO_2, Cl^-	Calcium, magnesium	Low	Very good	**Moderate**
Soft with free air supply	Oxygen, CO_2	. . .	High	Good	**High**
Soft or distilled with poor air supply	**Oxygen**	**. . .**	**Very high**	**Very poor**	**Very high**

Source: Ref 38

Water Temperature. The corrosion rate of zinc in water, and therefore that of the galvanized coating, increases with temperature to between 65 and 70 °C (150 and 160 °F), at which point the rate begins to decrease (Fig. 12).

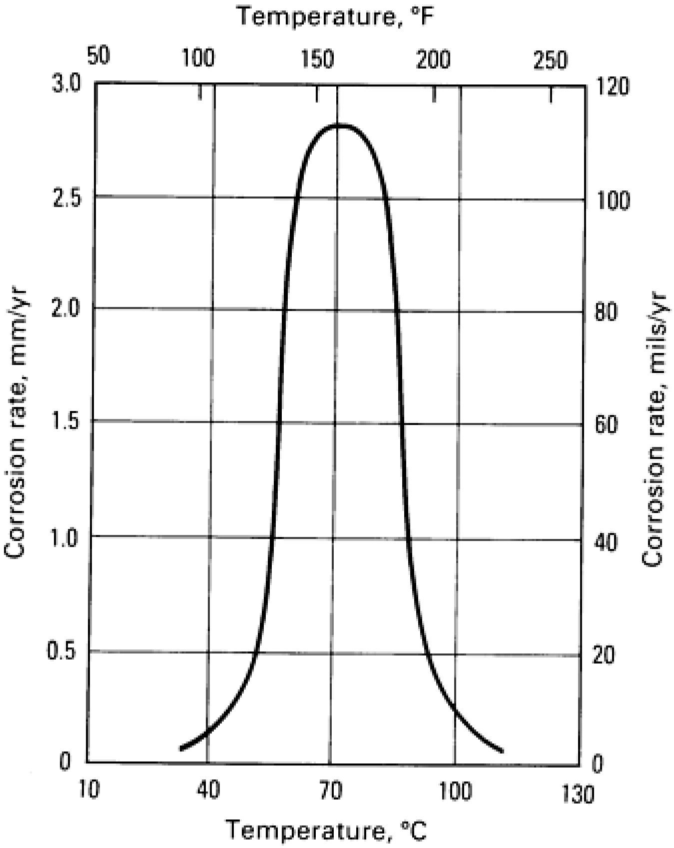

Fig. 12 Influence of water temperature on the corrosion rate of zinc in distilled, aerated water. Source: Ref 40

Water pH. Zinc is an amphoteric metal with the capacity to passivate by means of protective layers. The corrosion rate of zinc decreases with increasing pH and reaches a minimum at 12.0 to 12.5. Most waters are in the pH range of 6 to 8. The scale-forming ability of the water and the concentration of dissolved ions in the water are more important influences on the corrosion rate than pH in this practical exposure range.

Performance in Soils. The corrosion rate and performance of galvanized steels in soils are a function of the type of soil in which the steel is located. Soils can vary considerably in composition and can contain bound and unbound salts, organic compounds, products of weathering, bacteria and other microorganisms, dissolved gases (such as hydrogen, oxygen, and methane), acids, and alkalies. Soils vary in permeability, depending on the soil structure. Although the concentration of oxygen is lower in soils than in air, the CO_2 concentration is higher. Variation among soils is high, and corrosion conditions are complicated.

In general, soils in coarse, open textures are often aerated, and the performance of galvanized steel would be expected to be similar to that in air. In soils with fine textures and high water-holding capacities, such as clay and silt-bearing soils, corrosion rates are likely to be higher.

Soil resistivity is recognized as a reliable method of predicting the corrosivity of soils. High-resistivity (poor conducting) soil would be less corrosive than low-resistivity (good conducting) soil. Dry soils are poor conductors and are the least corrosive to zinc.

Performance in Contact With Other Metals. The galvanic behavior of dissimilar metals in electrical contact is a complex corrosion problem, partly because of the large number of metals used in various applications. Copper and brass in contact with zinc or a galvanized coating in a moist environment can cause rapid galvanic corrosion of the zinc. Installations that use zinc and copper or copper alloys should provide for electrical insulation between the two, and because zinc may also be attacked by dissolved copper, copper materials should be located downstream of the zinc in nonrecirculating water systems. With aluminum or stainless steel, the performance of hot dip galvanized steel is good if the environment is dry. In humid environments, isolation may be required.

Performance of Fully Alloyed Coatings. Coatings that consist entirely of iron-zinc alloy layers (without the free zinc η layer) result from the galvanizing of reactive steels. These coatings are characterized by a gray matte or mottled appearance. Fully alloyed coatings may exhibit premature rust-colored staining due to iron in the coating, but this should not be considered failure of the coating, because base metal rusting has not occurred. Fully alloyed coatings with thicknesses similar to normal coatings will give similar corrosion protection service.

High-Temperature Performance. When galvanized steel is continuously exposed to temperatures above about 200 °C (390 °F), the free zinc η layer may peel (Ref 41). The remaining alloy layers will not be affected and will continue to provide useful service life.

Joining of Galvanized Structural Members

Bolting is the most widely used method of joining galvanized steel. A number of standard galvanized fasteners are available for use with galvanized steel structural members (Table 10).

Table 10 Some standard galvanized fasteners

Description	**ASTM specification**	Grade or type
Carbon steel bolts	A 307	**Grade A, B**
High-strength bolts	A 325	**Type 1**
Transmission tower bolts	A 394	**Type 0, 1**
Quenched-and-tempered alloy steel bolts	**A 354**	**Grade BC**

Galvanized coatings in bearing-type connections, which develop shear resistance by allowing the bolts to bear on the plates, are not detrimental to performance and have along history of use--for example, in electrical utility transmission line towers. In friction-type connections, all loads in the plane of the joint are transferred by the friction developed between the connected surfaces. The load that can be transmitted is determined from the clamping force applied to the bolts and the coefficients of friction of the faying surfaces. Clean, galvanized mating surfaces have a coefficient of friction that is slightly lower than that of as-rolled steel. The coefficient of friction of galvanized surfaces can be made equal to that of uncoated steel surfaces by wire brushing or light grit blasting (Ref 40, 41). Neither treatment should be severe enough to produce breaks or discontinuities in the galvanized coating. The fatigue behavior of galvanized steel connections equals that of uncoated steel connections, regardless of whether the galvanized surfaces were wire brushed or gritblasted after galvanizing (Ref 40, 41, 42).

Welding. Zinc-coated steel can be satisfactorily welded by all common welding methods, but attention must be given to the possible generation of zinc fumes. Adequate ventilation, operator respiration units, or a fume-extracting welding unit should be used to avoid potential harmful effects. Extensive tensile, bend, radiographic, and fatigue tests show that the properties of sound metal inert gas or metallic are welds on galvanized steel are equivalent to those on uncoated steel (Ref 35).

Penetration of molten zinc into the weld metal is the primary factor in cracking of galvanized steel weldments. The crack begins at the root of the weld and may or may not extend to the surface. Recommendations to avoid fillet weld cracking include (Ref 35):

- Treat the base metal to reduce the amount of available zinc by, for example, beveling the standing plate in a tee joint at an angle of 15 to 45°
- Remove zinc from both faying surfaces by burning with an oxygen fuel gas torch or by shotblasting
- Provide a parallel gap of 1.6 mm ($\frac{1}{16}$ in.) between the weld elements
- Choose consumables that will give a low silicon content weld, for example, manganese silicate flux and 2% low manganese/low silicon electrodes for submerged arc welding. For CO_2 welding, low-silicon filler wire gives freedom from zinc penetration cracking, but causes a small amount of porosity. For shielded arc welds, use a low-silicon electrode and a rutile covering

Weld porosity can occur because of the volatilization of zinc during welding. Porosity can be reduced by making adequate provision for the escape of gases evolved during welding. Normal porosity does not reduce the static tensile strength below that specified for satisfactory low-carbon steel weld metal, but it will affect the fatigue strength of a fillet weld.

Weld Damage Repair. Galvanized materials damaged by field welding can be touched in with an organic or inorganic zinc-rich paint. Organic paint does not require a high degree of surface preparation and dries quickly. The paint must have

a zinc dust content of 95% and should be applied in several coats to a thickness of three times the galvanized thickness to provide equivalent protection.

Low-melting zinc-cadmium or zinc-tin-lead alloy rods can also be used for repair. The rod is heated to about 330 °C (625 °F) with an oxyacetylene torch, and the melted alloy is rubbed and spread over the damaged area. This gives equal protection, but is more expensive than paint touch up. The damaged area can also be zinc metallized by thermal spraying, but the equipment requirements may prevent convenient field use. Additional information on repair techniques is given in Ref 43.

Painting Galvanized Steel

Galvanized coatings, when used without further treatment, offer the most economical corrosion protection for steel in many environments. The galvanized coating makes an excellent base on which to develop a paint system. Painting of galvanized steel is desirable for aesthetics, as camouflage, as warning or identification markings, to prevent bimetallic corrosion, or when the anticipated environment is particularly severe (see the article "Organic Coatings and Linings" in this Volume for supplementary information on painting for corrosion protection).

In corrosive atmospheres, a duplex system of galvanized steel top coated with paint has several advantages that make it an excellent system for corrosion prevention:

- The life of the galvanized coating is extended by the paint coating
- The sacrificial and barrier properties of the zinc coating are used if a break occurs in the paint film
- Undercutting of damaged paint coatings, a major cause of failure of paints on steel, does not occur with a zinc substrate (Fig. 13)
- Surface preparation of a weathered zinc surface for maintenance painting is easier than that for rusted steel.

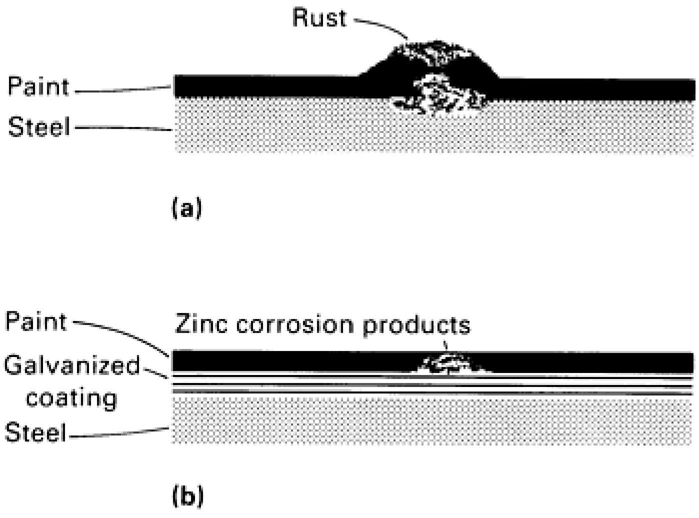

Fig. 13 Illustration of the mechanism of corrosion for painted steel (a) and painted galvanized steel (b). (a) A void in the paint results in rusting of the steel, which undercuts the paint coating and results in further coating degradation. (b) A void in the coating of a painted galvanized steel is sealed with zinc corrosion products; this avoids the undercutting seen in (a) and prevents further deterioration of the painted coating.

Synergistic Effects of Galvanized and Painted Systems. The galvanized coating prevents rusting of steel by acting as a barrier against the environment and by sacrificially corroding to provide cathodic protection. Painting the galvanized coating extends the service life of the underlying zinc because the barrier property of the paint delays the reaction of zinc with the environment. If a crack or other void occurs in the paint and exposes the galvanized coating, the zinc corrosion products formed tend to fill and seal the void; this delays further reaction.

When painted steel is exposed to the environment, rust forms at the steel/paint interface. Because rust occupies a volume several times that of the steel, the expansion resulting from rusting leads to rupture of the steel/paint bond. Further, rust is porous; it accumulates moisture and other reactants, and this increases the rate of attack on the steel. The result is undercutting, flaking, and blistering of the paint film, leading to failure of the paint coating (Fig. 13). Zinc corrosion products occupy a volume only slightly greater (20 to 25%) than zinc; this reduces the expansive forces and conditions that lead to paint failure.

A coating system consisting of painted galvanized steel provides a protective service life up to 1.5× that predicted by adding the expected lifetimes of the paint and the galvanized coating in a severe atmosphere (Ref 44). This is demonstrated in Table 11. The synergistic improvement is even greater for mild environments (Ref 45, 46).

Table 11 Synergistic protective effect of galvanized steel/paint systems

(a) Service life is defined as time to about 5% red rust.

Paint adhesion is the primary concern in painting galvanized steel. The surface of the zinc is nonporous and does not allow mechanical adhesion of the paint. Surface contaminants, such as oils, waxes, or postgalvanizing treatments, also effect adhesion. A fresh zinc surface is reactive to certain paint ingredients, such as fatty acids; this can produce zinc soaps and disrupt the zinc-paint bond.

Galvanized coatings can be successfully painted immediately after galvanizing or after extended weathering. The deliberate use of weathering is not recommended, because weathering may not be uniform, the time required is long (6 to 12 months), hygroscopic impurities can form that may be difficult to remove, and there is exposure to atmospheric pollutants.

Chemical etchants, such as acids or copper sulfate, should not be used. The action of these chemicals is difficult to control, surface preparation may be nonuniform, and the galvanized coating could be damaged if allowed to remain in extended contact with the chemicals. Long-term adhesion will suffer with this type of treatment, although initial adhesion may be obtained.

Mechanical roughening of the zinc surface through the use of a light blast can provide a good surface for painting. However, careful control of the blast pressure and flow rate must be exercised to avoid excessive removal of the galvanized coating.

Initial adhesion of the paint can be achieved through the use of a pretreatment primer to provide an adequate base for further coating. Long-term adhesion is obtained by the selection of top coat that is compatible with the primer and galvanized steel.

Pretreatment Methods. As with all painting operations, the surface to be painted must be free of contaminants that could affect the adhesion of the paint or the appearance of the painted article. Non-oily substances can be removed by brushing or scrubbing, then rinsing with water. Oily materials should be removed with a solvent, such as naphtha, turpentine, or mineral spirits, followed by a final wiping with clean cloths and clean solvent, to avoid spreading oil films on the surface.

Two-component wash primers meeting Steel Structures Painting Council (SSPC) specification SSPC-Paint 27 are ideal pretreatments. The primer is applied by spraying in thin coasts according to the recommendations of the manufacturer. The freshly prepared primer should be applied to a dry film thickness of 7.6 to 13 μm (0.3 to 0.5 mils).

Finish Coating. The primed material should be finish coated as soon as possible after priming treatment. Wash primers are moisture sensitive, and the vehicle may gel under high-humidity conditions and lose adhesion. The primer usually dries in 15 to 30 min, and it is dry enough to recoat after 30 to 60 min. Almost all paints will adhere to the wash primer.

Direct Application Systems. A more convenient alternative to natural weathering or pretreatment of the galvanized surface is the use of a paint system directly compatible with the surface. Alternatives are discussed below.

Zinc Dust-Zinc Oxide Paints. Federal specification TT-P-641G describes three types of zinc dust-zinc oxide paints. All three contain the same pigmentation of 4 parts zinc dust to 1 part zinc oxide; the only variation is in the paint base material. Types 1 and 2 (linseed oil and alkyd resin bases, respectively) are recommended for general use, and type 3 (phenolic resin base) is especially formulated for severe moisture exposure or underwater service. All are useful as primers for adherence and are satisfactory as finish coats. If color is required, the top coat can be pigmented. Other compatible top coats may be used, but those with very strong solvent systems should be avoided, particularly if used before proper aging of the base film.

Portland Cement in Oil Paints. These paints are compatible with either fresh or weathered galvanized coatings. Although they tend to be brittle, adherence is excellent. They are not as versatile as the zinc dust-zinc oxide paints and are usually limited to applications in which a high gloss is not required and an oil base is suitable. They are available in a wide choice of colors.

Other Direct Application Systems. Newer paint systems that have been successfully used on direct application to galvanized steel include epoxy resin based paints, chlorinated rubber based paints, vinyl copolymer based paints, coal tar epoxy paints, and acrylic latex emulsion paints.

Economics of Hot Dip Galvanizing

Corrosion control results in a negative cash flow for the owner of any facility. In selecting a system for corrosion control, the economic consequences of the selection should be determined. Initial cost should not be the determining factor in selecting a system. Instead, the desired service life of the project should be reasonably estimated, and the life cycle cost of several systems should be evaluated to determine the most economical system for the particular project.

A number of models have been developed for the economic evaluation of corrosion protection systems (Ref 47, 48, 49). The projected structure life, inflation and discount (cost of capital) rates, number of years in the maintenance cycle, estimated costs for future maintenance, and original system costs must be determined based on discounted cash flow techniques. In the private sector, tax and investment incentives must also be considered. Table 12 illustrates a simple analysis that does not take tax or investment incentives into account. Although the initial galvanizing cost is set at 25% above the paint cost, this is often not the case; in reality, the cost of galvanized steel is frequently lower than that of painted steel. More information on the use of engineering economy is available in the article "Corrosion Economic Calculations" in this Volume.

Table 12 Discounted cash flow analysis of galvanized versus painted steel

The time value of money is an important consideration when analyzing the economics of different coatings. This example assumes an inflation rate of 4%, a discount rate of 10%, a repaint cycle of 10 years, and an expected service life of 50 years. No tax or investment considerations are made. A repaint cost of 75% of the original cost is assumed, and the galvanizing cost is 25% greater than the paint cost.

Year	**Galvanizing**		Paint	
	Original cost	**NPW[(a)]**	**Original cost**	NPW[(a)]
0	$1.25	$1.25	$1.00	**$1.00**
10	. . .	. . .	. . .	**$0.43**
20	. . .	. . .	. . .	**$0.24**
30	. . .	. . .	. . .	**$0.14**
40	. . .	. . .	. . .	**$0.08**

Selected Applications of Hot Dip Galvanized Steel

Hot dip galvanized coatings are found in a wide variety of applications requiring long-term maintenance-free corrosion protection. The examples in this section will demonstrate the scope of galvanized steel use.

Bridges. The first all hot dip galvanized bridge in the United States was erected in 1966 at Stearns Bayou, Ottawa County, MI. The bridge is 128 m (420 ft) long and has a 9.1-m (30-ft) wide roadway with a 1.5-m (5-ft) walkway on each side. All the components of this bridge were hot dip galvanized. To avoid possible effects from road salting, telescoping splash plates in the joints were installed to divert deck drainage away from the beams.

When inspected in 1986, the average coating thickness on stringers and diaphragms was 112 μm (4.4 mils), which is enough to last another 60 to 100 years. The bearing pads, the most deteriorated component of the bridge, showed a coating thickness of 90 μm (3.5 mils). The article "Corrosion in Structures" contains detailed information on the use of hot dip galvanized steel structural members.

Pulp and paper mills contain a number of areas that, in the absence of corrosion protection, would rapidly deteriorate because of exposure to various chemicals. A paper mill in the northwest United States used galvanized structural steel pipe supports, ladders, cages, and miscellaneous steel items in the stock tank, black liquor, lime kiln, and paper machine areas. Galvanized steel was used during the original construction 19 years ago and for subsequent expansions. All of the galvanized steel is located outside in a humid environment subject to salt spray. When inspected in 1985, coating thicknesses ranged from 90 to 160 μm (3.5 to 6.5 mils). More information on materials of construction for pulp and paper mills is available in the article "Corrosion in the Pulp and Paper Industry" in this Volume.

Recreation. The Gettysburg Observation Tower overlooks the historic Gettysburg battle-ground in Gettysburg, PA. The structure was erected in 1974 with galvanized pipes and rolled-steel sections. An inspection in 1984 revealed coating thicknesses of 100 to 150 μm (4 to 6 mils); this is above the specification for newly galvanized material. Service life can be expected to be 100 years or more, assuming the environment does not change appreciably.

Utility Industry. A galvanized substation located near Knoxville, TN, and owned by the Tennessee Valley Authority was constructed in 1936 to handle 100,800 kW of electricity produced by a nearby dam. Substation structures are of a bolted lattice construction. The minimum coating thicknesses measured in a recent inspection were 70 μm (2.75 mils) on lattice angles and 50 μm (2.5 mils) on bolt heads. Based on estimations of the original coating weight, this substation will last another 30 years before maintenance coating will be required.

Other Applications. Hot dip galvanized steel coated by the batch process is used in oil refineries and petrochemical industries and for miscellaneous highway uses, such as guard rail, light and sign standards, and fencing. The coating has found extensive use in water and wastewater treatment plants, both in atmospheric and immersion service. Such applications of electrical utility transmission towers, microwave transmission stations, pole line hardware, cooling towers and cooling tube bundles, nuts, bolts, and various fasteners all involve extensive use of galvanizing.

Galvanized reinforcement bars, ties, and lintels for concrete and masonry reinforcement and support provide long-term corrosion protection in vital areas that are not normally visible. The use of galvanized materials in concrete reinforcement and masonry applications is ideal, because the normal pH of these materials before setting is about 12 to 12.5, which corresponds to the pH range in which corrosion of zinc is at a minimum.

Galvanizing Specifications

Galvanized coatings produced by the hot dip (batch) process are covered by numerous specifications. In addition to those already discussed in the text, the following are pertinent specifications under the authority of ASTM:

- A 123 "Standard Specification for Zinc (Hot-Galvanized) Coatings on Products Fabricated from Rolled, Pressed, and Forged Steel Shapes, Plates, Bars, and Strip"
- A 153 "Standard Specification for Zinc Coating (Hot Dip) on Iron and Steel Hardware"
- A 384 "Standard Recommended Practice for Safeguarding Against Warpage and Distortion During Hot-Dip Galvanizing of Steel Assemblies"
- E 376 "Standard Recommended Practice for Measuring Coating Thickness by Magnetic-Field or Eddy-Current (Electromagnetic) Test Methods"

Porcelain Enamels

Introduction

PORCELAIN ENAMELS are glass coatings that are applied primarily to fabricated sheet steel, cast iron, or aluminum parts to improve appearance and to protect the metal surface. Porcelain enamels are distinguished from other ceramic coatings by their predominantly vitreous nature and the types of applications for which they are used, and they are distinguished from paint by their inorganic composition and the fusion of the coating matrix to the substrate metal. Porcelain enamels of all compositions are matured at 425 °C (800 °F) or above. Because they offer only barrier protection to the metal substrate, porcelain enamel coatings must be free from defects and coating discontinuities to provide optimum protection.

The most common applications of porcelain enamels include major appliances, water heater tanks, sanitary ware, and cookware. Porcelain enamels are also used in a wide variety of applications ranging from chemical-processing vessels, heat exchangers, agricultural storage tanks, piping and pump components, and barbeque grills to architectural panels, signing, specially executed murals, and microcircuitry components. Table 1 lists some additional applications for porcelain enamels. Normally, porcelain enamels are selected for products or components where there is a need for one or more of the special service requirements that porcelain enamel can provide, such as chemical resistance, corrosion protection, weather resistance, specific mechanical or electrical properties, appearance or color needs, cleanability, or thermal shock capability.

Table 1 Some applications for porcelain enamels

Industrial products
Chemical reactors
Commercial heat exchangers
Food-processing vessels
Induction heating coils
Ion gun parts
Jet engine components
Microcircuitry boards
Mufflers
Transformer cases
General products
Camping equipment

Cooking and serving utensils
Grills
Hospital ware
Kitchen cabinets
Lighting reflectors
Meat scales
Silos
Tabletops
Telephone booths
Venetian blinds
Household appliances
Air conditioners
Broilers
Dishwashers
Freezers
Home laundry equipment
Ranges, gas and electric
Refrigerators
Space heaters
Water heaters

Architectural
Awnings
Baseboards
Chalkboards
Exterior buildings panels
Floor, roof, and wall tiles
Tunnel panels
Wall murals
Plumbing fixtures
Bathtubs and lavatories
Kitchen sinks
Laundry tubs
Tub enclosures
Signs
Advertising signs
Highway and traffic signs
House numbers
Street signs

Types of Porcelain Enamels

Porcelain enamels for sheet steel and cast iron are classified as either ground-coat or cover-coat enamels. Ground-coat enamels contain oxides that promote adherence of the enamel to the metal substrate. Cover-coat enamels are applied over ground coats to improve the appearance and properties of the coating. Cover coats can also be applied directly to properly prepared decarburized steel substrates. The color of ground coats is limited to various shades of blue, black, brown, and gray. Cover coats, which may be clear, semiopaque, or opaque, can be pigmented to take on a great variety of colors. Colors can also be smelted into the basic coating material.

For aluminum, neither ground coats nor adherence-promoting oxides are required. Single-coat systems are used for most applications. When two coats are desired, the first coat can be of any color. Porcelain enamels for aluminum are usually transparent and can be pigmented and opacified inorganically to produced the desired appearance.

The basic material of the porcelain enamel coating is called frit. Frit is a special glass of small friable particles produced by quenching a molten glassy mixture. Because porcelain enamels are usually designed for specific applications, the compositions of the frits from which they are made vary widely.

Enamel Frits for Sheet Steel. Alkali borosilicates are often used as ground coats on sheet steel. Their compositions vary with the intended application of the enameled product. For example, acid resistance is obtained by the addition of titanium dioxide (TiO_2) and a large increase in silicon dioxide (SiO_2) with a corresponding decrease in boron trioxide (BO_3). The resistance of the enamel to alkalies or water can be improved by adding zirconium oxide, usually as zircon, to the frit and by maintaining a high content of silicon dioxide. Table 2 lists compositions of frits for a regular porcelain enamel and of alkali-, acid-, and water-resistant ground-coat enamels for sheet steel.

Table 2 Melted-oxide compositions of frits for ground-coat enamels for sheet steel

Constituent	Composition, wt%			
	Regular blue-black enamel	**Alkali-resistant enamel**	**Acid-resistant enamel**	Water-resistant enamel
SiO_2	33.74	36.34	56.44	**48.00**

Na_2O	16.74	14.99	16.59	**18.48**
K_2O	0.90	1.47	0.51	**. . .**
Li_2O	. . .	0.89	0.72	**1.14**
CaO	8.48	4.08	3.06	**2.90**
BaO	9.24	8.59	. . .	**. . .**
ZnO	. . .	2.29	. . .	**. . .**
Al_2O_3	4.11	3.69	0.27	**. . .**

ZrO_2	. . .	2.29	. . .	**8.52**
TiO_2	. . .	. . .	3.10	**3.46**
CuO	. . .	. . .	0.39	**. . .**
MnO_2	1.43	1.49	1.12	**0.52**
NiO	1.25	1.14	0.03	**1.21**
Co_3O_4	0.59	1.00	1.24	**0.81**
P_2O_5	1.04	. . .	. . .	**0.20**
F_2	**2.32**	**2.33**	**1.63**	**1.94**

Weather resistance is usually a function of acid resistance. Porcelain enamels for outdoor use are made from various types of frits that produce the resistance and color desired. Resistance to thermal shock and high temperature is obtained by controlling the expansion of the glass coating.

Cover coats for sheet steel are applied over ground coats or directly to properly prepared decarburized steel. Electrostatic dry-powder cover coats can be applied over an electrostatic dry-powder ground coat, and the entire system can be matured in a single firing.

Cover-coat enamels made from titania-opacified frits are generally quite acid resistant; even in amounts too small to impart any opacity, titania imparts acid resistance. For alkali resistance, zirconium oxide is a desirable constituent.

Enamel Frits for Cast Iron. Compositions of frits for enamels for cast iron vary depending on whether the frit is applied by the dry process (the article to be coated is heated above the firing temperature, and the enamel is applied to the hot metal as a dry powder) or the wet process (an enamel slip is applied to the metal at ambient temperatures, dried, and fired). Dry-process enamels are commonly used for large cast iron fixtures because of their brilliance and ability to cover small surface irregularities. Acid resistance is imparted to these enamels by reducing the alumina content, by increasing silica, and by adding up to about 8% titanium dioxide. Dry-process enamels are seldom used in applications requiring resistance to severe thermal shock.

Ground coats are usually necessary to fill surface voids in castings. Ground coats for wet-process enamels are often mixtures of frit, enamel reclaim, and refractory raw material used at very low application weight. Ground coats for dry-process enamels are applied by the wet process and are fused to thin, viscous coatings that protect the casting surface from excessive oxidations while it is heated to enameling temperature.

Enamel frits for aluminum are usually based on lead silicate and on cadmium silicate, but they can also be based on phosphate or barium. The high-lead enamels for aluminum have a high gloss, good acid and weather resistance, and good mechanical properties. The phosphate enamels generally are not alkali resistant or water resistant, but may have good acid resistance. They melt at relatively low temperatures and are useful in many applications. The barium enamels are not as low melting as the lead or phosphate glasses, but they do have good chemical durability.

Surface Preparation

The adhesion and appearance of porcelain enamel depend on closely controlled cleaning and roughening of the metal surface. Complete removal of oil, sand, drawing compounds, weld oxide, and other surface contaminants is required.

Steel can be prepared by chemical or mechanical procedures. Special steels for porcelain enameling are discussed in the article "Selection of Steel Sheet for Porcelain Enameling" in Volume 1 of the 9th Edition of *Metals Handbook* and in the article "Sheet Formability of Steels" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of the *ASM Handbook*

Preparation of Steel

Chemical treatment usually involves the use of mechanized equipment in production operations. The parts to be enameled are dipped in or sprayed with a series of solutions.

When special low-carbon decarburized steel is direct-cover-coat enameled, it must be etched to remove a minimum of 22 g/m^2 (2 g/ft^2) of metal surface, and a nickel deposit of 0.9 to 1.3 g/m^2 (0.08 to 0.12 g/ft^2) of surface is required. Ferric sulfate ($Fe_2(SO_4)_3$) etching solution is often used to remove the required amount of metal surface; this results in a better bond than that obtained after etching with sulfuric acid (H_2SO_4).

A modification of the $Fe_2(SO_4)_3$ system--called oxy-acid--is also used. Oxy-acid etchant solution is a mixture of H_2SO_4, $Fe_2(SO_4)_3$, and ferrous sulfate ($FeSO_4$). The reactions involved are the same as with the $Fe_2(SO_4)_3$ system. The advantage of this system is that all of the reactions take place in one etching tank; two tanks are required for the $Fe_2(SO_4)_3$ method.

Metal preparation for "no nickel/no pickle" enameling requires at least the same amount of cleaning as conventional metal preparation does for conventional enamel. There is, however, no acid etching or nickel deposition required with the "no nickel/no pickle" system. One advantage of using this system is the reduction in wastewater treatment problems.

Mechanical preparation consists of abrasive blasting with steel shot or steel grit. Grit- or shotblasting is used on parts designed without pockets or crevices when configuration and thickness permit blasting without distortion. The flat areas of parts made with sheet steel thinner than 1.5 mm (0.06 in.) distort excessively when cleaned by this method.

Abrasive blasting is especially useful for preparing hot-rolled steel and parts that are to be enameled on one side only. The process is also used for preparing large parts and when enamels with poor bonding characteristics are used. Before blasting, oil and drawing compounds are removed by alkaline cleaning or by heating at 425 to 455 °C (800 to 850 °F) to burn off the organic contaminants.

Preparation of Cast Iron and Aluminum

Cast iron is prepared by blasting to remove adhering mold sand and the thin surface layer of chilled iron. Because the surface contains more combined carbon than is present in the remainder of the casting, the surface layer must be removed to prevent excessive evolution of gas during firing of the enamel.

Quartz sand is commonly used for abrasive cleaning of cast iron; however, steel shot, steel grit, and chilled cast iron grit propelled centrifugally from rotating wheels are generally used for cleaning sanitary ware. Zircon sand and fused alumina grit are used for special purposes.

After blasting, the casting is inspected for cracks, sand holes, slag holes, blow holes, fins, and washes. Cracks and larger holes are repaired by welding. Fins and washes are removed by grinding, and the repaired casting is blasted a second time before enameling.

Aluminum. The preparation of heat-treatable aluminum alloys for porcelain enameling involves the removal of soil and surface oxide and the application of a chromate conversion coating. Final drying removes all surface moisture; drying must be accomplished without contaminating the cleaned surface of the aluminum. Parts made of nonheat-treatable aluminum alloys require only the removal of soil, which can be done by alkaline cleaning or vapor degreasing.

The Porcelain-Enameling Process

Several basic methods are used to apply porcelain enamels to the base metal. These include dipping, flow coating, electrodeposition, manual spray, electrostatic spray, and dry-powder spray. The best method of application for a particular part is determined by quantity and quality requirements, the type of material being applied, units produced per hour, capital investment, labor cost, and, ultimately, part cost.

Application techniques can be manual or mechanized. Mechanization is used for high-volume part requirements of the same or similar shape. Hand application is necessary if a variety of parts must go through the same process system.

Regardless of the method of application, good porcelain-enameling techniques must be used to ensure uniform coverage in the areas requiring porcelain enamel protection. Excessive thickness, beads, or pooling of the porcelain enamel reduce product quality, and the product is more prone to chipping. Areas at which the coating is too thin do not receive the full protective and decorative capabilities of the porcelain enamel.

Dipping is widely used as a method of applying porcelain enamel, particularly when both sides of the parts require coverage. This method can be used for both ground-coat and cover-coat applications. Dipping is performed by immersing the part in the prepared porcelain enamel slip (a suspension of finely divided ceramic material in liquid), then withdrawing it and allowing the excess material to drain from the part. It is sometimes necessary to rotate, tilt, spin, or shake complex shapes to ensure uniform coverage. In areas where excessive porcelain enamel slip is retained on the part after draining, the excess should be removed by siphoning or wiping before the part is dried. Dip porcelain enamels are normally applied at thicknesses of 50 to 100 μm (2 to 4 mils). The AISI 300-series stainless steels are the preferred materials for dipping equipment.

In flow coating, the porcelain enamel slip is flowed onto the surface of the part. The process is applicable to high-volume continuous operations for parts requiring the same porcelain enamel. In automatic flow coating, the parts are placed on hangers at the correct angle for draining and are carried by conveyor through the flow coating chamber. To ensure complete coverage, the porcelain enamel slip is pumped at high volume and low pressure though nozzles that are directed at various areas of the part.

Another version of automatic flow coating involves the use of a constant-head tank to supply slip at a constant velocity to headers and nozzles that flood parts with slip as they are conveyed though the flow-coat chamber. The advantage of this system is that the flow to the nozzles is constant and not subject to variations present in pumped systems.

Automated flow coating is favored over hand dipping because it offers higher rates of production, improved coating quality, and reduced cost of the applied film. Control of the porcelain enamel slip and proper operation of the machine are important functions of flow coating. It is common practice to check the specific gravity and pickup of the porcelain enamel slip three to four times each hour. All parts of the flow-coating machine that contact the porcelain enamel slip should be constructed of 300-series stainless steel.

Spraying of the porcelain enamel slip is done primarily for one-side coverage. It is also used to reinforce enamel bisque (the dried, unfired coating) and to repair enameled surfaces. Spraying is ideal for parts that are too large for hand or mechanical manipulation, particularly where service and appearance requirements do not permit drain lines, beading, or buildup of the porcelain enamel. Spraying is the method that is most commonly used to apply porcelain enamels to aluminum; thicknesses of 65 to 90 μm (2.5 to 3.5 mils) are desirable.

Wet electrostatic spraying of porcelain enamel is used to reduce losses in material by charging the porcelain enamel slip during atomization to a potential of 100,000 to 120,000 V. The electrostatically charged droplets are attracted to the grounded parts being sprayed. A well-operated electrostatic unit can deposit up to 85% of the sprayed material on the part as compared to 30 to 50% in conventional spraying operations.

Electrostatic powder spraying is another method that can be used when many parts are being produced that require the application of the same porcelain enamel. The parts must be of a configuration that can be properly and evenly coated by this process. When these conditions are met, this is a very efficient method of applying porcelain enamel. Up to 99% of the material is used, with little or no direct labor required for the application operation. Smooth-running conveyors are required with this method of application to prevent loss of powder prior to firing the parts.

Powder is delivered to the spray guns from a feeder unit where it is diffused by clean compressed air into a fluidlike state. The fluidized powder is then siphoned by the movement of high-velocity air flowing through a venturi and is propelled through powder feed tubes to the spray gun. The powder feeder provides a steady, controlled flow of powder to the guns. Independent control of powder and air volume ensures the proper ratios to provide the desired thickness coverage on the product.

The powder is propelled toward the workpiece in the form of a diffused cloud. A high-voltage low-amperage power unit supplies current to the charging electrode, and this causes the powder to seek out and attach itself to the grounded workpiece.

The recovery equipment booth serves to collect and return the powder that is not held on the workpiece. The powder moves through a closed-loop system with the use of filters and final filters; thus, none of the airborne powder escapes into the environment.

Electrodeposition is another process that can be used to apply enamel to steel. The process uses a series of tanks in which the parts are submerged, and the enamel is deposited electrophoretically. This process is basically limited to direct-on enameling, but can be considered for two-coat/one-fire applications. The main advantages of this system are the very uniform appearance and the exceptionally thin enamel layers.

Drying and Firing. Parts coated with porcelain enamels are dried (if the enamel was applied by a wet process) and fired. Drying permits the application of an additional coating of enamel, if required, and allows the parts to be handled more easily. Parts are either air dried or dried with radiant or convection dryers. Convection drying consists of gradual heating of the parts to 120 °C (250 °F); cycle times range from 2 to 5 min. The coating is still wet during the initial stages of drying, so drying must be accomplished in an atmosphere free of dirt, scale, or dust. The parts are then fired in either continuous or batch-type furnaces at temperatures of about 425 °C (800 °F) for steel parts and 525 to 550 °C (980 to 1020 °F) for aluminum. More information on the porcelain-enameling process is available in the article "Porcelain Enameling" in *Surface Engineering,* Volume 5 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Process Variables

The thickness of the applied layer of porcelain enamel, the firing time, and the firing temperature markedly affect the properties of the coating. Increasing the thickness of the coating increases the resistance to burn-off and produces truer colors; however, thin coatings have the greatest flexibility.

Coating Thickness. The optimum thickness of porcelain enamel depends on the substrate metal and the service requirements of the part. On aluminum, porcelain enamel is applied to produce a fired enamel thickness ranging from about 65 to 125 μm (2.5 to 5 mils). A tolerance of ±13 μm (±0.5 mil) is required in order to maintain uniform opacity for a white enamel coating 115 μm (4.5 mils) thick.

On sheet steel, a ground coat about 50 to 100 μm (2 to 4 mils) thick is used to promote adhesion. To cover the ground coat, a very opaque white or pastel cover coat about 100 to 150 μm (4 to 6 mils) thick is required. Thus, a two-coat system on these products has a thickness ranging from 150 to 255 μm (6 to 10 mils).

Coatings for cast iron products are much thicker than those for sheet steel or aluminum. Dry-process coatings on cast iron products such as sanitary ware range from 1020 to 1780 μm (40 to 70 mils) in thickness. Coatings applied by the wet process are thinner than dry-process coatings; wet-process coatings range in thickness from 255 to 635 μm (10 to 25 mils).

Coating thicknesses for hot-water tanks normally range from 150 to 230 μm (6 to 9 mils), with 150 μm (6 mils) a generally accepted minimum thickness. Heat-exchanger surfaces, depending on end use, are sometimes double coated for added durability.

The thickness of the porcelain enamel on a large part of simple configuration can be closely controlled when application is by a mechanical spraying system that is adapted to the part. For example, mechanically applied porcelain enamel on curved silo panels measuring 2 × 3 m (6 × 9 ft) can be maintained within ±13 μm (±0.5 mil); however, when application is by hand spraying, the variation in enamel thickness is ±50 μm (±2 mils).

An enamel thickness of 65 to 180 μm (2.5 to 7 mils) is desirable for aluminum architectural panels. When white or light-colored enamel is used, however, the enamel thickness ranges above 75 μm (3 mils) in order to produce acceptable opacity. Two coats with a total thickness of about 125 μm (5 mils) result in more uniform opacity than one coat that is 125 μm (5 mils) thick. Additional details are available in Ref 1.

Firing Time and Temperature. Firing of porcelain enamel involves the flow and consolidation of a viscous liquid and the escape of gases through the coating during its formation. Within limits, time and temperature are varied in a

compensating manner. For example, similar properties and appearances develop when liners for household refrigerators are fired at 805 °C (1480 °F) for 2 $\frac{1}{2}$ min or at 790 °C (1450 °F) for 4 min. In all cases, there is a minimum practical temperature for the attainment of complete fusion, acceptable adherence, and desired appearance. Most ground-coat enamels for high-production steel parts exhibit acceptable properties over a firing range of 55 °C (100 °F) at an optimum firing time. However, control within 11 °C (20 °F) is ordinarily maintained to produce uniform appearance and allow interchangeability of parts. As the combined effects of firing time and temperature increase, resulting in more thorough firing, up to a maximum, the following conditions occur:

- Colors shift dramatically, particularly reds and yellows. In general, white and colors shift toward yellow. Usually, furnace temperature is changed to achieve minor adjustments in color matching
- Gloss of the enamel coating increases
- Chemical resistance of the enamel coating increases
- Gas bubbles are eliminated
- Enamel coating becomes more dense and brittle and less resistant to chipping
- Maximum adherence is attained in the optimum portion of the firing range

Color Matching and Control. In color matching, coloring oxides are usually used. Although preblended oxides for a specific color are available, they are more difficult to adjust. In most cases, two or three oxides are sufficient to match any specific color. Usually, the proper color intensity is obtained first; adjustment is then made for the desired color shade. Cadmium-sulfoselenide pigments, for red and yellow, are generally used with cadmium-stabilized clear frits.

Color stability can be adversely affected by improper mill additions. However, a color with only fair stability can be improved by the proper mill additions, and minor color adjustments, particularly white, are possible.

Sometimes, gum must be used to control bisque strength; sodium nitrite and urea are used to control tearing. Because these additions have a marked effect on some colors, they should be used in initial color matching.

Finer grinding reduces the intensity of the color. It is imperative that the fineness of the milled color be controlled within specific limits. Milling is usually stopped before completion to permit sample firing of the enamel and comparison with a color standard. Adjustments to the mill can then be made. Color can be controlled to some extent by variations in the fineness of the grinding. The thickness of the fired enamel coating affects many colors. In general, thick coatings produce lighter colors, and thin coatings result in darker colors.

The set and specific gravity of a colored enamel slip are important to the finished results. Mottling or color separation is possible if the colored enamel is applied too wet or too dry. Color corrections of electrostatic dry powder cannot be made by the enameler.

Flatness and Distortion. Sag and distortion of sheet steel parts result from low metal strength at the firing temperature, thermal stresses due to nonuniform heating and cooling, and transformation to austenite. Changes in design of the parts and firing practice alleviate the first two causes, and the use of extra-low carbon content or of special stabilized steels minimizes transformation to austenite.

Ground-coat enamels have a limited effect on the distortion of parts because their coefficients of thermal expansion approach that of steel. When a ground coat is applied to both sides of the metal, there is a counterbalancing of expansion and contraction stresses.

The effect of cover-coat enamels on the configuration and flatness of porcelain-enameled parts can be pronounced as a result of low coefficients of expansion and one-side application. The likelihood of distortion is greatly increased when multiple or thicker coats of cover-coat enamels are necessary on one surface. Sometimes, cover coats must be applied to the back side of parts to equalize the stresses.

Adjustments in the firing cycle can sometimes help to minimize distortion. A cycle with relatively slow heating and cooling rates is preferable to rapid heating and cooling.

Variations in the method of supporting the work during firing can often change the sagging characteristics to an appreciable degree. Furnace supports and fixtures can be designed to distribute the load and equalize heating and cooling rates. The design and fabrication of sheet steel parts for porcelain enameling are discussed in Ref 2.

Process Control

Proper workability during the application of wet-process porcelain enamels depends on:

- Control of the procelain enamel slip, particularly with respect to stability of suspension
- Weight of enamel slip deposited and retained per unit area
- Specific gravity, consistency, and particle size of the enamel slip
- Stability upon aging at ambient temperature

Stability of Suspension, or the ability of the various mill additions to keep the milled frit in suspension, is determined by both slip measurements and visual observation of any separation that occurs. Stability of the suspension is a function of many factors, but is usually controlled by the quantity of colloid, in the form of clay or bentonite, and electrolytes used to deflocculate the clay. Enamel slips for aluminum have a shorter shelf life than those for sheet steel.

Pickup weight of enamel and enamel retained per unit area are measured by draining the enamel on a flat or cylindrical shape of known weight and area and actually weighing the pickup of enamel in wet or dry form. This is a very useful test, particularly for dipping enamels, and it closely simulates actual production operations. During the test, the operator can observe any tendency toward sliding, excessively long or short drain time, and variations in setting time. The pickup of an enamel is a function of specific gravity, colloid content, total salts content and type, and consistency. These are controlled by varying water content, addition of salts, and fineness of grind.

The specific gravity of enamel slips is measured either by weighing a known volume in comparison with the weight of an equivalent volume of water or by the use of a hydrometer. Control of specific gravity is almost entirely a function of the ratio of water to solids. To ensure uniformity, testing for specific gravity is required for the preparation of all procelain enamel slips.

The consistency of a porcelain enamel slip for spraying is commonly determined by the slump test. In this test, a fixed volume of the porcelain enamel slip is allowed to flow out suddenly in a circular pattern on a calibrated plate, and the diameter of the resulting pool is measured immediately. This is a simple and useful test for procelain enamels that will be sprayed because it indicates uniformity of slip conditions between various millings. Other tests for consistency involve the use of viscosimeters of various types, including those that use the rotational, flow, and falling piston methods.

For porcelain enamel slips applied by dipping, a measure of drain time is a useful test. Drain time is the total elapsed interval between the time a standard size sample plate is removed from a container of well-stirred procelain enamel slip and the time at which the draining motion of the slurry on the sample has stopped.

The particle size of the frit for porcelain enamel slips is commonly determined by standard screen analysis. Reproducible measurements are easily obtained when a standardized shaking device is used. The particle size of the frit is important to the suspension characteristics of the procelain enamel slip, and slight solubility of the frits shows a major change with variation in the size of the particles.

Stability toward aging of porcelain enamel slips is measured by exposing a tested sample of the enamel to whatever temperatures are expected in normal service. Exposure is for many hours and days, and retests of the critical properties are made at intervals during testing. Aging usually has an effect on the stability of the suspension, pickup, setting time, and the consistency of the procelain enamel slip. Aging causes bubbly glass and poor surface quality of the fired enamel. Leaching of soluble elements such as sodium or boron from the frit is a cause of aging. This problem is more frequently encountered with less water-resistant frits. The effect is greater at higher temperatures.

Corrosion Resistance of Porcelain Enamels

Porcelain enamels possess excellent resistance to corrosion in a variety of environments. Enamels are formulated to have resistance to specific environments, along with ease of processing and minimum cost. Table 3 lists corrosion applications for porcelain enamels.

Table 3 Applications in which porcelain enamels are used for resistance to corrosive environments

Application	Corrosive Environment			
	Temperature		pH	Corrosive medium
	°C	°F		
Bathtubs	To 49	To 120	5-9	Water, cleansers
Chemical ware	To 100	To 212	12	Alkaline solutions
	To 100	To 212	1-2	All acids except hydrofluoric
	175-230	350-450	1-2	Concentrated sulfuric acid, nitric acid, and hydrochloric acid
Home laundry equipment	To 71	To 160	11	Water; detergents; bleach
Range exteriors	21-66	70-150	2-10	Food acids; cleaners
Range oven liners, conventional	66-315	150-600	2-10	Food acids; cleaners
Range burner grates	66-590	150-1100	2-10	Food acids; cleaners
Refrigerators	-18 to 66	0-150	2-10	Food acids; cleaners
Kitchen sinks	To 71	To 160	2-10	Food acids; water; cleaners
Water heaters	To 71	To 160	5-8	Water

(a) Applications include coal- and oil-fired boilers and black liquor evaporators; corrosive media would include ash from coal-fired boilers, corrosive condensates, and exhaust from black liquor evaporators.

Atmospheric Exposure. Porcelain enamels have excellent resistance in atmospheric exposure, including corrosive industrial atmospheres, gases, smoke, salt spray, and seacoast exposures. The weather resistance of procelain enamels is usually measured by the degree to which the coating maintains its original color and gloss. Enamels formulated for acid resistance usually have better atmospheric-corrosion resistance than other types. These enamels have shown no appreciable change in appearance after 15 years of exposure.

Waters. All porcelain enamels are completely resistant to water at room temperature. Resistance decreases at higher temperatures. Special porcelain enamels have been developed for hotwater storage tanks that can withstand continuous exposure to hot water for periods of 10 to 20 years. Natural waters, because of their varying compositions, have varying effects on porcelain enamels. Aerated water with a low dissolved solids content, for example, has been found to be more corrosive than hard water. Freezing and thawing cycles can cause some procelain enamels to spall or disintegrate; however, properly formulated and applied enamels can withstand thousands of freezing and thawing cycles without failure. Porcelain enamels can withstand salt spray tests (ASTM B 117) for days and even weeks without evidence of corrosion (Ref 3), and they can provide excellent service in intermittent or continuous exposure to seawater.

Soils. Porcelain enamels formulated to withstand both acid and alkaline attack provide good service in soils.

Acids. Resistance to acids varies widely, depending on composition and the application process used. The degree of attack by acids appears to depend less on the type of acid (with the exception of hydrofluoric) than on pH. Special formulations can provide excellent protection against aqueous solutions of most acids except hydrofluoric. The highest degree of acid resistance is obtained by sacrificing resistance to other media, such as alkalies. Figure 1 shows weight loss of a porcelain enamel in boiling mineral acids and in boiling water.

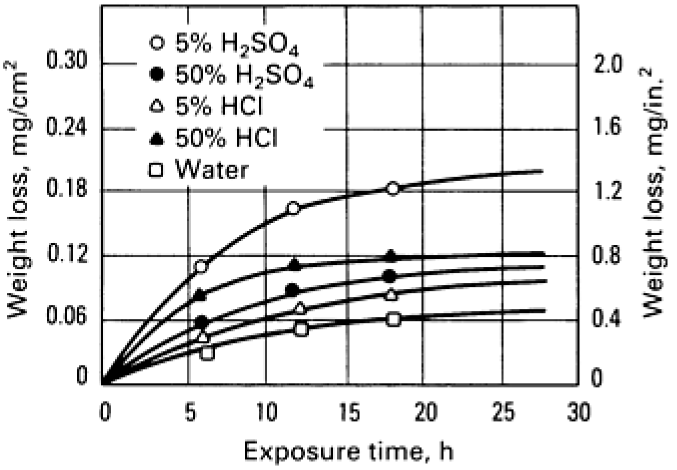

Fig. 1 Corrosion of a porcelain enamel in boiling water and boiling mineral acids. Source: Ref 4

Alkalies. Most porcelain enamels are unaffected by alkalies at room temperature. Special formulations provide alkali resistance to solutions with a maximum pH of 12 at temperatures to 100 °C (212 °F).

Organics. Porcelain enamels are completely resistant to attack by common organic solvents, dyes, greases, and oils. Enamels are not dissolved by these materials and do not absorb then. Acid-resistant porcelain enamels are required for organic material that hydrolyzes upon contact with moisture to form acid solutions.

High Temperatures. Porcelain enamels greatly reduce high-temperature oxidation of the base metal. This ability is largely due to the fact that the enamels themselves are fully oxidized and do not suffer further oxidation at elevated temperatures. They also form an effective barrier to the diffusion of oxygen into the metal. Protection depends on the temperature at which the enamel begins to soften and become more fluid. This temperature is normally about 205 °C (400 °F) below the firing temperature, but specially formulated enamels can provide oxidation protection to metals at temperatures to 1095 °C (2000 °F). Maximum service temperatures for porcelain enamels are shown in Table 4.

Table 4 Maximum service temperatures for porcelain enamels

Service temperature		Limiting conditions
°C	°F	
425	800	**Usual limit for enamels maturing at about 815 °C (1500 °F)**
540	1000	**Maximum for enamels maturing at about 815 °C (1500 °F), without reboil**
760	1400	**Operating limit for special high-temperature enamels**
1095	**2000**	**Refractory enamels useful for short periods for protection of stainless steels and special alloys**

The resistance of an enamel to thermal shock varies inversely with its thickness. Thermal shock failure occurs when the temperature gradient perpendicular to the surface is large enough to cause excessive differential shrinkage and tensile stress. Thermal shock resistance also depends on the design and section thickness of the coated part. Flexing of the metal due to localized thermal gradients parallel to the surface can produce bending and tensile stresses in the coating; therefore, an increase in the strength or rigidity of the part increases the resistance of the coating to thermal shock. Most porcelain enamels applied at conventional thickness can withstand abrupt temperature changes of 110 to 165 °C (200 to 300 °F).

Evaluation of Porcelain Enameled Surfaces

Specifications and quality control for porcelain enamel coatings require the evaluation of a range of properties, depending on the intended service of the porcelain-enameled product. Although material and process variables can be brought into approximate control by using small test panels, process control is maintained by the evaluation of finished parts, even though the mechanical and chemical tests entailed are destructive.

Standard test procedures are available for most porcelain enamels. Specific test methods for various properties are listed in Table 5. Some of these properties and tests are discussed below (refer to Table 5 for the title of the test, specification, or standard).

Table 5 Test methods, specifications, and standards for porcelain enamels

Designation[(a)]	Title of test, specification, or standard
Adherence	
ASTM C 313	**Adherence of Porcelain Enamel and Ceramic Coatings to Sheet Metal**
ASTM C 703	**Spalling Resistance of Porcelain Enameled Aluminum**
PEI T-29	**Adherence of Porcelain Enamel Copper Coats Direct To Steel**
Thickness	

ASTM C 664	**Thickness of Diffusion Coating**
ASTM D 1186	**Dry Film Thickness of Non-Magnetic Organic Coatings Applied on a Magnetic Base, Measurement of**
ASTM E 376	**Coating Thickness by Magnetic Field or Eddy-Current (Electromagnetic) Test Methods, Rec. Practice for Measuring**
Color and gloss	
ASTM C 346	**45-deg Specular Gloss of Ceramic Materials**
ASTM C 540	**Image Gloss of Porcelain Enamel Surfaces**
ASTM E 97	**Reflectance Factor of Opaque Specimens by Broad-Band Filter Reflectometry, 45 deg, 0 deg Directional**
ASTM C 347	**Reflectivity and Coefficient of Scatter of White Porcelain Enamels**
ASTM D 2244	**Color Differences of Opaque Materials, Instrumental Evaluation of**
ASTM D 1535	**Color by the Munsell System, Specifying**
ASTM C 538	**Color Retention of Red, Orange and Yellow Porcelain Enamels**
Chemical resistance and weather characteristics	
ASTM C 282	**Acid Resistance of Porcelain Enamels (Citric Acid Spot Test)**
ASTM C 614	**Alkali Resistance of Porcelain Enamels**
ASTM C 756	**Cleanability of Surface Finishes**
ASTM C 283	**Boiling Acid, Resistance of Porcelain Enameled Utensils to**
ASTM D 1567	**Detergent Cleaners for Evaluation of Corrosive Effects on Certain Porcelain Enamels, Testing**
ASTM C 872	**Lead and Cadmium Releases from Porcelain Enamel Surfaces**
Chipping resistance	
ASTM C 409	**Torsion Resistance of Laboratory Specimens of Porcelain Enameled Iron and Steel**

Abrasion resistance	
ASTM C 448	**Abrasion Resistance of Porcelain Enamels**
Thermal shock	
ASTM C 385	**Thermal Shock Resistance of Porcelain Enameled Utensils**
Tests related to preparation of coatings and substrates	
ASTM C 374	**Fusion Flow of Porcelain Enamel Frits (Flow-Button Methods)**
ASTM C 539	**Linear Thermal Expansion of Porcelain Enamel and Glaze Frits and Ceramic Whiteware Materials by the Interferometric Method**
ASTM C 285	**Sieve Analysis of Wet-Milled and Dry-Milled Porcelain Enamel**
ASTM C 839	**Compressive Stress of Porcelain Enamels by Loaded-Beam Method**
ASTM C 715	**Nickel on Steel for Porcelain Enameling by Photometric Analysis**
ASTM C 810	**Nickel on Steel for Porcelain Enameling by X-ray Emission Spectrometry**
ASTM C 632	**Reboiling Tendency of Sheet Steel for Porcelain Enameling**
ASTM C 694	**Weight Loss of Sheet Steel During Immersion in Sulfuric Acid Solution**
ASTM C 774	**Yield Strength of Enameling Steels After Straining and Firing**
ASTM C 660	**Production and Preparation of Gray Iron Coatings for Porcelain Enameling**
Tests related to continuity of coating	
ASTM C 536	**Continuity of Coatings in Glassed Steel Equipment by Electrical Testing**
ASTM C 743	**Continuity of Porcelain Enamel Coatings**
Specifications	
PEI S-100	**Specification for Architectural Porcelain Enamel on Steel for Exterior Use**

PEI ALS-105	**Recommended Specifications for Architectural Porcelain Enamel on Aluminum for Exterior Use**
PEI ALS-106	**Recommended Specifications for Porcelain Enamel Finishes on Aluminum Cookware**
WH-196-J	**Federal Specification--heater, water, electric and gas fired residential. (This covers resistance of porcelain enamels to hot water under "Solubility of Glass Lining.")**
Plumbing fixtures standards	
ANSI A 112.19.4	**Porcelain Enameled Formed Steel Plumbing Fixtures**
ANSI A 112.19.1M	**Enameled Cast Iron Plumbing Fixtures**

(a) ASTM, American Society for Testing and Materials; PEI, Porcelain Enamel Institute; ANSI, American National Standards Institute

Adherence refers to the degree of attachment of enamel to the metal substrate. Although none of the adherence tests in common use results in the quantified force per unit area required to detach the enamel by tensile force normal to the interface, various tests aimed at evaluating adherence are regularly used in the industry.

The standard adherence tests for porcelain enamel on steel are ASTM C 313 and PEI Bulletin T-29. The ASTM C 313 test is applicable only to steel substrates between 0.4 mm (0.016 in.) and 2 mm (0.082 in.) in thickness. The PEI T-29 test applies to direct-on cover coats on substrates with a thickness range of 0.7 mm (0.028 in.) to 1.3 mm (0.050 in.).

Both adherence tests for porcelain enamel on steel include deforming the metal and measuring the area from which the porcelain enamel is removed. The indicator of adherence is the adherence index, which is the ratio of the porcelain enamel remaining in the deformed are to that in the same measured area before deformation.

Enamels for cast iron pose a special problem because of the relatively greater thickness and rigidity of the metal substrate and the brittleness of the iron. Simple, unstandardized impact tests are used in these cases.

Resistance to spalling, a defect characterized by the separation of porcelain enamel from the base metal without apparent external cause, is the indicator used to measure the adherence of porcelain enamel on aluminum. Spalling can result from the use of improper alloys or enamel formulations, incorrect pretreatment of the base metal, or faulty application and firing procedures.

Two methods for determining resistance to spalling are outlined in ASTM C 703. Method A, which uses a 5% solution of ammonium chloride, requires a 96-h immersion of the tests specimen. Method B uses a 1% solution of antimony trichloride and requires a 20-h immersion of the test specimen.

The spall test is a pass/fail test. Failure is determined by either of two criteria. The first is the existence of spall areas of specified dimensions at specimen edges. The second criterion is the existence on the specimen interior (away from the edges) of spots exceeding specified dimensions or a spot level exceeding a specified density, usually spots/m^2 (spots/ft^2).

Thickness. The specifications for architectural porcelain enamel (PEI S-100 for steel and PEI ALS-105 for aluminum), the specification for porcelain-enameled aluminum cookware (PEI ALS-106), and the standards for porcelain-enameled formed steel plumbing fixtures (ANSI A112.19.4) and porcelain-enameled cast iron plumbing fixtures (ANSI A112.19.1M) all require a specific thickness for the porcelain enamel coating.

The procedure used for measuring the porcelain enamel thickness depends on the type of base metal used. For porcelain-on-steel products, enamel thickness is measured through procedures outlined in ASTM D 1186. For porcelain-on-

aluminum products, coating thickness is measured according to test procedures specified in ASTM E 376. In some cases, primarily laboratory investigations, measurement of porcelain enamel thickness is accomplished by using the procedures specified in ASTM C 664.

Color and Gloss. Porcelain enamel finishes are produced in literally hundreds of colors and many textures. This capability provides the manufacturers of appliances, cookware, outdoor grills, architectural panels, signs, decorative products, and many other applications with unusual design versatility as well as desirable performance properties.

The common method of specifying color is based on the capacity of the observed article to reflect light of different wavelengths (different colors). A physical standard, such as a plaque of porcelain-enameled steel, is provided as the color to be matched within stated limits. The difference in color between the control standard and the test specimen can be measured instrumentally by using the procedures specified in ASTM D 2244.

Gloss is particularly desirable in such products as appliances. However, high-gloss enamels capable of reflecting distinct images are not recommended for architectural porcelain enamel for exterior use.

The gloss of porcelain enamel can be measured by following procedures from two standards: ASTM C 346 and ASTM C 540. The test chosen for evaluating gloss depends on the purpose for which the porcelain enamel is used.

Acid Resistance. There are two standard tests for determining the acid resistance of porcelain enamels: ASTM C 282 (generally referred to as the citric acid spot test) and ASTM C 283 (generally known as the boiling acid test). The citric acid spot test is used as a testing and grading system for such porcelain enamel applications as appliances, plumbing fixtures, and architectural products. Evaluation is based on visual examination following wet or dry rubbing and blurring-highlight tests. The boiling acid test is designed primarily for cookware applications, and the results are expressed in weight loss per unit area.

Alkali Resistance. Home laundry equipment, dishwashers, and other porcelain enamel applications in which the surface is normally exposed to an alkaline environment at elevated temperatures require an alkali-resistant coating. The standard test for alkali resistance is ASTM C 614. This test covers the measurement of the resistance of a porcelain enamel to a hot solution of tetrasodium pyrophosphate. Alkali resistance is expressed in terms of weight loss for the area exposed to the test solution.

Weather Resistance. The long-term weatherability of porcelain enamel is of primary interest to specifiers and manufacturers of architectural porcelain enamel products intended for exterior use. The actual weathering performance of the material has been documented in a series of on-site exposure tests conducted by the National Bureau of Standards in cooperation with the Porcelain Enamel Institute.

The weathering of porcelain enamel is evaluated in terms of the changes in gloss and color that occur during outdoor exposure. Changes in gloss and color are measured by using the procedures outlined earlier. Weathering tests of up to 30 years show that porcelain enamels have considerable inherent gloss and color stability; rates of change are primarily influenced by enamel compositions, choice of colors (reds and yellows are most susceptible to color change), and the severity of the exposure site (seacoast and corrosive industrial environments have been found to have the most aggressive effect).

Spalling of enamels during exposure to weather occurs if improper materials and processing procedures have been used. The spalling resistance of weathered porcelain enamel on aluminum, for example, is best ascertained by using ASTM C 703.

In exposure tests, good correlation has been observed between acid resistance, as determined by the citric acid spot test, and the color retention of steel enamels. However, use of the acid spot test has shown an even stronger reliability in predicting color change in porcelain-on-steel. The correlation between acid resistance and color retention in porcelain-on-aluminum is somewhat less definitive but still observable. The best indicator for predicting the weatherability of red, orange, and yellow porcelain enamels is ASTM C 538. Because architectural porcelain enamel for exterior use is subjected to weathering for long periods of time, the specifications for porcelain enamel on aluminum (PEI ALS-105) and porcelain enamel on steel (PEI S-100) require compliance with specific levels of acid resistance, which are considered indicators of good weatherability.

Chipping Resistance. Relatively thick layers of porcelain enamel cannot be subjected to severe bending or other substrate deformation without fracture. However, coatings of 125 μm (5 mils) or less that are well bonded to a relatively thin metal substrate--for example, 26 gage 0.4546 mm (0.0179 in.) or less--can withstand the bending of the substrate to radii of curvature within its elastic limit and the bending to return to the original shape with little or no apparent damage. Chipping of typical porcelain enamel on sheet iron occurs at about the strain required for permanent deformation of the base metal.

Abrasion Resistance. The test for determining the resistance of porcelain enamel to various types of abrasion is ASTM C 448. The test consists of three parts. The first determines the resistance to surface abrasion of porcelain enamels for which the unabraded 45 ° specular gloss is more than 30 gloss units. Here the specular gloss of the specimens is measured before and after a specified abrasive treatment of the surface; the percentage of the original specular gloss that is retained is the surface abrasion index.

The second part of this test determines the resistance to surface abrasion of porcelain enamels for which the unabraded 45° specular gloss is 30 gloss units or less. The weight loss by a specific abrasive treatment--modified by an adjustment factor for each abrasive tester, lot of abrasive, and lot of calibrated plate glass standards used--results in an adjusted weight loss value. This is recorded as the index of resistance to surface abrasion.

The final portion of the test measures the resistance of porcelain enamels to subsurface abrasion. In this case, the scope of the linear portion of the abrasion time-weight loss curve is determined and then multiplied by an adjustment factor associated with each abrasion tester, lot of abrasive, and lot of calibrated plate glass standards used. The adjusted scope is taken as an index of the resistance to subsurface abrasion.

Thermal Shock Resistance. The standard used for evaluating the durability of porcelain-enameled utensils subjected to thermal shock is ASTM C 385. In this test, cooking utensils are subjected to a series of dry heating and quenching cycles until the utensil fails by removal of the enamel from the utensil.

Continuity of Coatings. Ensuring the continuity of the coating after manufacture is important in porcelain enamel or so-called glassed steel applications in which a prime purpose of the coating is to protect the substrate against corrosion.

There are two principal test methods for determining either discontinuity of coverage or potential discontinuity through too-thin coverage. For glassed steel equipment, the prescribed test procedure is ASTM C 536. For conventional porcelain-enameled products, such as appliances, plumbing fixtures, and architectural panels, the test most commonly used is ASTM C 743. Both tests essentially involve the use of electrical probes of relatively high voltage to discern either discontinuities in the coating or insufficient coverage for coating integrity in service use.

Resistance to Hot Water. Federal specification WH-196-J specifies a solubility test for determining the resistance of porcelain enamels to hot water. In this test, 89- × 89-mm (3.5- × 3.5-in.) sections cut from the outer wall of a water heater are tested at a rolling boil for 8 cycles of 18 h each in a special apparatus containing 400 mg of reagent grade sodium bicarbonate dissolved in 1 L of water. The resistance of the porcelain enamel is specified in terms of weight loss in milligrams per square inch exposed area. The weight loss allowed by WH-196-J is 2.3 mg/cm^2 (15 mg/in.^{2}).

Chemical-Setting Ceramic Linings

Gregory D. Maloney, Saureisen Cements Company

Introduction

INORGANIC CHEMICAL-SETTING CERAMIC LININGS have become one of the most widely used construction materials in designing protective linings for industrial installations in which high temperatures, aggressive corrosive media, and complicated substrate geometry exist, such as floors, trenches, sumps, reaction vessels, tanks, scrubbers, ducts, chimneys, and other air pollution control equipment. They are used in various industries, including power, steel- and metalworking, chemical, pulp and paper, refinery, waste treatment, and mining.

Inorganic monolithic linings have proved themselves in these industries because of their chemical resistance to both high and low concentrations of strong acids and solvents, thermal insulation that protects the substrates from extremely high temperatures, temperature resistance to 870 °C (1600 °F), good compressive and flexural strength for environments in which stress and strain are factors, and abrasion resistance. Monolithic linings can be applied by cast or gunite (shotcreting) methods over old and new steel or concrete as well as brick and mortar masonry. This article will discuss the function of monolithic linings, the use of these materials, the types of applications in which these materials can be successfully used, and the limitations of these linings.

History of Chemical-Setting Silicates

The progress of silicate cement development has changed over the years with growing technology to meet industry needs. The first silicate cements were composed of a sodium silicate (Na_2SiO_3) liquid and a combination of fillers, such as silica flour, clay, silica aggregates, and barytes, and were formulated as chemical-resistant mortars for use in ambient or high-temperature acid lining construction. This type of silicate cement was very slow in setting and had to be exposed to the open air or heat cured, which created construction delays. Another problem was that these cements were not water resistant. These problems were resolved by the use of acid washing, which helped set the cements and make them water resistant.

In the early 1920s, Na_2SiO_3 mortars were introduced that used an acid catalyst to insolubilize the silica gel; this produced a mortar that cured faster and was water resistant. The physical properties of the silicate mortar were unchanged; that is, the acid, temperature, and solvent resistance were maintained. Because the acid-catalyzed mortar was chemically activated upon mixing, it could set within 24 to 48 h. This was a distinct advantage for the construction industry because it allowed brick to be laid continuously without concern over the mortar being squeezed out of the joints or the brick sliding out of line. Typical setting agents used are ethyl acetate ($C_4H_8O_2$), zinc oxide (ZnO), sodium fluorosilicate (Na_2SiF_6), glyceryl diacetate, formamide (CH_3ON), metallic polyphosphates, and other amides or amines.

It was later determined that when Na_2SiO_3 mortars were exposed to sulfuric acid (H_2SO_4) the reaction product was sodium sulfate (Na_2SO_4), which is a salt that expands and grows through hydration. This sodium salt can pick up as much as 10 mol of water of crystallization with a resultant size increase of 150%, thus creating internal stresses in the structure in which it was used. As a result, monolithic linings and brick surfaces would sometimes crack or spall.

As time passed, industry required silicate technologies that would meet changing applications and structural designs. By the 1950s, potassium silicate (K_2SiO_3) cements were introduced using methods of insolubilizing the silicate. The K_2SiO_3 cements possess enhanced corrosion resistance, particularly in H_2SO_4 environments. Potassium silicate cements react with H_2SO_4 to form potassium sulfate (K_2SO_4), which is not a growth salt. This eliminates the problem of internal stresses when the mortar is exposed to H_2SO_4 solutions.

The introduction of K_2SiO_3 cements was a positive step in producing a material that was more suited for application technology and corrosive environments. The K_2SiO_3 cements offer improved physical properties, which are particularly beneficial in monolithic applications. Furthermore, K_2SiO_3 cements provide better workability with less tackiness and longer working times than Na_2SiO_3 cements. Additional advantages include greater resistance to strong acid solutions and sulfation, more refractoriness, and no efflorescence as with Na_2SiO_3 cements. By this time, Na_2SiO_3 and K_2SiO_3 materials were not only being used as mortars but were also being introduced in new areas of monolithic application as both castable and gunite grades.

Within the last decade, the modified silicates have been developed. Modified silicates are manufactured by the addition of a powder form of Na_2SiO_3 in conjunction with a proprietary ingredient added directly to the powder fillers. This process eliminates the need to have both powder and liquid on the job site; water is the only required addition. Although these products have been commercially available, high cost and potential for sulfation have limited their use. The modified silicates do not have the chemical properties of the other silicates. The only advantage appears to be their simplicity of mixing.

Advantages and Disadvantages

The Na_2SiO_3 and K_2SiO_3 cements were developed because a material was needed that was acid resistant in dilute-to-strong concentrations and that offered higher temperature resistance than chemical-resistant organic materials. The development of these silicate-base acidproof cements resulted in many advantageous characteristics, such as a 100% K_2SiO_3-bonded system that had resistance to most solvents and acids over a pH range of 0 to 7; that was water and vapor resistant without special treatment; and that could withstand all concentrations of H_2SO_4, nitric acid (HNO_3), hydrochloric acid (HCl), and phosphoric acid (H_3PO_4). In addition, the Na_2SiO_3- and K_2SiO_3-bonded cements can be applied over damp acid-attacked concrete or brick surfaces as long as these substrates have acid pH surfaces, and they cure chemically within 36 h, thus decreasing construction delays. These cements can be applied by gunite or cast methods. Detailed information on guniting (shotcreting) can be found in American Concrete Institute publication ACl 547R on refractory concrete.

Certain disadvantages were encountered during the development of the acid-resistant silicate cements. It was common knowledge that the silicate cements were not resistant to alkalies, hydrofluoric acid (HF), and fluoride salts. As previously mentioned, the Na_2SiO_3 cements formed a growth salt when exposed to H_2SO_4 that put undue internal stresses on the structure of the material.

Inorganic monolithic linings also have a certain amount of permeability compared to organic surfacing materials. Over time, acid can penetrate the lining and eventually reach the surface of the substrate. This problem is now being combated by using a dual-lining system, which includes a chemically resistant elastomeric membrane applied to the surface of the substrate.

Current Technologies

Monolithic and Membrane Dual Linings. Organic linings or coatings have been used in stacks and ducts, but they will usually deteriorate if temperatures exceed 260 °C (500 °F) in high-sulfur gases. There are many types of lining materials for stacks and ducts; however, because of unpredicted environmental conditions within a stack or duct, it may be difficult to select the best candidate material. Stacks that are designed with heat recovery units and/or scrubbers, combined with one or more flues inside the shell that can control the temperature, should be considered for dual-lining applications.

In recent years, the trend toward using the superior technology of dual linings has emerged and is being recommended where corrosion problems occur throughout industry. Figure 1 illustrates the design of a typical membrane/monolithic system in the chemical industry.

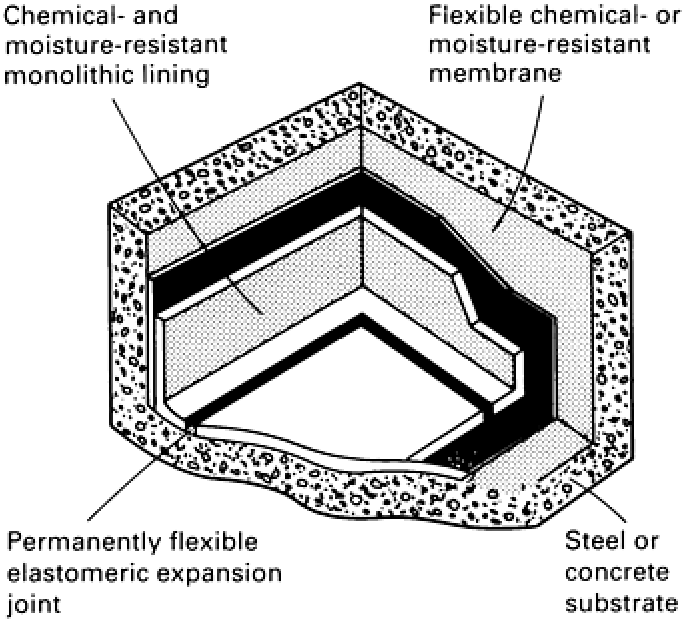

Fig. 1 Schematic of a chemical-resistant dual-lining system that provides double protection to the substrate in the form of a flexible membrane and a rigid surface layer. The flexible corrosion-resistant membrane is applied in direct contact with steel or concrete substrates. It is then covered by the monolithic cement lining, which provides protection over a broad pH range as well as against high temperatures.

There are numerous reasons for this new construction process. Condensation occurs not only on the face of the acid-resistant lining but can also penetrate and condense on the substrate to be protected. Although acidproof monolithic linings offer the proper chemical resistance, they are inherently inelastic, or brittle. In time, monolithic linings may tend to crack and absorb acids or acid gas condensate; therefore, it is advantageous to have a backup membrane. In many applications, the coefficient of thermal expansion of the monolithic lining may not match that of the substrate. Therefore, a flexible membrane will help accommodate stresses resulting from these differences in thermal expansion as well as other mechanically induced stresses.

For many applications, the monolithic lining should not be bonded to the substrate, and the membrane acts as a bond barrier. The concept of placing an impervious membrane between the substrate and inorganic linings has become a recommended practice. Some corrosion-resistant gunite manufacturers have installation specifications for use with membranes.

Membrane choices include asphaltics, resins, and synthetic elastomers. The membrane selected should resist the maximum acid concentrations and temperature expected. Organic linings can fail by disbonding, swelling, abrasion, and blistering from high temperature. Protection of an organic membrane with an inorganic barrier will minimize thermal exposure and mechanical abrasion to the membrane as well as the corrosive media that reach the membrane. An organic membrane compensates for some of the shortcomings of inorganic linings, such as cracking or spalling due to mechanical stresses from shrinkage, induced stresses, insufficient thermal expansion allowances, the anchoring system, vibration, and thermal or other stresses. To provide an effective barrier, inorganic linings are applied much thicker than typical organic coatings. They often contain fillers to act as reinforcement and to decrease shrinkage. Fillers are also incorporated to provide wear resistance for abrasive conditions.

The installation procedure for a dual-lining system is basically the same as if each component were being applied separately. These procedures are established for both organic coatings and inorganic monolithic linings. The condition of the working area and preparation of the surfaces follow standard practices used throughout the industry. Anchors are usually installed on the steel or concrete substrates before the organic membrane is applied.

Lightweight Insulating Materials. Industry has recently seen the development and application of improved lower-density, lightweight, insulating corrosion-resistant lining materials. The evolution of these products has followed the need to accommodate load limitations of structural supports and improved thermal protection of membrane coatings where substrate temperatures can range from 40 to 150 °C (100 to 300 °F) and even higher if process limits or gas cleanup systems experience frequent excursion or bypass conditions. Membranes require adequate thermal protection to retain physical and chemical properties throughout their service life. Because the membrane will also coat the studs, the inorganic coating must be thick enough to protect the membrane on the highest point of the studs. Therefore the inorganic lining material must not only protect the membrane from physical abuse but must also protect it from thermal deterioration.

When membranes are not used, condensation of chemicals from hot process streams should be designed to occur within a lining and not at the substrate. However, when membranes are used, the condensation can occur at the membrane, thus possibly reducing the required lining thickness. Therefore, inorganic silicate lining materials with lower thermal conductivity and density have been developed to meet these needs.

Application Procedures. Through the use of current technology, such as the dual-lining system and the availability of improved application techniques, corrosion protection practices have been greatly enhanced. Observations of successes and failures in various applications have led to the development of the following parameters, which must be addressed to specify the proper material. In any application, the primary consideration is the exposure environment. This includes the types and concentrations of chemicals, physical abuse, and temperatures. In this evaluation, it is important to remember that both the silicate monolithic lining and the membrane must resist the corrosive environment. The next consideration is the thickness of the monolithic lining. In high-temperature environments, the monolithic lining must be able to decrease the temperature through its thickness to a level that will not burn out the membrane applied to the substrate or the anchoring system. Once the materials that can resist the corrosive environment have been selected, the physical structure must be considered.

Steel. When a steel substrate is being used, sources of variation in electrical potential on the metal surfaces must be considered. These include mill scale, metal impurities, localized strains on parts of the metal, junctures of dissimilar metals, movement of electrolytes, weld joints, concentration cells, and externally imposed currents. Some or all of these differences in potential can occur on the surface and must be considered in the recommendation of a protective coating. The protective coating must provide the following properties to protect the steel:

- Physical protection to surface
- Prevention of concentration cells
- Dielectric properties
- Lower surface temperatures
- Prevention of electrolyte flow
- Deprivation of free oxygen from the surface

- Stress relief

Stress relief is an important factor in the design of a system. If a system does not compensate for relief in areas of high stresses, cracking will occur that can severely damage the entire system. Stresses on the system of major concern could result from vibration, unsupported surfaces, changes in planes, and welds.

The following five steps are application procedures that should be followed to ensure proper installation of a dual lining system. First, all areas of high stress that will result in movement of the steel structure, such as oil canning or vibration, must be externally supported. Second, the anchoring system should then be applied to the substrate. Anchors, such as V-type or longhorn studs, should be installed on the proper centerlines in a diamond or staggered pattern with the tines randomly oriented. Third, the steel surface must be stripped of all oil and grease by chemical cleaning. The metal should then be sandblasted to a Steel Structures Painting Council SP 10 Near-White Blast with a nominal 64-μm (2.5-mil) profile. Welds should be ground to a smooth, rounded radius with no sharp edges before blasting. Fourth, the appropriate membrane should be applied, ensuring that all of the studs are completely coated and that the system is free of pin holes.

The final step is to apply the monolithic lining. The two available methods of application should be considered. A castable material will shrink more than the gunitable material; therefore, expansion joints must be planned into the system in areas exceeding 6 × 6 m (20 × 20 ft) or where changes in planes will cause stresses to occur. A gunitable material will shrink less and therefore does not require expansion joints. Figure 2 illustrates the gunite application of K_2SiO_3 cement over steel ductwork in a fossil fuel power plant.

Fig. 2 Gunite application of 50 mm (2 in.) of K_2SiO_3 cement over steel ductwork in a coal-fired power plant

Concrete. In applications over concrete, as with steel, the first considerations are the corrosive environment and the thickness of the material. Once the materials have been selected, the physical structure must be considered. When the substrate is concrete, factors different from those associated with steel must be considered. Inorganic monolithics can be applied over old or new concrete surfaces. When concrete substrates are being used, the following questions should be answered:

- Is the concrete old acid-attacked concrete or new concrete?
- Is the concrete capable of supporting loads?
- Is the structure above grade or below grade?
- Does the concrete need to be waterproofed from the outside?
- Does the concrete structure have existing cracks?
- Is the concrete surface a high or low pH?

A combination of many of these items may apply and should be considered in the recommendation of the proper system. The following are the criteria for a concrete surface before a system may be applied. When working with old acid-attacked concrete, all loose and deteriorated concrete should be removed. The surface should be firm, hard, and at a

minimum pH of 5, and all surfaces should be brought back to grade and the slopes reestablished. When working with new concrete, the concrete should be firm and sound. All structural cracks should be repaired, and it should be cured for a minimum of 7 days. Slopes should be a minimum 3.2 mm ($\frac{1}{8}$ in.) to a maximum 6.4 mm ($\frac{1}{4}$ in.) per linear foot and should have attained a minimum compressive strength of 21 MPa (3000 psi).

The following five steps are application procedures that should be followed to ensure proper installation of a dual-lining system. First, the concrete should meet the standards outlined above. Second, the concrete should be cleaned of all oil, grease, and form release compounds by chemical cleaning, waterblasting, or scarifying. Third, the anchoring system should be placed at the specified centerline distance in a diamond-shape pattern with a random orientation of anchor tines. The anchoring system should consist of V-type or longhorn studs. Fourth, the membrane should be applied to the recommended thickness, ensuring that all studs are completely coated and that the coating is free of pinholes.

The final step is to apply the monolithic. The castable and the gunitable methods should both be considered. As stated above, when applying by the gunite method there is less shrinkage; therefore, there is no need for expansion joints in the monolithic. However, the lining will require control joints in the normal manner. Expansion joints are recommended with cast applications and should be installed at the perimeter of floor areas, equipment pads, and floor trenches; around floor drains, column bases, and protrusions; at changes in planes; and over expansion joints in concrete slabs not to exceed 6 m (20 ft) on centerlines.

Brick. A monolithic lining can be applied over acid-attacked masonry construction. The first step is the surface preparation of the brick. Flyash and other contaminants should be removed by sandblasting or waterblasting. All attacked or unsound mortar should be removed from the joints. Mortar joints should be cleaned to a depth of at least 13 mm ($\frac{1}{2}$ in.) to provide support for the monolithic lining. If the joints cannot be cleaned to this depth, it will be necessary to set longhorn or V-type anchors in the joints. The preferred method of application in this case is to gunite the material. Guniting allows the material to be applied under pressure, thus enabling the material to be packed into the 13-mm ($\frac{1}{2}$-in.) open joints and allowing the system to be supported by the studs or keying into the joints.

Corrosion Resistance

Monolithic linings are among the fastest growing products in the corrosion protection field because of their resistance to a wider range of corrosive media than most other construction materials. The following industrial applications illustrate the corrosion resistance and some uses of monolithic linings.

Wastewater treatment systems in the southern United States have experienced corrosion problems in areas of high temperatures, high humidity, and slow drainage. Consequently, millions of dollars have been spent in replacing the corroded concrete infrastructures in these wastewater treatment systems in wet wells, grit chambers, sewer lines, and aeration basins. This corrosion went unnoticed throughout the years because the corrosion mechanism was not understood. Most of the corrosion was not caused by discharged chemicals but was microbiologically induced. The concrete infrastructures are seldom completely filled and the combination of high temperatures and high humidity creates a perfect breeding ground for bacteria, fungi, algae, and gaseous products form decomposing sewage.

Carbon dioxide (CO_2), combined with hydrogen sulfide (H_2S) from the slightly warm and fermenting sewage, reacts with the damp concrete surfaces to form carbonates and calcium sulfate ($CaSO_4$). As this process proceeds, the pH becomes more acidic. Bacterial action results in the production of elemental sulfur from various sulfate reactions, with subsequent oxidation of elemental sulfur to H_2SO_4, which the bacteria secretes.

The H_2SO_4 then directly attacks the underlying portland cement concrete substrate and causes destruction of the infrastructure. There are documented cases of microbiologically induced corrosion having proceeded to the point at which structures collapsed in as few as 6 years or required major rehabilitation in as few as 4 years.

A proven method of rehabilitating deteriorated concrete wastewater structures involves applying a urethane-base membrane to the properly prepared substrate, followed by the pneumatic application of a 100% K_2SiO_3-bonded acid-resistant concrete. The urethane-base membrane is a two-component material with a high solids content and very low permeability. To ensure pinhole-free coatings, the membrane is applied in two or more coats to a wet film thickness

ranging from 1.6 to 3.3 mm (63 to 130 mils). These membranes are applied by airless spray with a spray tip pressure of approximately 28 MPa (4000 psi). The high pressure further helps to ensure pinhole-free application of the membrane. The substrate must be dry enough to accommodate the urethane membrane without reacting with the polyisocyanate catalysts usually used.

Therefore, it is sometimes desirable to apply a moisture-tolerant primer, such as a suitable formulated epoxy, to the damp concrete or to apply a fresh layer of concrete first. Following the proper application and cure of the urethane membrane, a veneer of a 100% K_2SiO_3 acidproof cement is applied over the membrane and anchors.

The chemical industry can be the most difficult of all industries in which to design a protective lining. The conditions within one plant can be staggering; there may be acids, alkalies, and solvents, along with extremely high temperatures and physical abuse. Potassium silicate base cements satisfy most of these conditions while maintaining economy. The combination of a wide range of chemical resistance, high physical strength, and refractoriness makes these cements leading candidates for many chemical plant applications.

For example, at a major Midwest chemical plant, the action of HCl by-products and ambient moisture on floors, digester tank supports, trenches, and sumps in $NiCl_2$ and $NiSO_4$ processing units produced very corrosive conditions. Restoration of the existing structures was accomplished with a K_2SiO_3 cement and an appropriate membrane.

In the $NiCl_2$ unit, the existing concrete floor was chipped out, and new concrete was poured; the steel beam supports for the digester tanks were also encapsulated with regular concrete. Both floor and digester foundations then received a trowel-applied asphaltic membrane. The membrane provided a flexible acid-, water-, and alkali-resistant barrier between the concrete substrate and the monolithic surfacing. The trowel-applied membrane system is applied at room temperature and offers the chemical resistance of hot-applied membranes for those areas where a hot membrane may not be practical or advisable.

The next step was to apply a K_2SiO_3 monolithic lining by casting into forms. The lining was 38 mm (1 $\frac{1}{2}$ in.) thick over foot traffic areas near the digesters; 38 to 50 mm (1 $\frac{1}{2}$ to 2 in.) thick around the encapsulated digester foundation, creating a collar; and 50 mm (2 in.) thick in forklift truck aisles. Finally, at the interface of the digester tank wall and the collar, an elastomeric urethane-base compound was used as a permanently flexible expansion joint.

In the $NiSO_4$-processing unit, the problem areas included trenches running among process equipment in two different buildings. In addition, the various collection sumps into which these trenches drained required restoration. As was done in the $NiCl_2$ area, the deteriorated concrete was reconstructed with new concrete. The asphaltic membrane was trowel applied. A K_2SiO_4 monolithic lining was cast over the membrane to 25 mm (1 in.) in the trenches, 25 to 38 mm (1 to 1 $\frac{1}{2}$ in.) in the sumps, and 38 mm (1 $\frac{1}{2}$ in.) on the floors, and the elastomeric urethane expansion joint compound was applied.

The service conditions for the two processing areas included a pH of 1 to 2 due to concentrations of HCl up to 32%, water, temperatures to 95 °C (200 °F), and vibrations from imposed loads as great as 3630 kg (8000 lbs) in the truck aisles. These applications were done by the casting method, but they could have easily been done by the gunite method.

CVD / PVD Coatings

Hugh O. Pierson, Ultramet

Introduction

VAPOR-DEPOSITED COATINGS modify the surface properties of materials. They are widely used and have been particularly successful in improving such mechanical properties as wear, friction, and hardness in cutting applications. Their use as corrosion-resistant coatings is also becoming widespread.

Deposition Processes

The vapor deposition processes fall into two major categories--physical vapor deposition (PVD) and chemical vapor deposition (CVD)--which in turn comprise various subcategories. Although these divisions often appear confusing and arbitrary, each has its own well-defined advantages and disadvantages, whether technical or economic. This is also true of the materials used in vapor deposition. Therefore, the need for a thorough understanding of both processes and materials is essential in order to select the optimum combination.

The major deposition processes that will be reviewed in this article are sputtering, evaporation, ion plating, and CVD. These processes all have one characteristic in common: The deposition species are transferred and deposited in the form of individual atoms or molecules. In this respect, they are fundamentally different from particulate or liquid deposition processes, such as thermal spraying or electroplating (see the articles "Thermal Spray Coatings," and "Electroplated Coatings" in this Volume). A primary benefit of vapor deposition is that it is essentially nondamaging to the environment, because there are no solvents or electrochemicals to dispose of. At a time when environmental-protection regulations are continually being tightened, this crucial factor favors vapor deposition over other processes that may be more harmful to the environment.

Sputtering is the principal PVD process. It involves the transport of a material from a source (target) to a substrate by means of the bombardment of the target by gas ions that have been accelerated by a high voltage. Atoms from the target are ejected by momentum transfer between the incident ions and the target. These ejected particles move across the vacuum chamber to be deposited on the substrate.

Figure 1 shows a schematic of the sputtering process. In its simplest form, the process occurs in an inert (noble) gas at low pressure (0.13 to 13 Pa, or 1×10^{-3} to 100×10^{-3} torr); in most cases, the gas is argon. Argon has higher mass than other noble gases, such as neon or helium, and is easier to ionize. Higher mass gives a higher sputtering yield, especially if the mass of the bombarding particle is of the same order of magnitude or is greater than that of the target atom. Other gases, such as oxygen or nitrogen, can also be used, but they may react chemically with the target. The sputtering process begins when an electric discharge is produced and the argon becomes ionized. The low-pressure electric discharge is known as glow discharge, and the ionized gas is termed plasma.

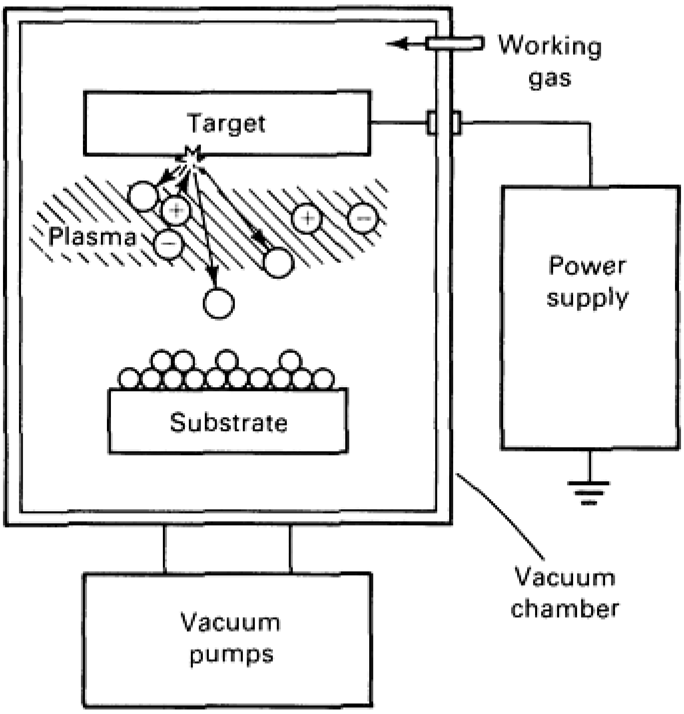

Fig. 1 Schematic of the basic sputtering process

The argon ions hit the solid target, which is the source of the coating material (and not to be confused with the substrate, which is the item to be coated). The target is negatively biased and therefore attracts the positively charged argon ions, which are accelerated in the glow discharge. This attraction of the ions to the target (also known as bombardment) causes the target to sputter, which means that material is dislodged from the target surface because of momentum energy exchange. The higher the energy of the bombarding ions, the higher the rate of material dislodgement.

Sputtering developed very rapidly in the 1970s in the semiconductor industry, in which the technique is essential for mass production. With the advent of the technique of magnetron, or magnetron-enhanced sputtering, two original primary disadvantages--nonuniform coverage and low deposition rate--have been largely eliminated. Sputtering is making rapid inroads in such corrosion applications as high-chromium alloy coatings on turbine blades and many other new applications that require high-quality coatings with good adhesion.

For the deposition of thin metal films (in the 1000- Å range), sputtering is the best technique. Deposition is feasible in a controllable manner for both compound and elemental targets (the source of the coating material). Adhesion is good and can be further improved by sputter cleaning the substrate or by bias sputtering. Large equipment is readily available, and sputtering has become a highly automated process. The quality, structure, and uniformity of the deposit are excellent. The disadvantages of sputtering include its thickness limitation and high cost. It is also a line-of-sight process that requires special fixtures and shaped targets to coat uniformly; furthermore, the coating of compound curves, recesses, and holes is difficult.

Evaporation was the first PVD process used on an industrial basis for the aluminum metallization of plastics and glass for decorative purposes. Originally the most widely used process, evaporation has now been overtaken by sputtering. The metallization process is relatively simple and well adapted to mass production.

The basic evaporation process involves the transfer of material to form a coating by physical means alone, essentially vaporization. Practically all metals can be evaporated, making evaporation a universal process with regard to metals. Like sputtering, it is a line-of-sight process; therefore, to achieve efficiency of coverage and uniformity, it is necessary to use multiple evaporation sources and to rotate or move the substrate uniformly to expose all areas.

Unlike other vapor deposition processes, evaporation is a low-energy process, with particle energy averaging 0.2 to 0.3 eV as compared to 10 to 40 eV for sputtering, 200 eV or more for ion plating, and 100 keV for ion implantation. The term low energy means that adhesion of the particle to the substrate may be marginal. In addition, the temperature of the substrate is not increased by the deposition, which means there is little or no diffusion. Because no strong physical or chemical action takes place at the interface (as opposed to ion plating or CVD, for example), particular care must be taken to remove all impurities in the chamber and to have a perfectly clean substrate. The basic process (with an electron beam source) is illustrated in Fig. 2.

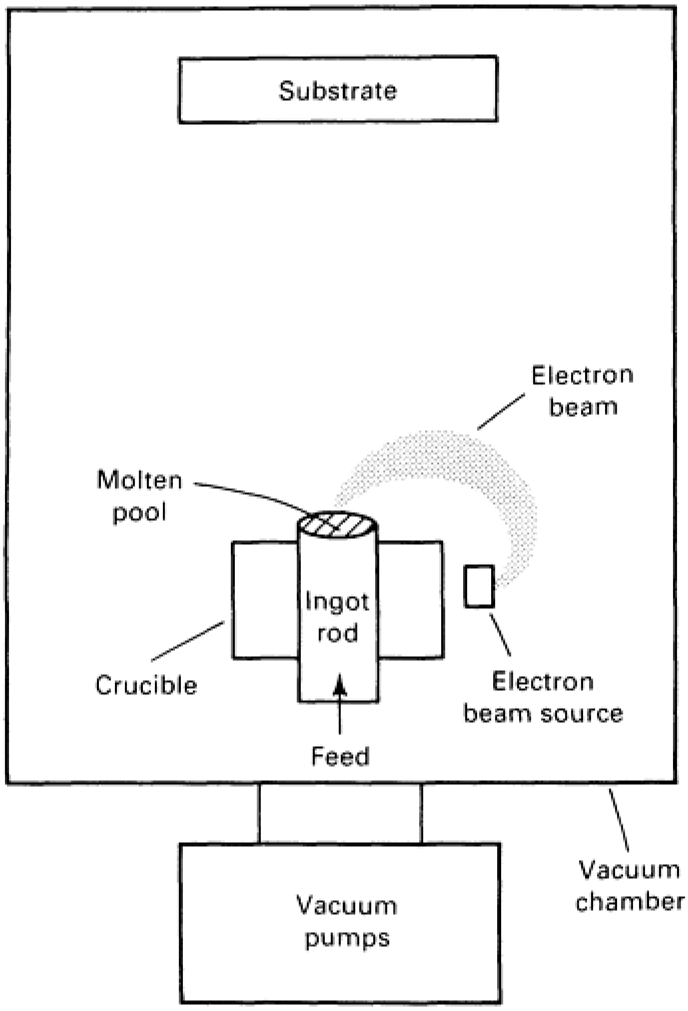

Fig. 2 Schematic of the basic evaporation process

Very large evaporation equipment, which was developed for the optical industry, is commercially available. Coatings of several microns in thickness can be rapidly deposited. The disadvantages of this method are nonuniform coverage (limited to line of sight) and relatively low adhesion unless glow discharge cleaning is used (glow discharge cleaning removes surface atoms from the substrate). Evaporation is very successful in applications in which adhesion and good structure are not critical, such as decorative and optical uses. Aluminum is the principal evaporation material; chromium and stainless steel are also widely used. Because improvements in technique have improved quality, evaporation is not used for critical corrosion applications.

Ion plating is actually a hybrid concept based on the evaporation (or sputtering) mechanism coupled with a glow discharge (Fig. 3). There are three possible deposition systems: resistance evaporation, electron beam evaporation, and sputtering. All three systems general a plasma by a glow discharge, thus imparting a large increase in the energy of the deposition species.

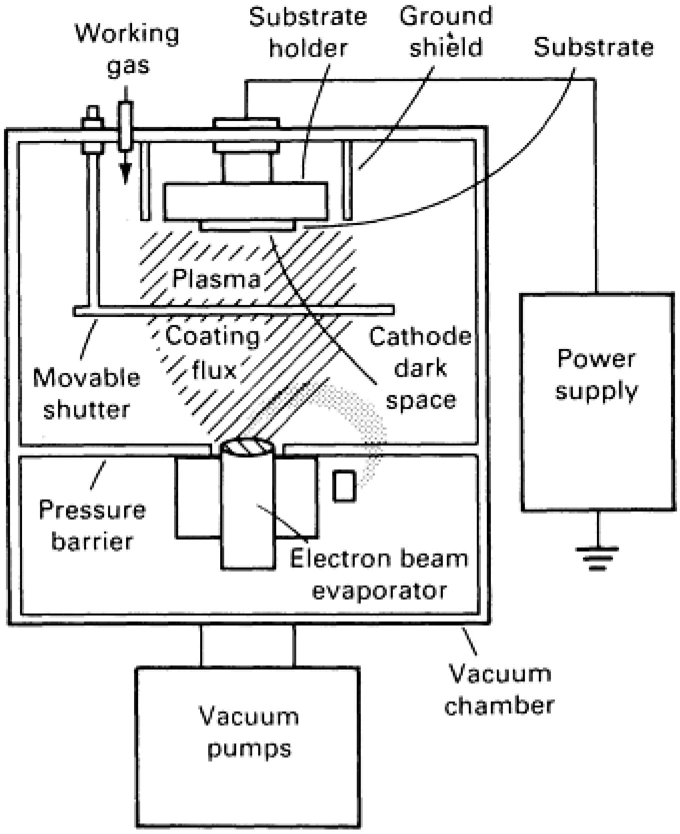

Fig. 3 Schematic of the basic ion plating process

It is generally accepted that plasma plays the same part as high temperature in improving the adhesion and increasing the reactivity of the coating; an ion passing through a potential of 100 eV acquires an equivalent temperature of 106 K. The simplest forms of ion plating are ion nitriding and ion carburizing, in which nitrogen or carbon ions are obtained from the ionization of nitrogen or a hydrocarbon. These react with a steel substrate to form nitrides or carbides. If the deposition species is ionized in a reactive gas, a compound is formed with some of the gas atoms, and deposition of the compound occurs. Ion plating is widely used and is gradually replacing pack cementation or diffusion.

Because ion plating is a glow discharge process in which a plasma is formed, it is necessary to have at least a threshold gas pressure to maintain the plasma. This is different from standard nonionized evaporation, in which the minimum pressure obtainable is preferred. The net effect of this higher gas pressure is to increase the number of collisions with gas molecules and therefore produce more scattering of the deposition species, which in turn diminishes the importance of the line-of-sight principle and improves coverage.

The deposited species in ion plating have higher energy than those of evaporation or sputtering processes; this results in improved adhesion as well as a deposit with improved structure and fewer imperfections. In addition, if a sputtering system is used, it is easy to sputter the surface of the substrate to clean it before deposition.

On the negative side, the equipment is more complicated and therefore more expensive than either evaporation or sputtering equipment, and the process is more exacting. The level of ionization can be difficult to control, which may result in uneven deposition. Although the process has not yet reached the total reliability necessary for automated operation and total acceptance, its advantages are such that it is rapidly gaining in popularity.

Chemical vapor deposition is a well-established deposition process that is extensively used in the semiconductor and cutting tool industries. It has the unique ability to deposit thick, dense, high-quality films (up to 6.4 mm, or $\frac{1}{4}$ in. in thickness or more) at a cost that is generally lower than that of PVD processes. The high temperature (about 1000 °C, or 1830 °F) necessary for CVD promotes good adhesion but also considerably restricts the type of substrate that can be coated to ceramics, refractory metals, and special alloys.

In most cases, steel will require heat treatment in a vacuum or protected atmosphere after CVD coating and will often change dimensions sufficiently to require postdeposition machining if tolerances are close. Another constraint resulting from the high temperature of deposition is the stress in the deposit due to the difference in thermal expansion between substrate and deposit. These stresses may be sufficient to cause cracking, spalling, and loss of adhesion. The new technique of plasma CVD can be used at much lower temperatures in, for example, semiconductor applications, but the resulting films tend to incorporate impurities.

The materials that can be easily deposited by CVD are more limited than with PVD. Chemical vapor deposition is particularly useful for depositing compounds and refractory metals and lends itself very well to corrosion applications.

Figure 4 shows a schematic of CVD laboratory equipment. The reactive gases are metered in the mixing chamber. They then pass into the deposition chamber and contact the heated part to be coated (sample); at this point, they react and deposition occurs. By-products are removed through the vacuum system.

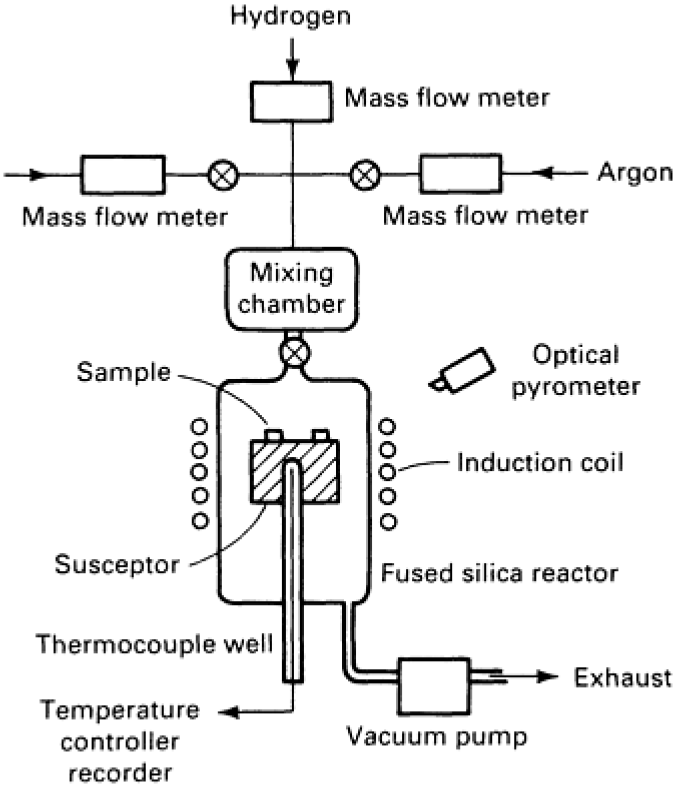

Fig. 4 Schematic of a laboratory CVD reactor

Chemical vapor deposition reactions can occur over the full range of pressure. Low pressure increases boundary-layer diffusion and uniformity, often at the expense of deposition efficiency. Each application and each reaction must be analyzed to determine the optimum conditions for deposition.

Coating Materials and Applications

The list of materials that can be vapor deposited is extensive and covers almost any coating requirement: the most important materials are given in Table 1. Aluminum and aluminum alloys are among the most widely used deposition materials and are gradually replacing cadmium in many corrosion applications. Sputtered chromium and stainless steel are also making great inroads in corrosion applications. A promising material is titanium nitride. It is hard, very stable, and refractory, and it has good lubricating characteristics and a pleasing gold appearance. It is widely used in wear applications, such as cutting tools, and in decorative applications. It is usually applied by sputtering or ion plating, and it holds potential for corrosion protection.

Table 1 Some corrosion-resistant vapor-deposited materials

Material	Deposition process
Aluminum	**Evaporation**
Chromium	**Sputtering**
Nickel	**CVD, sputtering**
Rhenium	**CVD**
Tantalum	**Sputtering, CVD**
Titanium	**Evaporation, sputtering**
Tungsten	**CVD, sputtering**
Boron	**CVD**
Carbon	**CVD, ion plating**
Titanium diboride	**Evaporation, CVD**
Silicon carbide	**Sputtering, CVD**
Titanium carbide	**Sputtering, evaporation, CVD**
Tungsten carbide	**Sputtering, CVD**
Boron nitride	**CVD**
Silicon nitride	**Sputtering, ion plating**
Titanium nitride	**CVD, sputtering, ion plating**
Aluminum oxide	**Sputtering, ion plating**
Molybdenum silicide	**Sputtering, ion plating**
Nickel-chromium alloys	**Sputtering**

Gold alloys	**Evaporation**
Borazon	**CVD**
MCrAlY	**Evaporation, sputtering**
Bronze	**Evaporation, sputtering**

The properties of these materials vary widely and reflect the complexity of selecting a corrosion-resistant coating for a given substrate or a given environment and the need to conduct a thorough analysis of the problem. This is especially true when cost is the primary factor. For example, gold is an ideal material for many corrosion applications, but would of course be cost prohibitive in most cases. Before selecting a material and process for a corrosion resistance application, the following considerations should be reviewed:

- Availability and cost of the coating material
- Cost, size, complexity, and availability of the deposition equipment
- Resistance to the chemical environment of the coating material
- Compatibility with the substrate, especially thermal expansion mismatch
- In special applications, such as aerospace, high-temperature resistance, radiation resistance, and high-vacuum stability

Chemical vapor deposited and PVD coatings have the advantage that the film (if thick enough) is essentially pore free and fully dense. Penetration by moisture and gases to the substrate is greatly reduced, if not eliminated. Despite this, the role played by CVD/PVD coatings in corrosion protection remains small. Some current applications are discussed below.

Coating for Graphite. Graphite is perhaps the best material for applications requiring high strength and low density at very high temperatures. It is used as a hot-pressed material or as a carbon-carbon composite, which is a combination of graphite fibers and a carbonized resin matrix. Graphite is used exclusively in such applications as rocket nozzles or advanced turbine components. However, its disadvantage is a lack of oxidation resistance above 500 °C (930 °F). By using CVD to coat the graphite with silicon carbide, it is possible to provide oxidation protection up to 1650 °C (3000 °F). Silicon carbide oxidizes to form a silicon oxide surface that will prevent further oxidation. Advanced studies to further increase the oxidation temperature of graphite are in progress using such oxides as hafnia.

Aluminum Coating of Steel. The coatings of steel (and other metals) with aluminum by ion plating is an industrial process with excellent potential for large-scale production. It replaces hot dipping of aluminum on steel, which has been in use for many years. During immersion in hot dipping, a brittle intermetallic compound layer of iron-aluminum is formed; this limits the formability of the steel. In addition, the coating contains iron impurities, which may be a severe shortcoming in highly corrosive environments (Ref 1).

Electroplated cadmium is another commonly used system for the corrosion protection of steel and other metals. However, it can cause hydrogen embrittlement of high-strength steel and titanium. In addition, cadmium has a low melting point (320 °C, or 608 °F) and presents environmental problems because of its toxicity. A process has recently been developed for applying aluminum on metals by ion vapor deposition, which has none of the restrictions of hot dipping or cadmium electroplating. This process falls under military specification MIL-C 83488.

Vapor deposition of aluminum does not produce hydrogen; therefore, it does not cause embrittlement. Vapor-deposited aluminum protects against stress-corrosion cracking (SCC) and has a temperature limit of 495 °C (925 °F). It is less expensive than most other barrier coatings. Applications for vapor-deposited aluminum in the aerospace industry include fuel and pneumatic line fittings (in place of anodizing), electrical connectors to replace cadmium, powder metallurgy parts, fasteners, electrical black boxes, corrosion and SCC protection of depleted uranium and titanium alloys, and electromagnetic interference compatibility (Ref 2).

Alloy Coatings for Gas Turbines. Gas turbines can be divided into three general categories: aircraft turbines using highly refined fuels with operating temperatures between 900 and 1150 °C (1650 and 2100 °F) (new designs require even higher temperatures); marine turbines using moderately refined fuels, which operate at 700 to 870 °C (1290 to 1600 °F) and are exposed to salt corrosion; and industrial turbines operating at 760 to 925 °C (1400 to 1700 °F) and using moderately refined fuels, often with high sulfur contents. The primary material problems in these applications are oxidation and high-temperature corrosion. These problems are becoming more acute with the trend toward higher operating temperatures for better performance and improved fuel economy.

Until recently, thermal spraying of refractory alloys to protect exposed parts constituted the bulk of the market. An estimated $25 million worth of refractory powder was used in 1985 for gas turbines alone (Ref 3). In the last few years, PVD coating by electron beam evaporation and sputtering have gained wide acceptance. These coatings consist of alloys of chromium, aluminum, and yttrium with cobalt, nickel, or iron and are known generically as MCrAlY. They are successfully used on aircraft turbines. Recent developments have shown an improvement factor of four over previously used diffusion coatings for protection against sulfidation corrosion (Ref 4). Large production units are available. For example. 100-μm (4-mil) thick films, usually NiCoCrAlY or CoCrAlY, are deposited by electron beam evaporation.

Marine gas turbines are subject to severe sulfidation, oxidation, and hot corrosion, especially in the presence of sodium sulfate (Na_2SO_4). Electron beam evaporated CoCrAlY coatings have considerably increased the service lives of first-stage blades. Further improvements have been achieved by using high-chromium low-yttrium alloys.

Industrial turbines normally do not require corrosion protection unless high-sulfur fuels are used, for example, as in Saudi Arabia. In such cases the hot corrosion problem can be solved by using thin-film CoCrAlY coatings and a very large (200-kW) electron beam coater capable of handling industrial turbine parts weighing up to 40 kg (90 lbs).

Thermal Spray Coatings

Robert H. Unger, TAFA Inc.

Introduction

THERMAL SPRAY COATINGS provide effective long-term corrosion protection of iron and steel over a wide range of corrosive environments. Corrosion protection can be obtained for up to 20 years without maintenance and up to 40 years with minimal maintenance. Such long-term protection has been documented for both atmospheric and immersion service in numerous industrial and marine applications.

Thermal spraying is a particularly versatile technique because it can be used both in-shop or on-site. This article will discuss the various thermal spray processes, the types of coatings produced, and the protection these coatings can provide in various environments. Some of the advantages of thermal spraying are the ability to apply significantly thicker coatings than galvanizing, excellent paintability, no heat distortion from processing, no curing requirements, and the capability of applying coatings in the field.

Fundamentals of the Process

Thermal spraying comprises a group of processes in which finely divided molten metallic or nonmetallic material is sprayed onto a prepared substrate to form a coating. The sprayed material is originally in the form of wire or powder. As the coating materials are fed through the spray unit, they are heated to a molten or plastic state and propelled by a stream of compressed gas onto the substrate. As the particles strike the surface, they flatten and form thin platelets that conform and adhere to the irregularities of the prepared surface and to each other. They cool and accumulate, particle by particle, into a lamellar, castlike structure. The spray gun generates the necessary heat for melting through combustion of gases, an electric arc, or a plasma. Figure 1 illustrates a general thermal spraying process.

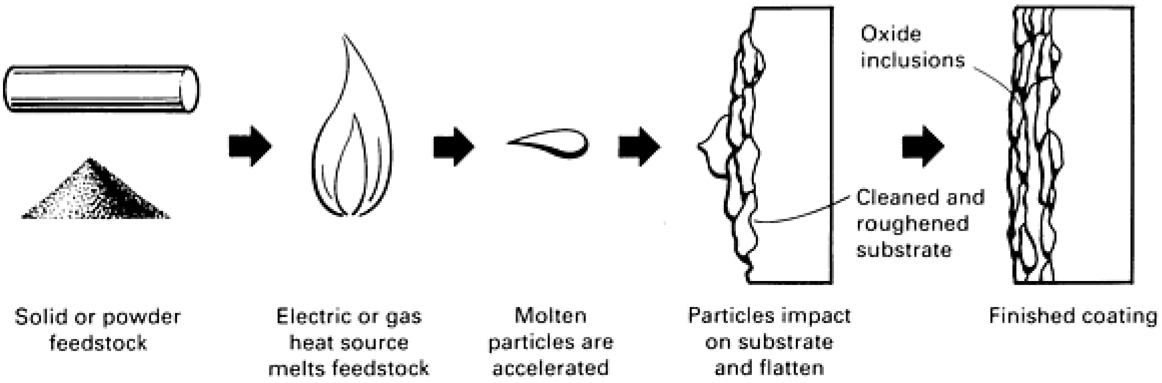

Fig. 1 Schematic of the general thermal spray process

The deposited structures of thermal spray coatings differ from those of the same material in the wrought form because of the incremental nature of the coating buildup and because the coating composition is often affected by reaction with the process gases and the surrounding atmosphere while the materials are in the molten state. For example, where air or oxygen is used as the process gas, oxides of the material applied may be formed and become part of the coating. The as-applied structures of all thermal spray coatings are similar in their lamellar nature; the variations in structure depend on the particular thermal spray process used, the processing parameters and techniques employed, and the material applied.

The bond between the sprayed coating and the substrate is generally mechanical. Proper surface preparation of the substrate before spraying is often the most critical influence on the bond strength of the coating. Surface preparation techniques will be discussed in the section "Surface Preparation" in this article.

Methods of Deposition

The most common methods of depositing thermal spray coatings can be classified as wire flame, powder flame, electric arc, and plasma.

Wire flame spraying, the oldest spray process, uses the heat from a chemical reaction as the melting source. Common fuel gases are acetylene, methyl-acetylene-propadiene (MAPP), propane, propylene, and natural gas, each combined with oxygen. Acetylene is the most widely used because of the higher temperatures it produces. Any material available in the form of wire and capable of being melted below 2480 °C (4500 °F) can be flame sprayed. Figure 2 shows a schematic of the wire flame spraying process.

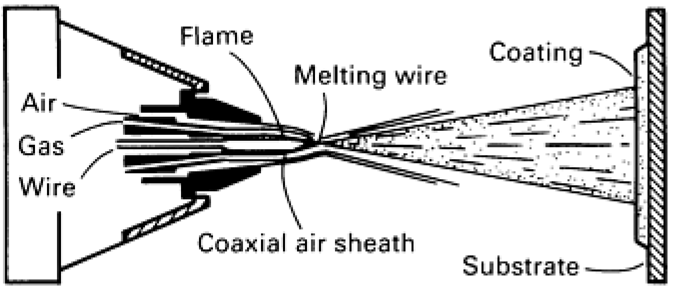

Fig. 2 Schematic of the wire flame spray process

The gas flame is used only to melt the material. Spraying is accomplished by surrounding this flame with a coaxial stream of compressed gas--for example, air--to atomize the molten material and to propel it onto the workpiece.

Wire flame spraying is widely used in the on-site spraying of zinc, aluminum, and zinc/aluminum alloys because of its low capital investment, portability, and ease of operation. In general, wire flame sprayed coatings exhibit lower bond strengths, higher porosity, a narrower working-temperature range, and higher heat transmittal to the substrate than plasma or electric arc sprayed coatings.

The powder flame spray process also uses combustion gases as the heat source, but with a powder feedstock (Fig. 3). This offers the advantage of being able to spray nonmetallic materials that are not available as wire. In its simplest form, the gun requires no compressed air supply. The powder feedstock is stored in a hopper mounted on top of the gun, and a small amount of oxygen from the gas supply is diverted to carry the powder by aspiration into the oxygen-fuel gas flame, in which it is melted and carried by the flame onto the workpiece. The equipment is lighter and more compact than other forms of thermal spray equipment, but because of the lower particle velocities obtained, the coatings generally have lower bond strength, higher porosity, and a lower overall cohesive (interparticle) strength than the coatings produced by other thermal spray processes.

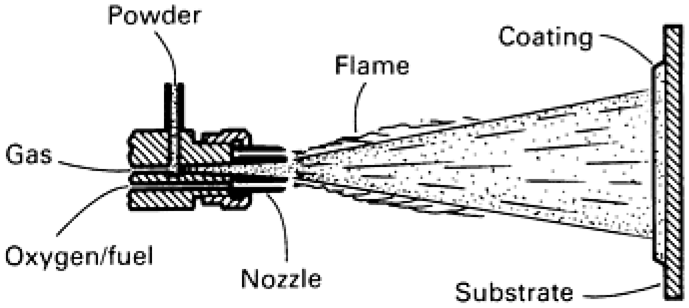

Fig. 3 Schematic of the powder flame spray process

Electric arc spraying uses metal feedstock in wire form without the need for combustion gases. Figure 4 shows a schematic of the electric arc spraying processes. Two feedstock wires serve as electrodes, which are initially insulated from each other and advance to meet at a point in an atomizing gas stream. A potential is applied across the wires so that an arc is formed at the intersection tips where the wires melt. A stream of gas, usually compressed air, flows across the arc zone and strips off the liquid metal to form molten droplets that are propelled onto the substrate.

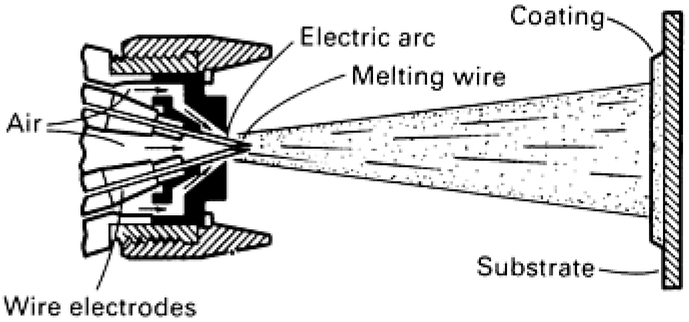

Fig. 4 Schematic of the electric arc spray process

Because of the high temperatures in the arc zone, the coatings have excellent adhesion and high cohesive strength. The superheating of the particles leads to metallurgical interactions after impact of the particles on the metal substrate. These localized interactions can often lead to small weld spots; this increases bond and cohesive strengths considerably compared to flame spraying. Substrate heating is also significantly lower than in other processes because of the absence of the heat from a flame.

The electric arc spray system, like the flame spray system, is light and portable and is commonly used for on-site anticorrosion spraying. A portable generator can be used to supply electricity for remote jobs.

The plasma spray process uses coating materials in the form of powders, which are melted with a plasma heat source (Fig. 5). Plasma provides controllable temperatures that range well above the melting point of any known substance. To generate the plasma, inert gas is passed through an electric arc contained within the gun; the arc, in turn, heats the gas. The hot gas issuing from the gun is called plasma and resembles a bright flame. Powder feedstock is introduced into the plasma stream, becomes molten, and is accelerated and carried to the workpiece by the free plasma stream.

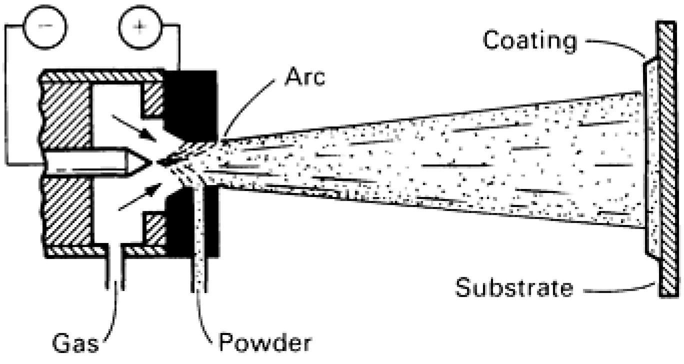

Fig. 5 Schematic of the plasma spray process

The plasma system produces excellent coatings, but the equipment is complex and expensive to operate. For most anticorrosion spraying, particularly on-site work, the other spray processes usually provide adequate coatings, and plasma is not generally used. Plasma spraying is often used where coatings are needed to provide corrosion protection against chemical or high-temperature corrosion and where the work can be done in-shop.

Surface Preparation

Thermal spray coatings rely primarily on mechanical bonding to the substrate surface. Because bonding relies on this mechanical interlocking of spray particles with the substrate surface, preparation of the surface is critical to a successful coating. Preparation of the substrate before spraying is virtually the same for all thermal spray processes.

Cleaning and Degreasing. Chemical cleaning is used on parts that are contaminated or impregnated with material that cannot be removed by other methods. Surfaces can be chemically cleaned by vapor degreasing, steam, hot detergent washing, or application of an industrial cleaning solvent. Degreasing is usually the most economical and safest way to remove lubricants and oils.

Grit blasting is the most frequently used surface preparation procedure. The roughening cleans the surface of contamination that may inhibit bonding and creates an irregular profile of minute surface irregularities. This enhances the adhesion of the coating. Before application of the thermal spray coating, a steel substrate should be blasted to a white-metal condition (according to Steel Structures Painting Council specification SSPC-SP5-82) with an appropriate surface profile (75 μm, or 3 mils). Sharp grit should be used, because the substrate must be cleaned and given an anchor tooth profile for a proper mechanical bond. Coarse-grit (18 to 24 mesh) materials are also used, such as aluminum oxide, chilled iron grit, coal slag, copper slag, and silica sand.

Rough threading is often used in conjunction with grit blasting for cylindrical surfaces. It consists essentially of machining a thread form on the area to be sprayed. This type of preparation provides excellent adhesion of the coating to the substrate.

Bond coats are often used when an extremely high bond strength is desired or when mechanical deformation of the substrate is not possible or practical. This involves spraying materials that are exothermic and self-bonding. Nickel-aluminum alloys, aluminum bronze, and molybdenum are the most commonly used bond materials. A thin coating (normally about 50 to 125 μm, or 2 to 5 mils) of bond material is generally applied before the corrosion-resistant overcoat. Care should be taken to ensure that the bond material is compatible with the overcoat and that a galvanic cell with not be created, which may be detrimental to the performance of the coating system.

Preheating of the substrate is often beneficial. Preheating to 65 to 95 °C (150 to 200 °F) will eliminate surface condensation and will reduce shrink differentials between the coating and the substrate. It is generally employed only with the flame spray processes, which use their flame as the heat source for warming the substrate.

Coating Selection for Atmospheric and Immersion Environments

Zinc and aluminum and their alloys are the metals most widely used for thermal spray anticorrosion coatings. They are extensively used for the corrosion protection of iron and steel in a wide range of environments and have been shown to provide very long-term protection (over 20 years) in both marine and industrial locations. The British Standards Institute Code of Practice (Ref 1) specifies that only these electrochemically active metals will give protection of greater than 20 years for every type of environment considered and that, in areas of immersed seawater or in seawater splash zones, only sealed sprayed zinc or aluminum will give such protection. Corrosion tests of thermal spray coated steel conducted by the American Welding Society confirm the remarkable effectiveness of sprayed zinc and aluminum coatings over long periods of time in various hostile environments (Ref 2).

Under most conditions, zinc and aluminum are more corrosion resistant than steel; therefore, they form an effective barrier film between the steel substrate and the atmosphere. More important, because they are anodic to steel, they also act galvanically to protect the ferrous substrate from corrosion in electrolytic solutions, such as saline environments. In effect the metallized coating serves as a sacrificial anode. This prevents corrosion of the steel substrate even where the coating coverage is incomplete or suffers mechanical damage.

Zinc and aluminum coatings both provide excellent protection in a wide variety of marine and industrial environments. In general, aluminum corrodes less rapidly than zinc in highly acidic conditions, but zinc performs better than aluminum in alkaline conditions. Aluminum is chosen for the protection of steel in chemical plants or in other applications in which the temperature is likely to exceed 120 °C (250 °F). Sprayed zinc coatings are used in coal mines because of the possibility of

impact spark generation between aluminum and rusty steel (Ref 3). Zinc is normally the preferred metal for the protection of steel in fresh cold waters; aluminum is used in aqueous solutions above 65 °C (150 °F).

Thermal spray zinc and aluminum coatings are progressively supplanting both painting and hot-dip galvanizing for reasons of effectiveness and economics. Thermal spray coatings have a predictable life, require a single application, protect damaged areas cathodically, have good abrasion resistance, and do not require drying.

The size or shape of the structure to be protected is not a limiting factor. Components can be metal sprayed in-plant or on-site, and automation is possible for long runs of identical work. The thickness of the metal coating can be controlled according to the degree of protection required. The life of the metal coating is proportional to the coating weight per unit area. For a very long service life or in highly corrosive conditions, it is possible to increase the coating thickness to enhance corrosion protection.

Sprayed zinc or aluminum coatings can be applied in thicknesses ranging from 50 to 500 μm (2 to 20 mils) (Ref 4). Furthermore, parts that are not to be coated can be masked during spraying, and the coating thicknesses can be varied in different areas of the same structure. Areas of coating discontinuity or insufficient thickness can easily be rectified by additional spraying.

Both aluminum and zinc coatings have good adhesion to grit-blasted steel. Spraying does not cause excessive heating of the substrate; therefore, there is no distortion or effect on the mechanical properties of the steel. All grades of steel can be sprayed.

A limited amount of porosity (usually <15%) is an inherent feature of thermal spray coatings. In the case of active metal coatings, such as zinc or aluminum, porosity is not a deficiency. Pores will not result in substrate attack, because of the protection afforded by galvanic action. In fact, the natural surface porosity provide an excellent base for sealers or topcoats where these are desired for decorative purposes or to extend the life of the coating.

Over the years, zinc and aluminum thermal sprayed coatings have been used in a broad variety of corrosion protection programs. In Europe, where metal spraying for corrosion protection has been used far more widely than in the United States, there are numerous case histories of successfully sprayed structures, some as long as 40 years ago, that have been kept in good condition with minimal maintenance (Ref 5).

The selection of a zinc or aluminum coating systems depends on the service environment and the desired life. Table 1 lists such coatings for atmospheric and immersion service, but is intended to serve only as a guide in choosing a coating systems.

Table 1 Thermal spray coatings for atmospheric and immersion service

Exposure environment	Thickness of coating systems for 20-year expected life

Zinc-Aluminum Alloys. Corrosion protection can also be provided by the use of zinc-aluminum alloys, such as Zn-15Al. This alloy does not have the performance record of pure zinc or aluminum, but studies in Europe and Japan and, more recently, in the United States suggest that such alloys combine the advantages of zinc and aluminum and may outperform both in certain environments (Ref 6). The Zn-15Al alloy is now available in either wire or powder form. Installed costs are comparable to either pure zinc or aluminum.

Other Coating Materials. Austenitic stainless steels, aluminum bronze, nickel-base alloys, and MCrAlY, among other materials, are also thermal sprayed to combat corrosion in certain applications. Selection of a specific alloy depends on the particular environment. When using these alloys, it must be understood that these coatings will not galvanically protect the underlying steel. This can be a particular problem due to the porosity of thermal spray coatings. Great care must be taken to ensure that these coatings are properly sealed in order to prevent penetration of the corrosive medium to the underlying steel and subsequent corrosion at the coating/substrate interface.

Coating Selection for High-Temperature Environments

Thermal spray coatings are extensively used by industry to protect steel components and structures from heat oxidation at surface temperatures to 1095 °C (2000 °F). By ensuring long-term protection, thermal spray coatings show real economic advantages during the service lives of such items. Coatings are particularly effective in protecting low-alloy and carbon steels. Table 2 lists thermal spray coatings for use in high-temperature applications.

Table 2 Thermal spray coatings for elevated-temperature service

Service temperature	**Coating metal or alloy**	Coating thickness	
		µm	mils
Up to 550 °C (1020 °F)	Aluminum	175	**7**
Up to 550 °C (1020 °F) in the presence of sulfurous gases	Ni-43Cr-2Ti	375	**15**
550-900 °C (1020-1650 °F)	Aluminum or aluminum-iron	175	**7**
900-1000 °C (1652-1830 °F)	Nickel-chromium or MCrAlY	375	**15**
900-1000 °C (1650-1830 °F) in the presence of sulfurous gases	**Nickel-chromium, followed by aluminum**	**100**	**4**

Source: Ref 7

Aluminum has been widely used to protect such steels in a number of applications involving high surface temperatures. Nickel-chromium alloys and some of the MCrAlY alloys have also provided protection in severe environments.

Coatings for Temperatures to 550 °C (1020 °F). Sprayed aluminum coatings provide excellent oxidation resistance and cathodic protection against corrosion by industrial atmospheres, hot gases, and condensation products at temperatures to 550 °C (1020 °F). Sealing of the sprayed aluminum coatings, although not essential, may be desired for decorative purposes or to maintain a clean appearance. A high-temperature aluminum-pigmented silicone paint is generally recommended.

Nickel-chromium alloys provide good protection over this temperature range in the presence of sulfurous gases. To achieve adequate protection, nickel-chromium alloys should have a chromium content of at least 40% (Ref 8). The addition of a small amount of titanium is also advantageous for increasing corrosion resistance and strengthening the coating-substrate bond (Ref 9).

Coatings for Temperatures From 550 to 900 °C (1020 to 1650 °F). For service temperatures in this range, sprayed aluminum or aluminum alloy coatings 150 to 200 μm (6 to 8 mils) thick have proven to be effective. At these temperatures, sprayed aluminum diffuses into the steel surface. These aluminized coatings are nonporous, consisting essentially of an aluminum-iron alloy containing about 15% Al. During prolonged service at 550 to 900 °C (1020 to 1650 °F), the aluminum-iron diffusion process continues, resulting in the depletion of aluminum at the steel surface; therefore, oxidation resistance is progressively impaired.

The aluminum-sprayed steel is often heat treated before being put into service in order to bring about the required diffusion. If a high-bonding thermal spray process, such as electric arc spraying is used, the heat-treating step is not always necessary. Electric arc sprayed steel can be put directly into service and can be heat treated during operation.

Coatings for Temperatures From 900 to 1000 °C (1650 to 1830 °F). Nickel-chromium alloy coatings 375 μm (15 mils) thick can be used for protection at temperatures in this range. In the absence of sulfurous gases, the alloys generally range in composition from Ni-15Cr-25Fe to Ni-20Cr. For environments containing sulfurous gases, a nickel-chromium alloy, followed by a supplementary protective coating of 100 μm (4 mils) of sprayed aluminum, has shown to be an effective system. During heat treatment or service, the aluminum diffuses into the nickel-chromium alloy, forming an aluminum-rich layer that is highly resistant to sulfurous gas attack (Ref 7).

Work with superalloys has shown that FeCrAlY alloys, when thermally sprayed in an inert atmosphere, offer a stable system with good ductility and oxidation resistance at these high temperatures (Ref 10). Specifically, inert electric are sprayed FeCrAlY is applied to tungsten alloy fibers to produce a very strong corrosion-resistant fiber-reinforced superalloy for use in turbine blades at very high temperatures.

Sealing of Thermal Sprayed Coatings

Sealers or topcoats are commonly used to extend the life of thermal spray coatings and for decorative purposes. They are generally applied in a minimum of two coats; the first coat is thinned to allow proper penetration into the coating pores. Common sealers include vinyls, epoxies, phenolics, and polyurethanes. Such materials are discussed in detail in the article "Organic Coatings and Linings" in this Volume.

Sealers are not always necessary for zinc or aluminum coatings, because of the galvanic protection afforded. However, they are commonly used in most environments to seal the pores of the coating and to extend surface life. A sealed coating also generally gives a more pleasing appearance.

Sealers are essential for most immersion or chemical corrosion applications. In particular, materials other than zinc or aluminum, which do not galvanically protect the steel, must be sealed to prevent coating failure due to the porosity of the coating.

Quality Control and Inspection

Inspection and quality control procedures for thermal sprayed coatings are similar to those used for other types of coatings.

Quality of Surface Preparation. The abrasives used for surface preparation should be inspected to ensure that they meet specifications for grit size, type, and cleanliness. After the blasting operation, the surface should be visually inspected to ensure that the substrate is clean. A profilometer can be used to inspect for adequate surface roughness. Standard coupons or photographs may also be used as visual standards to ensure proper surface preparation. These are readily available from the SSPC, or they can be prepared in advance by the applicator.

Coating Quality. Generally, certification of the coating material can be readily obtained from the material supplier. This certifies that the material meets proper specifications for such qualities as chemical composition and physical characteristics. The spray equipment should be operated and maintained according to the standards of the manufacturer.

The installed coating can be visually inspected for surface finish and defects. Coating thickness can be verified by destructive testing, which consists of removing the coating with a knife or chisel. More commonly, the thickness of zinc or aluminum coatings is verified by using a magnetic dry-film thickness gage.

Typical Applications

Thermal spray coatings, primarily zinc and aluminum, have been successfully used to combat corrosion in a wide range of applications. Steel structures and components that have been zinc or aluminum sprayed include TV towers, antennae, radar, bridges, light poles, girders, ski lifts, and countless other similar structures. In addition, thermal spray coatings, primarily aluminum, offer years of protection in marine applications, such as buoys and pylons. Aluminum spraying has been used in offshore oil rigs for well head assemblies, flare stacks, walkways, and other structural steel components.

Shipboard components, both above and below deck, commonly use aluminum spraying. The United States Navy, in particular, uses aluminum spraying extensively to combat corrosion (Ref 11). There are countless approved applications for sprayed metal coatings aboard Navy ships (Ref 12).

Numerous immersion applications have also employed zinc or aluminum spraying, for example, dams and sluice gates. The interiors of potable water storage tanks are also sprayed with zinc to provide corrosion protection of the steel without the threat of contaminating the water with a solvent that may be present in an epoxy coating system.

Aluminum has also been used to control chemical corrosion in such applications as storage tanks for fuels or other liquids. The interiors of railroad hopper cars are often sprayed to protect them against sulfuric acid (H_2SO_4) corrosion when hauling coal.

Stainless steels, Hastelloy alloys, and other alloys can also be effective against chemical corrosion for storage vessels, rolls, pumps, and other structures. The coatings must be properly sealed when using these alloys.

Common applications involving high-temperature corrosion include coating exhaust stacks, chimneys, flues, rotary kilns and dryers, catalytic crackers, and furnace parts. These generally involve use of an aluminum or nickel-chromium alloy coating such as those previously described.

One specific high-temperature corrosion application that has met with great success in recent years is the coating of boilers in paper mills, power plants, and chemical plants. Water-wall tubes in these applications suffer severe corrosion because of the high sulfur content of the burning fuel, the high operating pressures, and abrasion (Ref 13). A 375-μm (15-mil) coating of Ni-43Cr-2Ti alloy offers extremely good protection against this very severe corrosion at temperatures up to 550 °C (1020 °F) (Ref 8).

Anodic Protection

Carl E. Locke, University of Kansas

Introduction

ANODIC PROTECTION is the most recently developed of all the various corrosion control methods available. This method was first used in the field in the late 1950s. Anodic protection did not become commercially successful until the early 1970s, and it is currently used on a smaller scale than other corrosion control techniques. This article will provide a brief history of the technique, will discuss anodic protection use, and will compare anodic and cathodic protection. A more complete description of all aspects of anodic protection is available in Ref 1.

History

The scientific principles of passivity on which anodic protection is based can be traced to experiments by Faraday and Schobein in the 19th century (Ref 1). Work by C. Edeleanu published in 1954 (Ref 2) was responsible for further investigations and developments at the Continental Oil Company. This later work resulted in several installations of anodic protection to control the corrosion of chemical plant equipment (Ref 3, 4, 5, 6). Simultaneous investigations at the Pulp and Paper Institute of Canada led to installation of anodic protection to protect pulp and paper digesters (Ref 7, 8, 9).

Commercialization of anodic protection was begun by Continental Oil Company through licensing agreements, and only a few companies are currently marketing anodic protection. The most active of these companies are Canadian-based corporations that sell, engineer, and install anodic protection systems in the United States.

Anodic Protection Use

Anodic protection has been most extensively applied to protect equipment used to store and handle sulfuric acid (H_2SO_4) (Ref 10). Sales of anodically protected heat exchangers used to cool H_2SO_4-manufacturing plants have represented one of the more successful ventures in the past few years. These heat exchangers are sold complete with the anodic protection systems installed and have a commercial advantage in that less costly materials can be used.

Protection of steel H_2SO_4 (>78% concentration) storage vessels is perhaps the most common application of anodic protection. Companies in North America and Europe sell systems primarily for these storage vessels and the heat exchangers. There is little activity directed toward developing applications to protect metals from corrosion by other chemicals. However, in the USSR, a substantial amount of effort is devoted to installing anodic protection in a wide variety of systems. Several recent applications are discussed in Ref 11.

Anodic protection is used to a lesser degree than the other corrosion control techniques, particularly cathodic protection (see the article "Cathodic Protection" in this Volume). This is because of the limitations on metal-chemical systems for which anodic protection will reduce corrosion. In addition, it is possible to accelerate corrosion of the equipment if proper controls are not implemented. The understanding of anodic protection is also not as widespread as for other techniques. Anodic protection does have a place in the corrosion control area, for which it is the most feasible and economical technique, and use of this technique is expected to increase slowly in coming years.

Comparison of Anodic and Cathodic Protection

Cathodic protection has been used since the middle of the 19th century and has gained widespread acceptance. Anodic protection is sometimes confused with cathodic protection, but the two techniques are fundamentally different. Basically, the difference concerns which electrode is protected; the cathode is protected in cathodic protection, and the anode is protected in anodic protection. However, there are other, more significant theoretical differences. The background and theory of both methods are discussed in Ref 12.

Cathodic protection is based on using electrochemistry to slow or stifle the corrosion reaction. Currents generated by galvanic metallic couples or external dc current supplies flow in such a direction as to shift the cathode potential to a value at which the corrosion reaction will not occur. Other descriptions of cathodic protection state that the currents result in the metal to be protected becoming a cathode over the entire metal surface and shifting the anodic reaction to an external electrode. In principle, any corrosion system can be cathodically protected as long as there is a continuous ionic path between the external anode and the metal to be protected. The only limitations are ones of economics and practicality due to current and voltage requirements.

Anodic protection, like cathodic protection, is an electrochemical method of controlling corrosion, but is based on a different electrochemical principle. Anodic protection is based on the phenomenon of passivity. A limited number of metals in a limited number of chemicals have the property of passivity. The electrochemical nature of achieving passivity requires that the potential of the metal be controlled. This is not necessary for most of the applications of cathodic protection. Current requirements for anodic protection can be much lower than those required for cathodic protection, but this is not always the case for all systems.

Background and Theory

Anodic protection can be used to control the corrosion of metals in chemicals that exhibit very interesting behavior when subjected to anodic polarization. This behavior can be studied with an experimental setup, as illustrated in Fig. 1. When the potential of the working electrode relative to the reference electrode is controlled and shifted in the more anodic (positive) direction, the current required to cause that shift will vary. If the current required for the shift has the general type of behavior with respect to potential shown in Fig. 2, the metal is termed active-passive and can be anodically protected. Few systems exhibit this type of behavior. The metals and solutions that have been found to have active-passive properties and that can be anodically protected include:

Solutions	Metals
Sulfuric acid **Phosphoric acid** **Nitric acid** **Nitrate solutions** **Aqueous ammonia** **Organic acids** **Caustic solutions**	**Steels** **Stainless steels** **Nickel** **Nickel alloys** **Chromium**

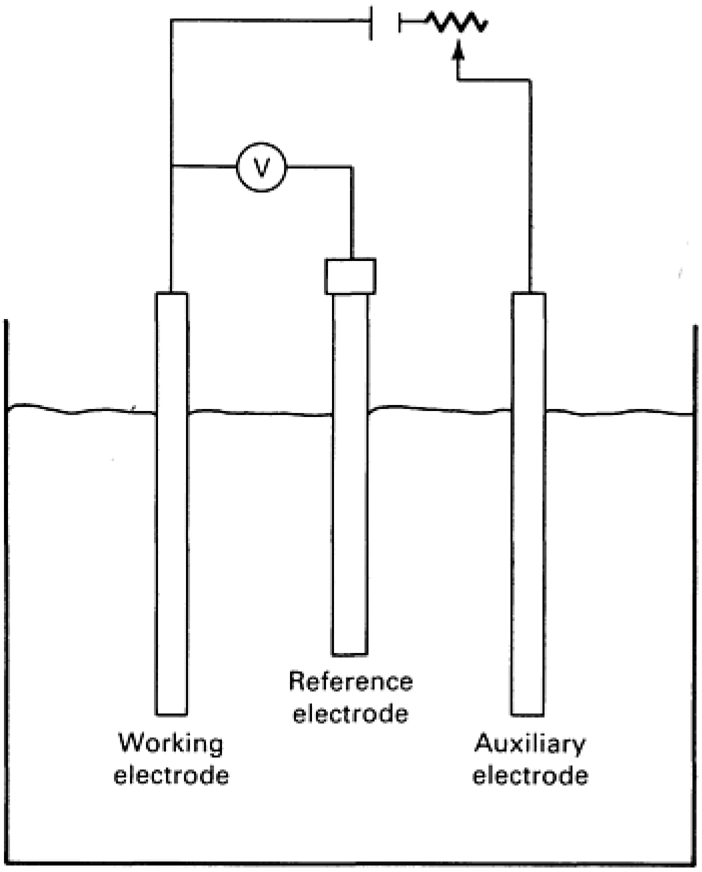

Fig. 1 Schematic of experimental apparatus used for anodic polarization studies. Current flow between the working electrode and the auxiliary electrode forces a shift in potential between the working electrode and the reference electrode. V, voltmeter. Source: Ref 15

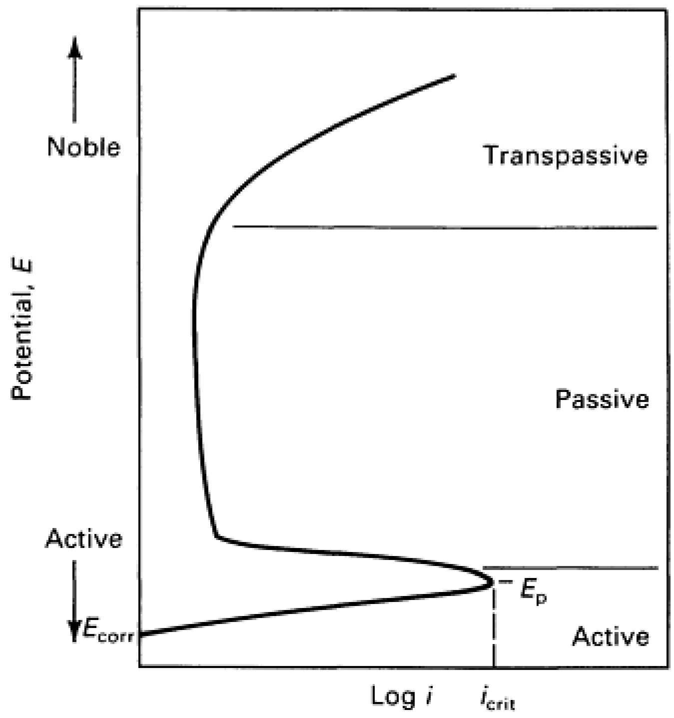

Fig. 2 Schematic anodic polarization curve. Metal-environment systems that have this type of anodic polarization behavior are termed active-passive and can be anodically protected. Source: Ref 15

The corrosion rate of an active-passive metal can be significantly reduced by shifting the potential of the metal so that it is at a value in the passive range shown in Fig. 2. The current required to shift the potential in the anodic direction from the corrosion potential E_{corr} is several orders of magnitude greater than the current necessary to maintain the potential at a passive value. The current will peak at the potential value shown as E_p (Fig. 2). The current required to achieve passivity (protection) is typically a few hundred milliamps per square foot wetted area. The current necessary to maintain passivity is usually 10.76 $\mu A/m^2$ (1 $\mu A/ft^2$) or less.

This interesting anodic polarization behavior results from the formation of a surface layer on the metal that is relatively insoluble in the chemical environment. This passive film is not yet completely understood.

Passivity is the phenomenon responsible for the high corrosion resistance of stainless steels. It can be variously defined, but a reasonable definition is that passivity is the loss of chemical reactivity experienced by some metals in special environments. These metals and alloys, when passive, behave as noble metals. This noblelike behavior is attributed to the presence of a thin oxide film on the metal surface. The mechanism of formation, the composition, and the structure of the passive film have been extensively studied, but are not well understood.

Passivity can be achieved by alloying and by chemical means in addition to the electrochemical method described in this section. Anodic protection can be used to form the passive film on metals in chemical systems that would normally be corrosive; at other times, anodic protection can be used to maintain the passivity of the metal so that process upsets or changes do not force the metal to become active and corrode.

Equipment Required for Anodic Protection

Figure 3 shows a schematic of an anodic protection system for a storage vessel. Each of these components has specific requirements that will be discussed below. In addition, the various items used for each component of the system will be briefly described.

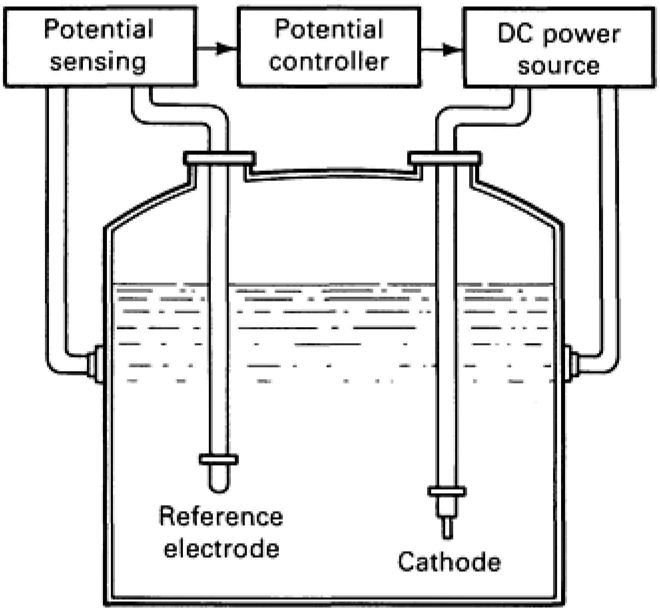

Fig. 3 Schematic of an anodic protection system. One or more cathodes, a reference electrode, a potential sensing and controlling circuit, and a dc power supply are required for each anodic protection system. The vessel wall is made the anode of the circuit by current forced between the cathode and the tank wall. The currents are controlled so that the potential of the wall with respect to the reference electrode is shifted and maintained in the passive region (see Fig. 2). Source: Ref 1

Electrodes

The cathode should be a permanent-type electrode that is not dissolved by the solution or the currents impressed between the vessel wall and electrode. The cathodes used in most of the first applications of anodic protection were made of platinum-clad brass (Ref 1, 2, 3, 4, 5, 6). These electrodes were excellent electrochemically, but they were costly, and the area contacting the solution was limited by this cost. Because the overall circuit resistance between cathode and vessel wall is proportional to the electrode surface area, it is advantageous to use large surface area electrodes. Therefore, many other, less costly metals have been used for cathodes. Metals that have been used for cathodes in anodic protection systems, as well as the chemical environments in which they were used, include:

Metals	Environment
Platinum on brass	**Various**
Steel	**Kraft digester liquid**
Illium G	**H_2SO_4 (78-105%)**
Silicon cast iron	**H_2SO_4 (89-105%)**
Copper	**Hydroxylamine sulfate**

Stainless steel	**Liquid fertilizers (nitrate solutions)**
Nickel-plated steel	**Chemical nickel plating solutions**
Hastelloy C	**Liquid fertilizers (nitrate solutions), H_2SO_4, Kraft digester liquid**

The electrode size is chosen to conform to the geometry of the vessel and to provide as large a surface area as possible. The location of the cathode is not a critical factor in simple geometries, such as storage vessels, but in heat exchangers, it is necessary to extend the electrode around the surface to be protected. Multiple cathodes can be used in parallel to distribute the current and to decrease circuit resistance.

Reference electrodes must be used in anodic protection systems because the potential of the vessel wall as the anode must be controlled. The reference electrode must have an electrochemical potential that is constant with respect to time and that is minimally affected by changes in temperature and solution composition. Several reference electrodes have been used for anodic protection, including:

Electrode	Solution
Calomel	**H_2SO_4**
Ag-AgCl	**H_2SO_4, Kraft solutions, fertilizer solutions**
Mo-CoO_3	**Sodium carbonate solutions**
Bismuth	**NH_4OH**
Type 316 stainless steel	**Fertilizer solutions, oleum**
Hg-$HgSO_4$	**H_2SO_4, hydroxylamine sulfate**
Pt-PtO	**H_2SO_4**

The reference electrode has been a source of many problems in anodic protection installations because of its more fragile nature with respect to the cathode.

Potential Control and Power Supply

Potential Control. As mentioned above, the potential of the vessel wall with respect to the reference electrode must be controlled in anodic protection installations. The potential control circuitry has two functions. First, the potential must be measured and compared to the desired preset value. Second, a control signal must then be sent to the power supply to force the dc current between the cathode and vessel wall. In early systems, this control function was done in an on-off method because of the high costs of electronic circuitry. The more sophisticated and extremely low-cost circuitry

currently available has resulted in all systems having a continuous proportional-type control. The amount of current forced through the circuitry is that required to maintain the potential at the preset control point.

The dc power supplies have the identical design and requirements as the rectifiers for cathodic protection with one exception. Because of the nature of the active-passive behavior of the vessel, the currents required to maintain the potential of the vessel wall in the passive range can become very small. Some design of dc power supplies must be specially modified to reduce the minimum amount of current put out of the power supply.

The packaging of these electronic components occasionally involves special requirements because most of the installations are made in chemical plants. Explosion-proof enclosures are sometimes required, and chemically resistant enclosures are necessary in other installations.

Design Concerns

Design of an anodic protection system requires knowledge of the electrochemical parameters of the metal-solution system, the geometry of the equipment to be protected, any special operational conditions, and the special requirements of the environment around the system. The electrochemical parameters of concerns of concern are the potential at which the vessel must be maintained for corrosion protection, the currents required to establish passivity, the currents required to maintain passivity, and the solution resistivity. The electrode potential can be determined directly from the polarization curve. The currents can be estimated from the polarization data, but they are time dependent, and the variation of the currents with respect to time must be estimated. Empirical data available from field installations are the best source of this information (Ref 1).

Solution resistivity is important in the determination of the overall circuit resistance. The power requirements for the dc power supply should be as low as possible to reduce operating costs. The solution resistivity will usually be sufficiently low that the circuit resistance will be controlled by the cathode surface area in contact with the solution.

Applications

Anodic protection has been used for storage vessels, process reactors, heat exchangers, and transportation vessels containing various corrosive solutions. Sulfuric acid is used in the largest number of systems in operation throughout the world. Anodic protection has been successful in preserving product quality through reduction of metal pickup by the solution, in extending the useful life of the vessels, and in allowing the use of a lower-cost alloy. Examples of these applications will be given below.

Storage Vessels. Storage of H_2SO_4 in strengths of 93% and above in low-carbon steel vessels has met with some success in terms of vessel life. Anodic protection has been successful in reducing the amount of iron picked up during storage. This enhances the economic worth of the product in that pure acid is more valuable than contaminated acid. Field studies have shown that the iron content of H_2SO_4 in concentrations of 93% and above increases at rates of 5 to 20 ppm per day of storage, depending on acid concentration, vessel size, acid residence time, and storage temperature (Ref 1). Several anodic protection systems have been successful in reducing the rates of iron pickup to 1 ppm per day or less. The level of purity of the acid has been sufficient to meet market demands for low iron content acid.

However, tanks constructed since the 1970s have been made with steel containing low amounts of copper. Steel with low copper content will corrode readily in these acids (Ref 13). Anodic protection of the newer vessels has been successful in lowering the corrosion rate by a factor of four to five, and vessel life has been greatly extended.

Heat Exchangers. A large market has developed for anodically protected heat exchangers as replacements for cast iron coolers. Shell and tube, spiral, and plate-type exchangers have been sold complete with anodic protection as an integral part of the equipment (Ref 1, 10, 11). Sulfuric acid of 96 to 98% concentration at temperatures up to 110 °C (230 °F) has been handled in AISI type 316 stainless steel exchangers by the use of anodic protection. Corrosion rates have been reduced from unprotected rates of more than 5 mm/yr (200 mils/yr) to less than 0.025 mm/yr (1 mil/yr), and cost savings have been substantial because of extended equipment life and the higher-purity acid that was produced by using these protected heat exchangers. Several other corrosive systems have also been handled in anodically protected heat exchangers (Ref 1).

Transportation Vessels. Sulfuric acid will continue to pick up iron during transportation in trucks, railroad cars, and barges. Anodic protection has been applied to these vessels to maintain the purity of the acid and to extend storage time. These applications are described in Ref 1, 11, and 12.

Galvanic Cathodes. The potentials of metals have been maintained in the passive region by using the potential differences between metals to achieve anodic protection by galvanic methods. Unlike cathodic protection, nothing is sacrificed, but the protection is achieved. A titanium pipe has been used to protect a steel vessel containing ammonium hydroxide (NH_4OH) solution, and platinum has been used to protect a stainless steel tank containing H_2SO_4 (Ref 14, 15). A combination of galvanic and impressed current protection that uses graphite cathodes for the anodic protection system is described in Ref 16. The graphite supplies sufficient current to maintain protection, but additional current can be supplied through the graphite electrodes to reestablish protection, if needed.

Economics

Economic justification of anodic protection is based on the same factors as in any comparison of corrosion control methods. Protection of H_2SO_4 storage vessels can be accomplished with baked phenolic linings or anodic protection. Because an anodic protection system has some basic requirements (electrodes, potential controller, and power supply) independent of tank size, anodic protection is more economically feasible for larger tanks. A detailed comparison of the economics of lining and anodically protecting steel storage vessels can be found in Ref 1. This comparison indicates that anodic protection is 42.5% less expensive per ton of acid storage capacity than a baked phenolic lining for a vessel with a capacity of about 18,000 Mg (20,000 tons). Costs of the lining are 74.3% less expensive per ton of acid storage capacity than the anodic protection cost of a 907-Mg (1000-ton) capacity vessel.

Anodic protection for other equipment when a less costly alloy can be used has been compared in terms of economics to the absence of protection. The anodically protected heat exchangers used in H_2SO_4-manufacturing plants have been shown to reduce maintenance costs by almost 95% (Ref 17). These reduced maintenance costs, combined with the improved quality of the acid produced in the plant, have provided an attractive return on the investment required for the anodically protected exchangers.

Many other applications of anodic protection have also been found to economically feasible, by using standard methods of engineering economics comparisons (see the article "Corrosion Economic Calculations" in this Volume). As experience is gained and confidence in this new method increases, there should be several other applications for which anodic protection will be shown to be the best economic alternative.

Cathodic Protection

Robert H. Heidersbach, Metallurgical Engineering Department, California Polytechnic State University

Introduction

CATHODIC PROTECTION is an electrochemical means of corrosion control in which the oxidation reaction in a galvanic cell is concentrated at the anode and suppresses corrosion of the cathode in the same cell. Figure 1 shows a simple cathodic protection system. The steel pipeline is cathodically protected by its connection to a sacrificial magnesium anode buried in the same soil electrolyte.

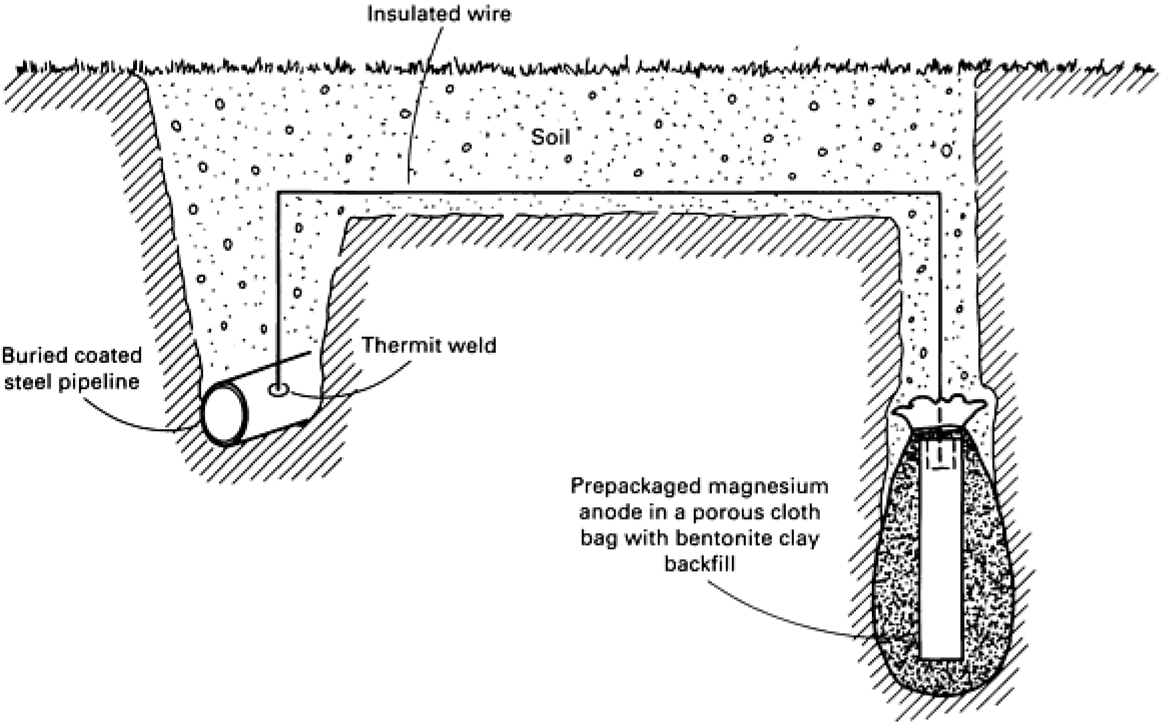

Fig. 1 Cathodic protection of buried pipeline using a buried magnesium anode

Cathodic protection is different from anodic protection (see the article "Anodic Protection" in this Volume). In cathodic protection, the object to be protected is the cathode, but in anodic protection, the object to be protected is the anode.

Anodic protection can be used on only a limited number of alloys in certain restricted environments, but cathodic protection can, in principle, be applied to any metal. In practice, cathodic protection is primarily used on carbon steel. The effectiveness of cathodic protection allows carbon steel, which has little natural corrosion resistance, to be used in such

corrosive environments as seawater, acid soils, salt-laden concrete, and many other corrosive environments. Properly designed and maintained cathodic protection systems can prevent corrosion indefinitely in these environments.

Cathodic protection was first suggested by Sir Humphrey Davy in the 1820s as a means of controlling corrosion on British naval ships (Ref 1). It became common in the 1930s on the Gulf Coast of the United States, where it was used to control the corrosion of pipelines carrying high-pressure hydrocarbons (natural gas and petroleum products). Much of the terminology of cathodic protection still relates to corrosion control of onshore buried steel pipelines.

Virtually all modern pipelines are coated with an organic protective coating that is supplemented by cathodic protection systems sized to prevent corrosion at holidays in the protective coating (see the article "Corrosion of Pipelines" in this Volume). This combination of protective coating and cathodic protection is used on virtually all immersed or buried carbon steel structures, with the exception of offshore petroleum production platforms and reinforced concrete structures.

Offshore platforms are usually uncoated but cathodically protected (see the article "Corrosion in Petroleum Production Operations" in this Volume). Cathodic protection causes changes in the chemistry of seawater near the protected structure, and this causes the precipitation of a natural coating on the structure that reduces the need for cathodic protection current. Concrete structures normally rely on the protectiveness of the concrete cover to prevent the corrosion of embedded steel (see the article "Corrosion in Structures" in this Volume). When corrosion of embedded steel occurs because of a loss of this protectiveness, cathodic protection is sometimes used to extend the life of the already deteriorated structure.

Fundamentals of Cathodic Protection

Table 1 shows the theoretical electrochemical potentials obtained by pure metals in 1 *N* solutions of their own ions. This abbreviated electromotive series is described in most chemistry or corrosion textbooks (Ref 2) and in the article "Thermodynamics of Aqueous Corrosion" in this Volume.

Table 1 Standard electromotive force series for selected metals

Metal-metal ion equilibrium (unit activity)	Potential at 25 °C (77 °F), V
Noble or cathodic (protected)	
Ag/Ag^+	**+0.80**
Cu/Cu^{2+}	**+0.34**
H_2/H^+	**(reference) 0**
Fe/Fe^{2+}	**-0.44**
Zn/Zn^{2+}	**-0.76**
Al/Al^{3+}	**-1.66**
Mg/Mg^{2+}	**-2.36**
More active or anodic	

Figure 2(a) shows two of these metals--iron and zinc--separately immersed in a weak mineral acid. The chemical reactions that occur in Fig. 2(a) are:

$$Fe \rightarrow Fe^{2+} + 2e^-$$
Oxidation reaction **(Eq 1a)**

$$2H^+ + 2e^- \rightarrow H_2$$
Reduction reaction **(Eq 1b)**

$$2H^+ + Fe \rightarrow Fe^{2+} + H_2$$
Net reaction **(Eq 1c)**

$$Zn \rightarrow Zn^{2+} + 2e^-$$
Oxidation reaction **(Eq 2a)**

$$2H^+ + 2e^- \rightarrow H_2$$
Reduction reaction **(Eq 2b)**

$$2H^+ + Zn \rightarrow Zn^{2+} + H_2$$
Net reaction **(Eq 2c)**

Both metals corrode, and both corrosion (oxidation) reactions are balanced by an equal reduction reaction, which in both cases involves the liberation of hydrogen gas from the acid environments. The two corrosion reactions are independent of each other and are determined by the corrosivity of hydrochloric acid on the two metals in question.

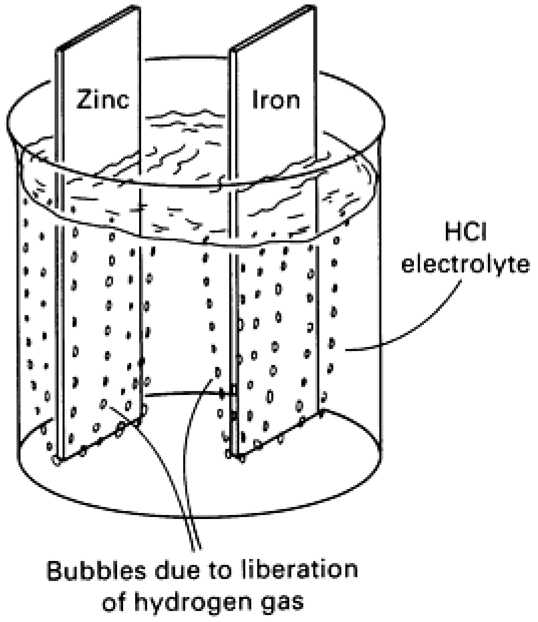

Fig. 2(a) Corrosion of zinc and iron in hydrochloric acid

If the two metals were immersed in the same acid and electrically connected, (Fig. 2(b), the reactions for zinc would then become:

$$Zn \rightarrow Zn^{2+} + 2e^-$$
Oxidation **(Eq 3a)**

$$2H^+ + 2e^- \rightarrow H_2$$

Reduction **(Eq 3b)**

Almost all of the oxidation reaction (corrosion of zinc) has been concentrated at the zinc electrode (anode) in Fig. 2(b), and almost all of the reduction reaction (hydrogen liberation) has been concentrated at the iron electrode (cathode). The oxidation of the zinc anode in Fig. 2(b) is much faster than that in Fig. 2(a). At the same time, most of the corrosion of iron in Fig. 2(a) has stopped in Fig. 2(b). As shown schematically, the zinc anode in Fig. 2(b) has been used to cathodically protect the iron cathode in Fig. 2(b).

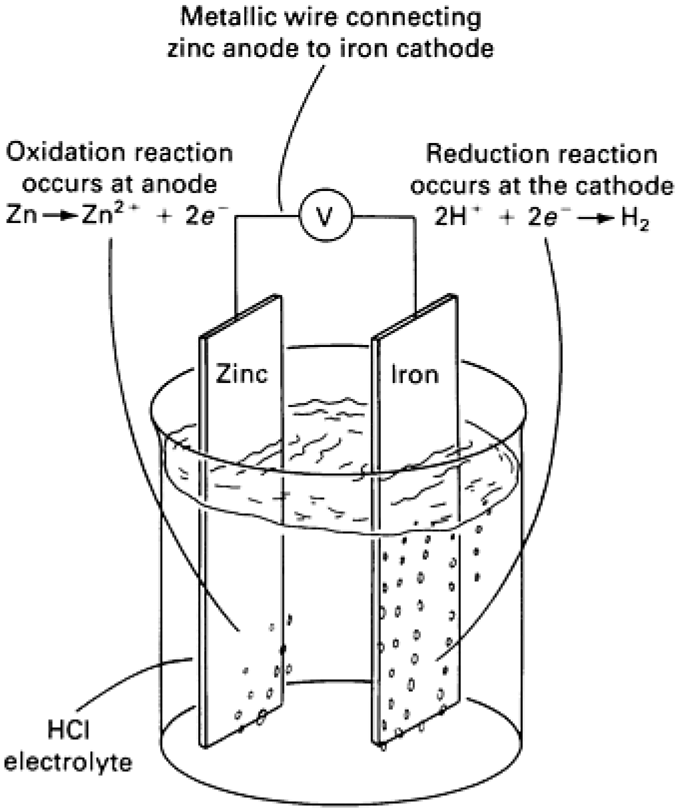

Fig. 2(b) Cathodic protection of iron by zinc in hydrochloric acid

Of course, some corrosion of the iron may still occur; whether or not this happens depends on the relative sizes of the zinc and iron electrodes. Some reduction of hydrogen may still occur on the zinc anode. The anode is the electrode at which a net oxidation reaction occurs, whereas cathodes are electrodes at which net reduction reactions occur. With proper design, the oxidation rate on the cathode will be suppressed to the point at which it becomes negligible. If this takes place, cathodic protection has been achieved.

All cathodic protection systems require an anode, a cathode, an electric circuit between the anode and cathode, and an electrolyte. Thus, cathodic protection will not work on structures exposed to air environments. The air is a poor electrolyte, and it prevents current from flowing from the anode to the cathode.

Types of Cathodic Protection

There are two types of cathodic protection: sacrificial anode, or passive, systems and impressed-current, or active, systems. Both types are widely used.

Sacrificial anode systems are simpler. They require only a material anodic to the protected steel in the environment of interest. A simple sacrificial anode cathodic protection system used to control corrosion on a buried pipeline is shown in Fig. 1.

Figure 3 shows an impressed-current system used to protect a pipeline. The buried anodes and the pipeline are both connected to an electrical rectifier, which supplies direct current to the buried electrodes (anodes and protected cathode) of the system. Unlike sacrificial anodes, impressed-current anodes need not be naturally anodic to steel, and in fact, they seldom are. Most impressed-current anodes are made from nonconsumable electrode materials that are naturally cathodic to steel. If these electrodes were wired directly to a structure, they would act as cathodes and would cause accelerated corrosion of the structure they are intended to protect. The direct current source reverses the natural polarity and allows the materials to act like anodes. Instead of corrosion of the anodes, some other oxidation reaction, that is, oxygen or chlorine evolution, occurs at the anodes, and the anodes are not consumed.

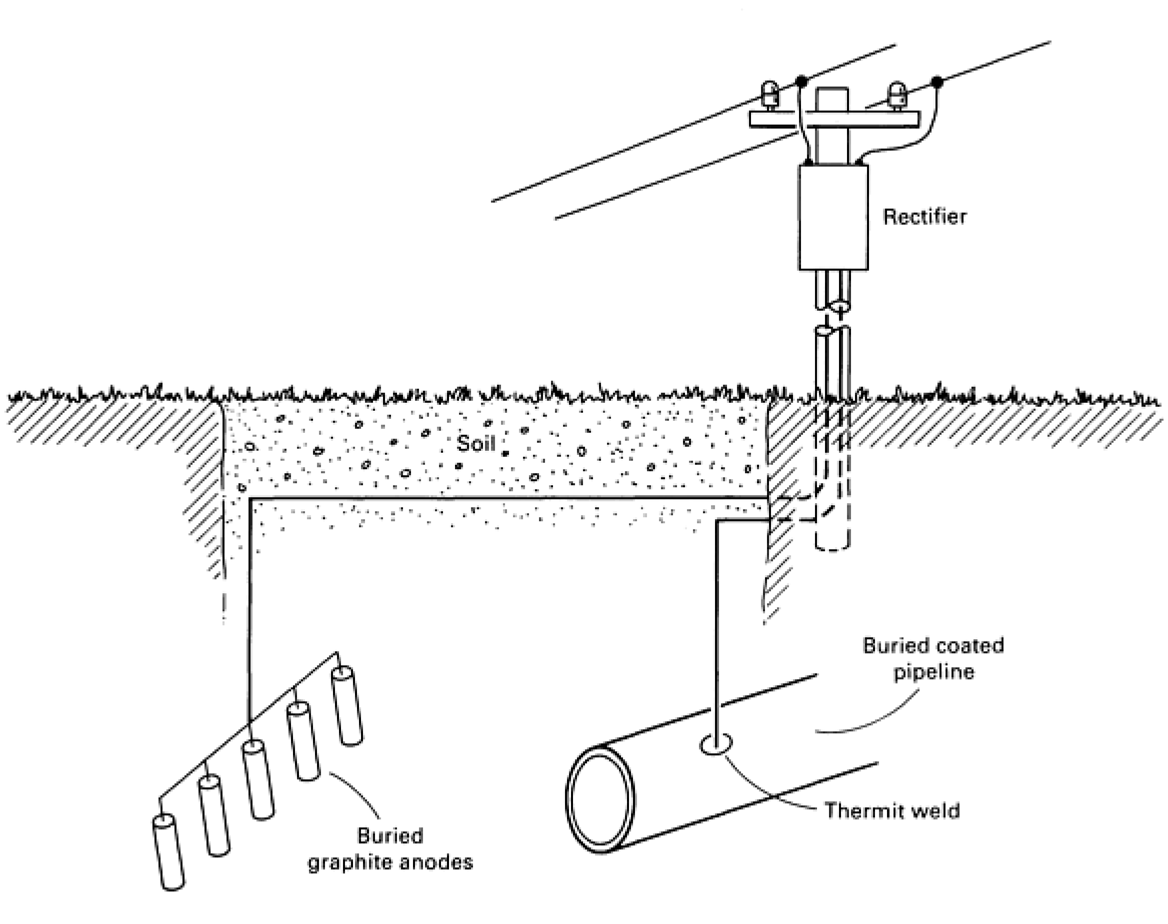

Fig. 3 Impressed-current cathodic protection of a buried pipeline using graphite anodes

Impressed-current systems are more complex than sacrificial anode systems. The capital expenses necessary to supply direct current to the system are higher than for a simple connection between an anode and a cathode.

The voltage differences between anode and cathode are limited in sacrificial anode systems to approximately 1 V or even less, depending on the anode material and the specific environment. Impressed-current systems can use larger voltage differences. The larger voltages available with impressed-currents allow remote anode locations, which produce more efficient current distribution patterns along the protected cathode. These larger voltages are also useful in low-conductivity environments, such as freshwater and concrete, in which sacrificial anodes would have insufficient throwing power.

Large voltages can have disadvantages. It is possible to overprotect high-strength steels and cause hydrogen embrittlement. Coating debonding is also possible (Fig. 4). Debonding occurs when moisture penetrates a coating and

hydrogen is generated at the metal surface beneath the coating. The gas can accumulate until pressure causes blisters or cracks in the protective coating. Once this coating damage occurs, the demands for protective current increase and may exceed the capabilities of the system.

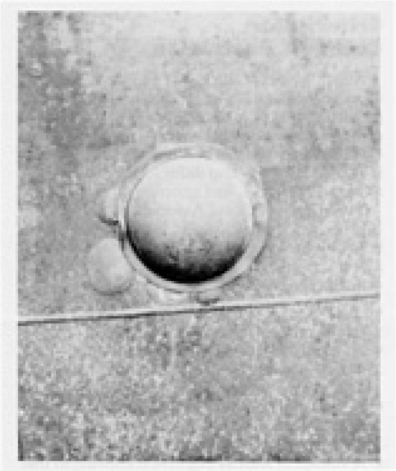

Fig. 4 Debonded organic coating near a high-silicon cast iron button anode

Aluminum is especially vulnerable to overprotection. All cathodic reactions cause the immediate environment to become somewhat more basic (less acidic) than they are in the absence of cathodic protection. Unlike steel, aluminum is an amphoteric metal with increased corrosion susceptibility in acids and bases. If the environment around an aluminum structure becomes too basic; it will corrode at an accelerated rate. Thus, the cathodic protection of aluminum can cause cathodic corrosion if too much current is supplied to the cathode (see also the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume).

Table 2 lists some of the important differences between impressed-current and sacrificial anode cathodic protection systems. Selection of a cathodic protection system usually depends on tradeoffs among the advantages of each type of system. For example, most offshore petroleum production platforms use sacrificial anodes because of their simplicity and reliability, even though the capital costs would be lower with impressed-current systems.

Table 2 Comparison between sacrificial anode and impressed-current cathodic protection systems

Sacrificial anode system	Impressed-current system
Simple	**Complex**
Low/no maintenance	**Requires maintenance**
Works best in conductive electrolytes	**Can work in low-conductivity electrolytes**
Lower installation costs for smaller installations	**Remote anodes possible**
Higher capital investment for large systems	**Low capital investment for large systems**
	Can cause the following problems:

	Stray current corrosion
	Hydrogen embrittlement
	Coating debonding
	Cathodic corrosion of aluminum

Criteria for Cathodic Protection

A number of criteria have been used for determining whether or not a structure is cathodically protected from corrosion. This is an area of controversy within the industry, and it is likely that existing standards will change over the next few years. Criteria also differ for buried utilities, offshore structures, and concrete structures.

The original National Association of Corrosion Engineers specification for buried utility pipelines proposed the following criteria for determining when a steel or cast iron structure is cathodically protected (Ref 3):

- A voltage of -0.85 V relative to a copper/saturated copper sulfate electrode
- A negative (cathodic) voltage shift of at least 300 mV caused by the application of cathodic protection current
- A minimum negative (cathodic) voltage shift of 100 mV determined by interrupting the current and measuring the voltage decay
- A voltage at least as negative (cathodic) as that originally established at the Tafel segment of the *E*-log *I* curve (Fig. 5)
- A net protective current from the electrolyte into the surface

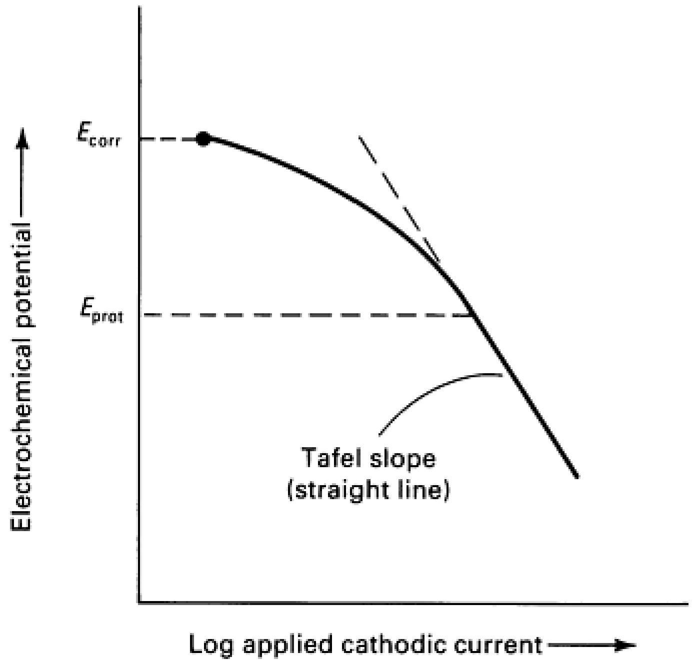

Fig. 5 Tafel slope criterion for determining cathodic protection. See the article "Kinetics of Aqueous Corrosion" in this Volume for detailed explanations of these diagrams.

All of the above criteria are currently in use, but the most common and most widely applicable criterion is the -0.85 V versus a copper/copper sulfate reference cell. Most structures can be inspected to determine if they are protected relative to this standard. The only equipment necessary is a reference cell (Fig. 6) and a wire lead that can be connected to the structure in question. The other criteria require recordkeeping, the ability to interrupt current (impossible for most sacrificial anode designs), and more sophisticated survey equipment.

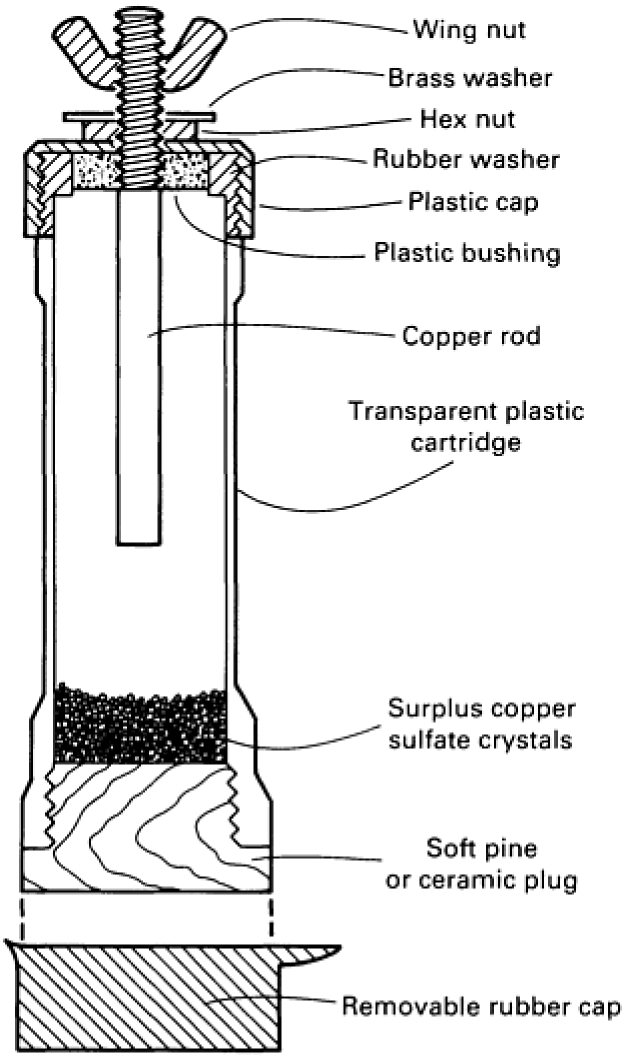

Fig. 6 Copper-saturated copper sulfate reference electrode

Copper sulfate electrodes can become contaminated by seawater, and it is common to use -0.805 V versus silver/silver chloride as the protection potential for marine structures (Ref 4). Both criteria are the same; only the reference electrode material is different. These criteria are based on early research by the National Bureau of Standards (Ref 3).

The reader is cautioned that the sign convention used in this article agrees with that used by the U.S. cathodic protection industry. Much of the scientific and international literature uses the opposite sign convention for positive and negative electrical terminals. Regardless of the sign convention chosen, the importance point is that electrons should flow into the protected structure from the external circuit.

Anode Materials

Different requirements for sacrificial anodes and impressed-current anodes lead to the use of widely different materials for these applications.

Sacrificial anodes must be anodic to steel in the environment of interest. They must also corrode reliably (avoid passivation). Impressed-current anodes can be cathodic to steel, but they must have low consumption rates when connected to a cathodic protection power source.

Sacrificial Anodes

Commercial sacrificial anodes include magnesium, zinc, and aluminum alloys. The energy characteristics of these alloys are given in Table 3.

Table 3 Energy characteristics of sacrificial anode alloys

Alloy	**Energy capability**		Consumption rate	
	A·h/kg	**A·h/lb**	**kg/A·yr**	lb/A·yr
Aluminum-zinc-mercury	2750-2840	1250-1290	3.2-3.0	**7.0-6.8**
Aluminum-zinc-indium	1670-2400	760-1090	5.2-3.6	**11.5-8.0**
Aluminum-zinc-tin	920-2600	420-1180	9.4-3.4	**20.8-7.4**
Zinc	810	370	10.7	**23.7**

Magnesium anodes are the only sacrificial anodes that are routinely specified for use in buried soil applications. Most magnesium anodes in the United States are supplied with a prepackaged bentonite clay backfill in a permeable cloth sack (Fig. 1). This backfill ensures that the anode will have a conductive environment and will corrode reliably. The additional materials is less expensive than the soil resistivity surveys that would be needed to determine if the backfill is necessary.

Some magnesium anodes have been used off-shore in recent years in an attempt to polarize the structures to a protected potential faster than would occur if zinc or aluminum alloy anodes were used. Magnesium tends to corrode quite readily in salt water, and most designers avoid the use of magnesium for permanent long-term marine cathodic protection applications.

Figure 7 shows a magnesium anode used to control corrosion on a glass-lined domestic water heater. Similar cathodic protection arrangements are found on most domestic water heaters in the United States.

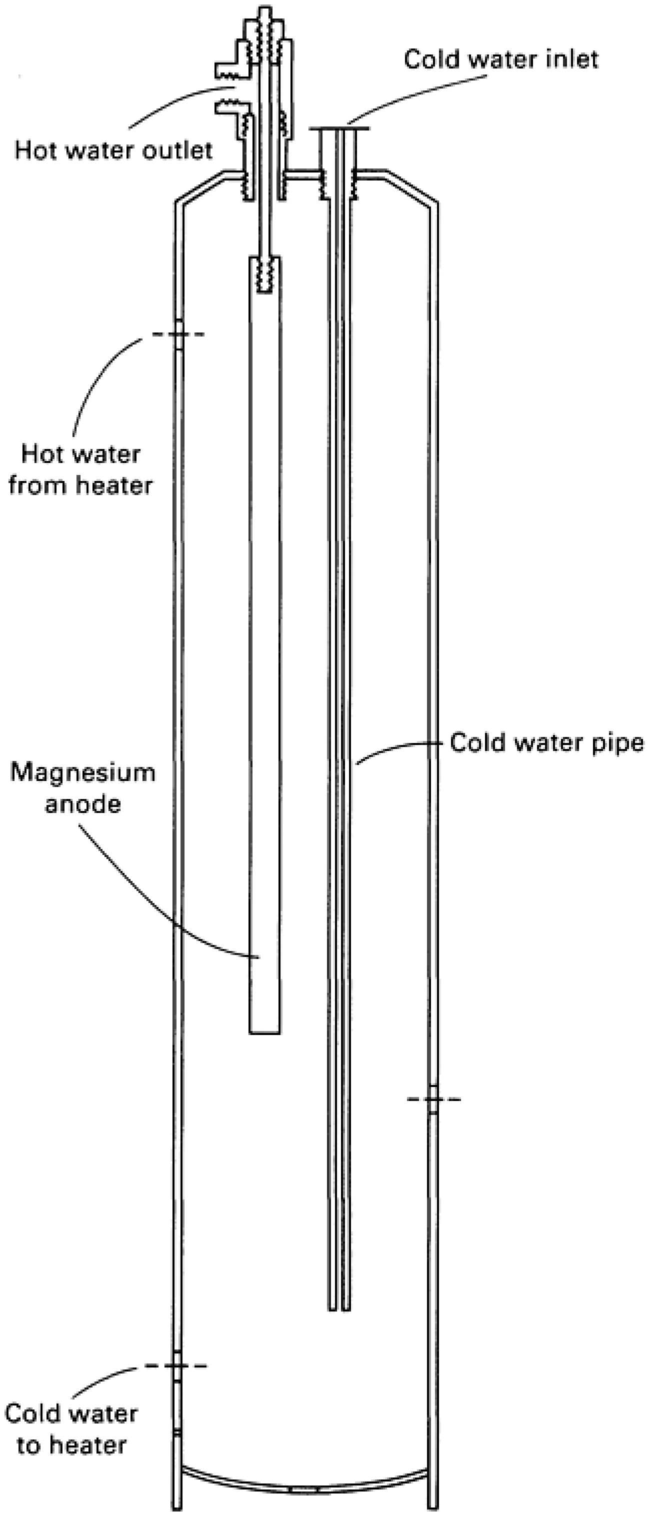

Fig. 7 Magnesium anode used to cathodically protect glass-lined steel water heater

Zinc is used for cathodic protection in freshwater and marine water. Zinc is especially well suited to cathodic protection on ships that move between salt water and harbors in brackish rivers or estuaries. Figure 8 shows zinc anodes on the underside of a small fishing boat. Aluminum anodes would passivate in the harbors and might not work when they return to sea. Zinc anodes are also used to protect ballast tanks, heat exchangers, and many mechanical components on ships, coastal power plants, and similar structures.

Fig. 8 Zinc anodes on the underside of a fishing boat

The weight of zinc is an advantage for marine pipelines. Bracelet anodes (Fig. 9) are attached at pipe joints to provide ballast and to prevent corrosion in the water-mud environment, in which aluminum might passivate.

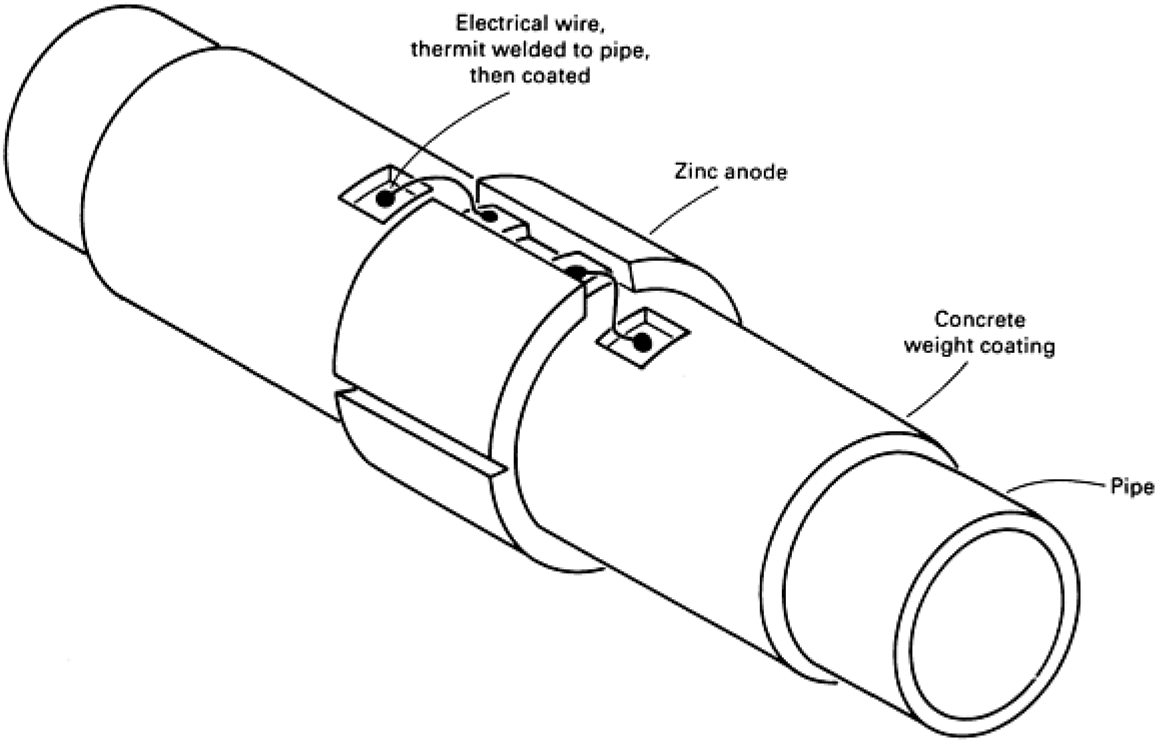

Fig. 9 Zinc bracelet anode at a joint in an offshore pipeline

Aluminum is used on offshore structures where its light weight provides significant advantages. Welded-on aluminum anodes for an offshore platform are shown in Fig. 10. Aluminum does not passivate in salt water if certain alloying additions, such as tin, antimony, and mercury, are present. Toxicity questions prevent the use of aluminum alloys with mercury additions in U.S. waters.

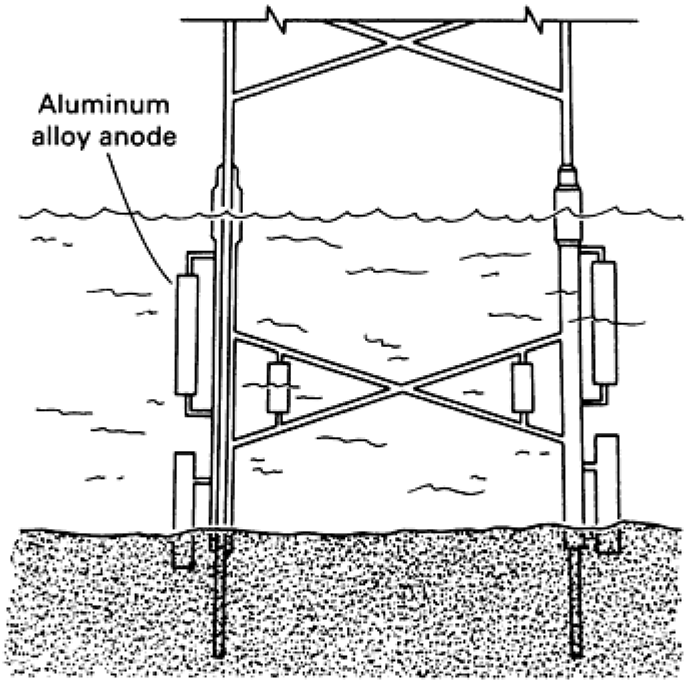

Fig. 10 Welded-on aluminum sacrificial anodes used to protect on offshore platform

Impressed-Current Anodes

Impressed-current anodes must be corrosion resistant and otherwise durable in the environment in which they are used. Consumption rates for lead alloy, platinum, graphite, and high-silicon cast iron impressed-current anode materials are given in Table 4.

Table 4 Consumption rates of impressed-current anode materials

Material	**Typical anode current density**		Consumption rate per A·yr
	A/m^2	**A/ft^2**	
Pb-6Sb-1Ag	160-220	15-20	**0.045-0.09 kg (0.1-0.2 lb)**
Pt (plated on substrate)	540-1080	50-100	**0.006 g**
Pt (wire or clad)	1080-5400	100-500	**0.01 g**
Graphite	10.8-40	1-4	**0.225-0.45 kg (0.5-1.0 lb)**

High-silicon cast iron (Fe-0.95C-0.75Mn-14.5Si-4.5Cr) is used for onshore cathodic protection applications and in other locations where abrasion resistance and other mechanical damage considerations are important. High-silicon cast iron anodes are available in solid rods, tubular form, and various cast shapes in a wide variety of sizes to meet the

demands of specific applications. For example, solid rods range from 30 mm in diameter × 230 mm in length ($1\frac{1}{8}$ × 9 in.) at 0.45 kg (1 lb) to 115 mm in diameter × 1525 mm in length (4.5 × 60 in.) at 100 kg (220 lb). The smaller rods are used for protecting underground freshwater storage tanks, and the larger rods are used in more aggressive seawater or ground bed applications. Figure 4 shows a high-silicon cast iron button anode on a navigational lock on the Tennessee River. This anode must withstand collisions with small vessels, trees, rocks, and so on. The coating debonding shown in Fig. 4 is due to improper circuit design and cannot be attributed to the use of high-silicon cast iron anodes. Detailed information on designing impressed-current cathodic protection systems with high-silicon iron anodes is available in Ref 5.

Graphite anodes are extensively used for onshore pipeline cathodic protection applications in which they can be buried in multiple-anode ground beds (Fig. 3). Graphite anodes, which have very low electrode-to-environment resistances, are normally available in 75-mm diam × 1525-mm long (3- × 60-in.) and 100-mm diam × 2000-mm (4- × 80-in.) rods. Because of the brittle nature of the material, graphite must be stored and handled carefully.

Polymeric anodes are used to mitigate the corrosion of reinforcing steel in salt-contaminated concrete (Fig. 11). The system consists of a mesh of wirelike anodes, which are made of a conductive polymer electrode material coated onto copper conductors. The conductive polymer not only serves an an active anode material but also shields the conductors from chemical attack. These mesh anodes are designed and optimally spaced to provide long-term uniform protection at low current densities. The anode mesh is placed on the surface of a reinforced concrete structure, covered with an overlay of Portland cement or polymer-modified concrete, and then connected to a low-voltage dc power source. The properties of polymeric anodes used for construction applications are given in Table 5.

Table 5 Properties of polymeric mesh anodes used for construction applications

Properties	Typical data
Recommended maximum design current output in soil	**52-mA/m (16-mA/ft) length**[a]
Recommended maximum design current output in water	**10-mA/m (3-mA/ft) length**
Maximum pressure rating (hydrostatic)	**7 MPa (100 psi)**
Maximum temperature rating	**65 °C (150 °F)**
Minimum installation temperature	**-18 °C (0 °F)**
Chemical resistance per ASTM D 543 for 7 days at ambient conditions with weight gain less than 1%	
3% NaCl	**Pass**
3% Na_2SO_4	**Pass**
10% NaOH	**Pass**
ASTM oil #1	**Not recommended**
Crude oil	**Not recommended**

(a) Average current output for anode in coke breeze backfill when maximum current density is 82 mA/m (25 mA/ft). ASTM D 543, "Standard Test Method for Resistance of Plastics to Chemical Reagents," can be found in Vol 08.01 of the *Annual Book of ASTM Standards.*

Precious metals are used for impressed-current anodes because they are highly efficient electrodes and can handle much higher currents than anodes fabricated from other materials. Precious metal anodes are actually platinized titanium or tantalum anodes; the platinum is either clad to or electroplated on the substrate. The small precious metal anode shown in Fig. 12 performs the same function as materials weighing several times more.

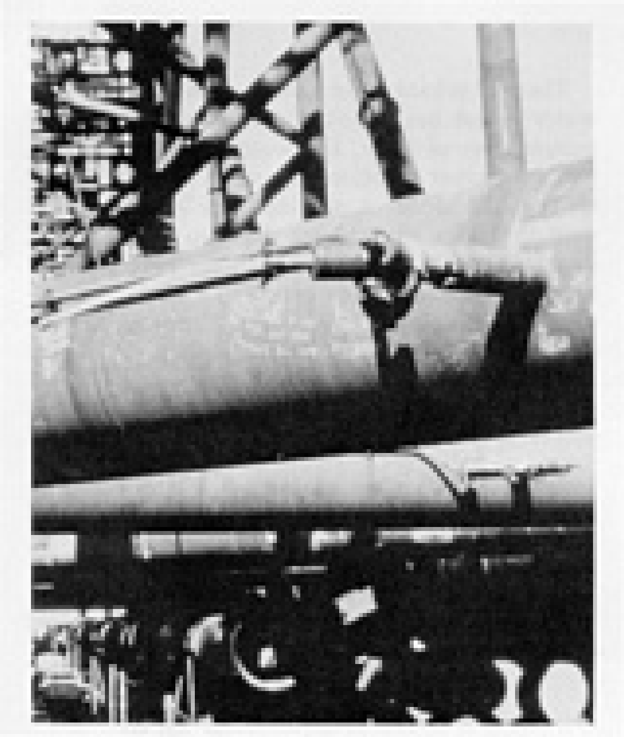

Fig. 12 Precious metal impressed-current anode on offshore platform prior to launching in the North Sea. Courtesy of W.H. Thomason, Conoco, Inc.

Lead alloy anodes, containing 2% Ag, or 1% Ag and 6% Sb, are used for cathodic protection system in seawater. Lead alloy anodes should not be buried in the sea bottom or used in freshwater applications.

Ceramic anodes are the newest materials available for cathodic protection anodes. These anodes are supplied either as oxide coatings on transition metal substrates or as bulk ceramics. Their use as cathodic protection anodes for protecting reinforcing steel in concrete is new but the oxide coated transition metal anodes have been used since the late 1960s in the chlor-alkali industry as anodes for chlorine production and seawater electrolysis, and cathodic protection of water tanks and buried steel structures, among other industrial processes.

The oxide/metal composite anodes for chlorine environments consist of a mixed ruthenium dioxide (RuO_2) and titanium oxide (TiO_2) coating sintered onto a pure titanium (grade 1) substrate (Ref 6). Such materials, which are produced in sheet, mesh, and wire form, are based on patented dimensionally stable anode (DSA) technology (Ref 6). These anodes are so named because they remain unchanged with regard to their shape, geometry, and dimensions during their entire operating life. Figure 13 shows examples of a mixed oxide/titanium mesh anode, based on DSA technology, that is used to prevent corrosion of reinforcing steel in concrete.

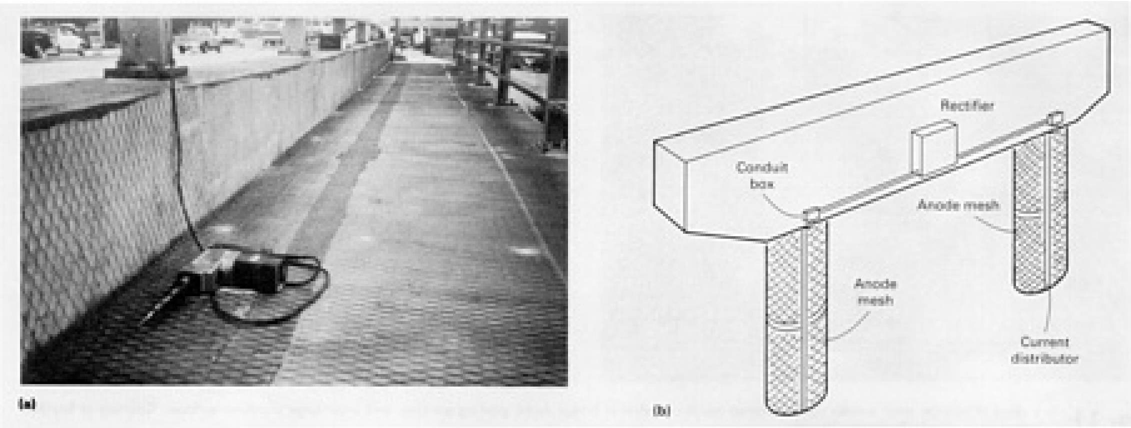

Fig. 13 Use of mixed oxide/titanium anode mesh for cathodic protection. (a) Sidewalk and barrier wall installation. (b) Installation of anode mesh on a bridge substructure. Courtesy of ELTECH Systems Corporation

The basic chemical constituents of the bulk ceramic anodes are suboxides of titanium, with Ti_4O_7 and Ti_5O_9 being the principal components. Such conductive ceramics are resistant to both oxidation and reduction in strong acid and basic environments. Some characteristic properties of conductive ceramics are given in Table 6.

Table 6 Properties of bulk ceramic anode materials

Electrical resistivity
250-1000 × 10^{-6} Ω·cm. Resistivity decreases as density increases.
Thermal expansion
5 × 10^{-6} °C
Thermal conductivity
10 to 20 W/m·K

Power Sources

Impressed-current cathodic protection requires external power sources. The most common source of electricity is a local power utility. This will normally involve the dc rectifier arrangement shown in Fig. 3. Remote locations can use solar cells (Fig. 14), thermoelectric current sources, special fuel-driven electric generators, or even windmills.

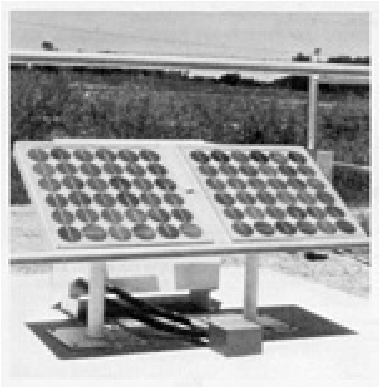

Fig. 14 Solar cells used to provide electricity for the cathodic protection of a buried pipeline

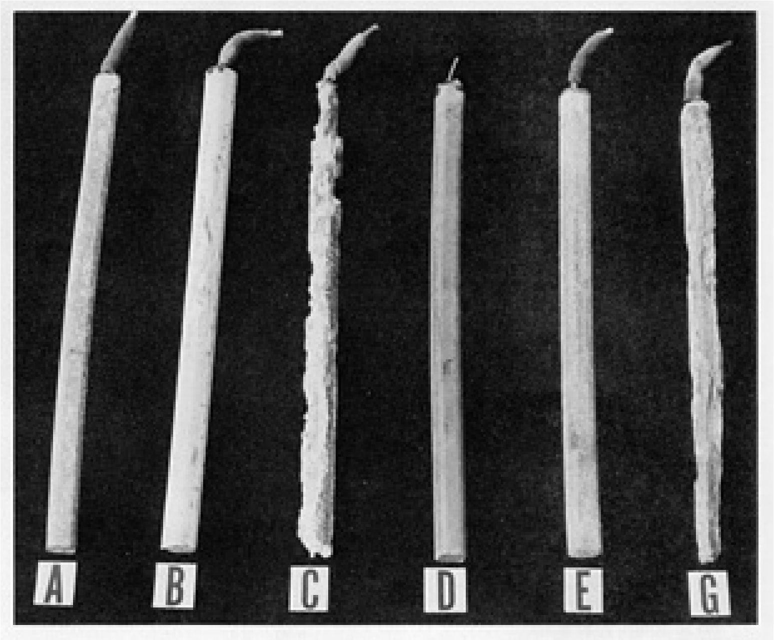
Design

Most cathodic protection design is conducted by consulting companies that specialized in corrosion control. Design procedures vary among organizations, but the following general guidelines are frequently followed for onshore buried structures (Ref 7):

- Decide whether impressed-current or sacrificial anodes will be used
- Decide on the design life of the system
- Determine or assume the condition of the coating. From this, the current density for cathodic protection can be estimated
- Calculate the maximum electric current required
- Determine the number and type of anodes required and their respective spacing
- Calculate the ground bed resistance. Figure 15 shows the effect of soil resistivity and pH on the corrosion of zinc sacrificial anodes
- Calculate the lead wire size
- Calculate the required dc voltage
- Determine the rectifier size
- Locate the ground bed



Site	Soil	Location	Internal drainage	Range of resistivity, Ω· cm	pH
A	Sagemoor sandy loam	Toppenish, WA	Good	400	**8.8**
B	Hagerstown loam	Loch Raven, MD	Good	12,600-37,300	**5.3**
C	Clay	Cape May, NJ	Poor	400-1150	**4.3**
D	Lakewood sand	Wildwood, NJ	Good	13,800-57,500	**5.7**
E	Coastal sand	Wildwood, NJ	Poor	1320-49,500	**7.1**
G	**Tidal marsh**	**Patuxent, MD**	**Poor**	**400-15,500**	**6.0**

Fig. 15 Corrosion of zinc anodes that were galvanically connected to type 304 stainless steels for 4 years at six different underground test sites. Courtesy of E. Escalante, National Bureau of Standards

The advent of computers has changed some cathodic protection design, test, and inspection procedures (Ref 8), but most cathodic protection is still designed and tested in the manner described in U.S. government publications from the 1960s and 1970s (Ref 7, 9, 10, 11). Additional information on computer-aided cathodic protection can be found in the article "Marine Corrosion" in this Volume (see the section "Cathodic Protection").

Case Histories

The following examples provide specific details that supplement the general guidelines listed above. These examples have been selected to familiarize the design engineer with the steps to be followed in selecting a specific corrosion control method. An additional case history of an offshore platform cathodic protection design procedure can be found in the article "Marine Corrosion" in this Volume. Other examples are available in Ref 7 and 9, 10, 11, 12, 13, 14.

*Resistance Calculations**

The resistance of impressed-current anodes buried in soil can be lowered by surrounding them with carbonaceous backfill material, such as coke breeze (crushed coke) or flake graphite. This is particularly beneficial in high-resistance soils. If soil resistance is ten or more times the backfill resistively--500 to 1000 Ω· cm--the voltage drop of anode current passing through the backfill may become negligible with respect to the voltage drop through the soil. Thus, the resistance of a backfilled anode can be considered to be lower than that of a nonbackfilled anode because the backfilled anode is effectively longer and of greater diameter.

Increasing the diameter and/or the length of a cylindrical anode will decrease its anode-to-electrolyte resistance. However, changes in length have a greater effect than changes in diameter.

Many engineers first measure structure-to-anode resistance by actually impressing current into installed anodes. In this way, a rectifier can be sized to fit the circuit resistance without relying on questionable test and empirical data. Testing installed anodes for the purpose of sizing rectifiers has the disadvantage of delaying completion of an installation. However, it means that sufficient cathodic protection current will be supplied in an efficient manner.

Single Anode. The following formulas as relations developed for a single cylindrical anode (Ref 5):

$$R_v = \frac{0.0052\rho}{L}\left(2.3 \log 10 \frac{8L}{d} - 1\right)$$

$$R_h = \frac{0.0052\rho}{L}\left(2.3 \log 10 \frac{4L^2 + 4L\sqrt{s^2 + L^2}}{ds} + \frac{s}{L} - \frac{\sqrt{s^2 + L^2}}{L} - 1\right)$$

where R_v is the electrolyte-to-anode resistance, single vertical anode to remote reference (in ohms), R_h is the electrolyte-to-anode resistance, single horizontal anode to remote reference (in ohms), ρ is the electrolyte resistively (in ohm centimeters), *L* is the length of anode (in feet), *d* is the diameter of anode (in feet), and *s* equals twice the depth of the anode (in feet).

For a single vertical anode, the following simplified expression can be used:

$$R_v = \frac{\rho}{L} K$$

where R_v, ρ, and *L* are as given above, and *K* is the shape function representing the anode length to anode diameter ratio, which can be obtained from Table 7.

Table 7 The shape function, *K*, obtained by dividing the anode length by the anode diameter in any units

One-Row Vertical Anode Group. The total anode-to-electrolyte resistance for a group of vertical anodes, connected in parallel and equally spaced in one row, is expressed as follows:

$$R_n = \frac{1}{n} R_v + \frac{\rho\rho P}{S}$$

where R_n is the total anode-to-electrolyte resistance for a group of vertical anodes equally spaced and in one row (in ohms) (a remote cathode is assumed), n is the number of anodes, ρρ is the soil resistivity, measured with pin spacing equal to S (in ohm-centimeters), R_v is as given above, P is the paralleling factor obtained from Table 8, and S is the spacing between adjacent anodes (in feet).

More Than One Row Vertical Anode Group. An anode group composed of two or more rows of vertical anodes, separated by a distance substantially larger than that between the anodes within a single row, has a total resistance approximately equal to the total parallel resistance of all the rows. The usual formula for paralleling resistances:

$$\left(\frac{1}{R} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \ldots\right)$$

is used.

Vertical and Horizontal Anode Groups--Simplified. If vertical anode dimensions are assumed to be 8 to 12 in. in diameter and 10 ft in length and if the horizontal anode dimensions are assumed to be 1 ft^2 in cross section, 10 ft in length, and 6 ft below the surface of the electrolyte (these assumptions are useful when designing anode system with high-silicon cast iron anodes in soils in which effective backfill has been installed around the anodes), then the following empirical formula can be used:

$$R_v = \frac{\rho F}{537} \qquad R_h = \frac{\rho F}{483}$$

where R_v is the electrolyte-to-anode resistance, any number of vertical anodes to remote reference (in ohms), R_h is the electrolyte-to-anode resistance, any number of horizontal anodes to remote reference (in ohms), ρ is the electrolyte resistivity (in ohm-centimeters), and *F* is the adjusting factor for groups of anodes (from Table 9). Note: where only one anode is used, *F* = 1.0.

Table 9 Adjusting factors, *F*, for parallel anodes

Approximate anode-to-electrolyte resistance values for single anodes are quickly and easily obtained rom the following:

- R_v = 0.002ρ, for a vertically installed 60-in. anode in a 10-ft column of backfill, 1 ft in diameter
- R_v = 0.005ρ, for a vertically installed 2- × 60-in. anode, without backfill
- R_v = 0.006ρ, for a vertically installed 1 $\frac{1}{2}$- × 60-in. anode, without backfill
- R = anode-to-electrolyte resistance for a single anode (in ohms)
- ρ= resistivity of electrolyte (in ohm centimeters)

Example 1: Cathodic Protection System for Steel Storage Tanks.

An impressed-current cathodic protection system is being designed to stop corrosion on the bottoms of several large-diameter steel storage tanks that are in contact with the soil. In order to distribute current to all surfaces, seventeen 1 $\frac{1}{2}$- × 60-in. high-silicon cast iron anodes will be installed vertically in coke breeze backfill. These anodes will be spaced 20 ft apart; the backfill is approximately 8 ft in length and 10 in. in diameter. The average soil resistance is 4500 Ω· cm at anode depth. What will be the total anode to soil resistance after installation?

*Solution.*Because anodes are to be installed around the periphery of tanks, single-row configuration is assumed, and Table 7 must be consulted for the shape function *K*, where:

$$\frac{L}{D} = \frac{8}{0.833} = 9.604$$

$$K = 0.0175$$

$$R_v = \frac{\rho}{L} K = \frac{4500}{8} \times 0.0175 = 9.844\ \Omega$$

$$R_n = \frac{1}{n} R_v + \frac{\rho \rho P}{S} = \frac{1}{17} 9.844 + \frac{4500 \times 0.00150}{20}$$

$$R_n = 0.579 + 0.338 = 0.917\ \Omega = \text{total resistance between all anodes and soil}$$

Example 2: Cathodic Protection of a Pipeline.

An impressed-current cathodic protection unit is to be connected to a pipeline. The right-of way is limited, and space permits only three 1 $\frac{1}{2}$- × 60-in. anodes, which must be installed horizontally because of a rock shelf. These anodes are to be backfilled with coke breeze (effective size is 10 ft in length × 1 ft^2 in cross section) and laid side by side parallel to each other, 6 ft below grade and 10 ft apart. The cathodic protection unit must supply 5.0 A to protect the pipeline adequately. If cable, connection, and pipe-to-soil resistance are neglected, what dc voltage must the rectifier power supply be capable of producing? Soil resistivity is 12,000 Ω· cm at a depth of 6 ft.

Solution:

$$R_h = \frac{\rho F}{483} = \frac{12\,000 \times 0.460}{483} = 11.42\ \Omega$$

From Ohm's law: $E = IR = 5.0 \times 11.42 = 57.10$.

Therefore, the rectifier must produce 58 V.

Cathodic Protection of Steel Pile Structures[**]

Example 3: Use of Zinc Sacrificial Anodes to Protect a Pipe Pile Structure.

A pier structure 20 ft wide extending 150 ft from the shore consists of sixteen 16-in. diam steel pipe piles, 40 ft long, that support the pier deck. The piles will be driven so that 14 ft will be in the soil zone, 8 ft in the submerged zone, 3 ft in the tidal zone, and 5 ft in the atmospheric/splash zone (Fig. 16).

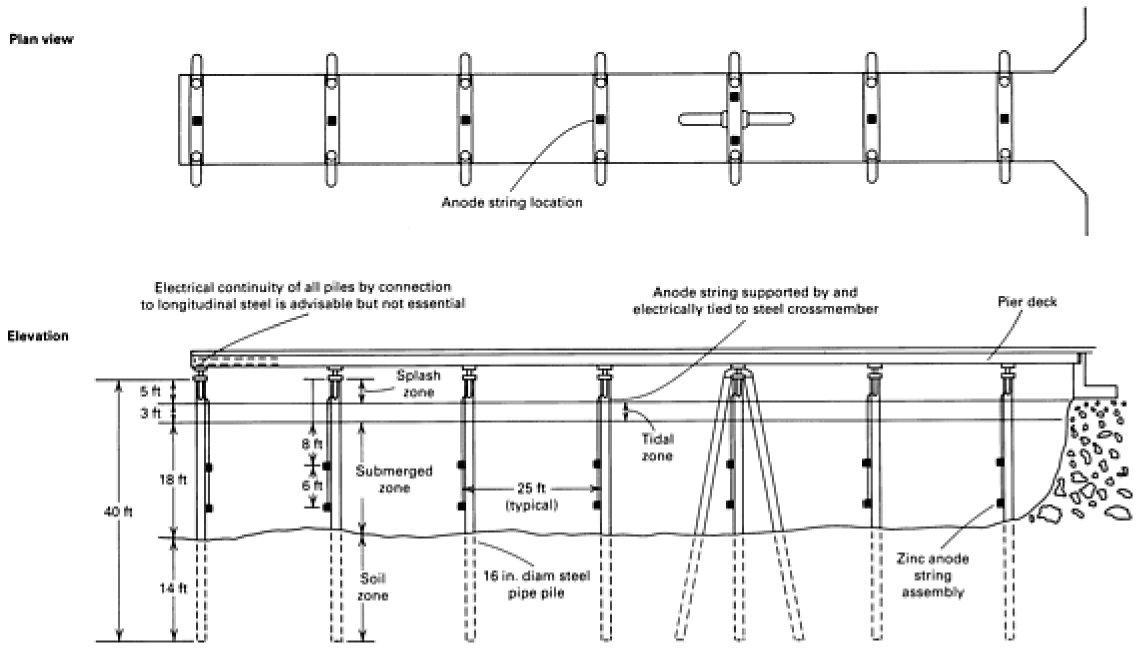

Fig. 16 Protection of a steel pipe pile pier with a protective coating and zinc sacrificial anodes

The pier is located in a calm saltwater bay. The water is not badly polluted and has an average temperature of 62 °F. The water samples taken at three different locations show an average resistivity of 25 Ω·cm. A decision has been made to coat the piles with 16-mil dry-film thickness of coal tar epoxy and to apply cathodic protection in the form of a sacrificial anode system.

Calculation of Steel Areas Exposed to the Specified Zones:

$$\text{Area in atmospheric/splash zone} = \pi D L n = \pi\left(\frac{16}{12}\right)(5)(16) = 335 \text{ ft}^2$$

$$\text{Area in tidal zone} = \pi D L n = \pi\left(\frac{16}{12}\right)(3)(16) = 201 \text{ ft}^2$$

$$\text{Area in submerged zone} = D L n = \pi\left(\frac{16}{12}\right)(18)(16) = 1206 \text{ ft}^2$$

$$\text{Area in soil zone} = \pi D L n = \pi\left(\frac{16}{12}\right)(14)(16) = 938 \text{ ft}^2$$

where D is the diameter of the pile (in feet), L is the length of pile in the specified zone (in feet), and n equals the number of piles.

Current Requirement Calculations (Table 10):

Tidal Zone:

- The total area of steel in this zone is 201 ft^2.
- Assume 10% coating damage during installation:
- Area of bare steel = 201 × 0.10 = 20 ft^2
- Area of coated steel = 201 × 0.90 = 181 ft^2
- Current required to polarize the bare steel = 20 ft^2 × 35 mA/ft^2 = 0.7 A
- Current required to polarize the coated steel = 181 ft^2 × 5 mA/ft^2 = 0.9 A
- Total current required to maintain protection of the steel during high tide = 0.7 + 0.9 = 1.6 A

Submerged Zone:

- Area of steel in submerged zone = 1206 ft^2
- Assume 15% coating damage during installation:
- Area of bare steel = 1206 × 0.15 = 181 ft^2
- Area of coated steel = 1206 × 0.85 = 1025 ft^2
- Current required to polarize the bare steel = 181 ft^2 × 35 mA/ft^2 (corrosion in the area known to be high) = 6.3 A
- Current required to polarize the coated steel = 1025 ft^2 × 5 mA/ft^2 = 5.1 A
- Total current required to polarize the steel in the submerged zone = 6.3 + 5.1 = 11.4 A
- Current required to maintain protection of the bare steel = 181 ft^2 × 10 mA/ft^2 = 1.8 A
- Current required to maintain protection of the coated steel = 1025 ft^2 × 1.5 mA/ft^2 = 1.5 A

- Total current required to maintain protection of the steel in the submerged zone = 1.8 + 1.5 = 3.3 A

Soil Zone:

- The total area of steel in this zone is 938 ft^2. Assume 50% coating intact after pile-driving operations:
- Area of bare steel = 938 × 0.50 = 469 ft^2
- Area of coated steel = 938 - 469 = 469 ft^2
- Current required to polarize the bare steel = 469 ft^2 × 5 mA/ft^2 = 2.3 A
- Current required to polarize the coated steel = 469 ft^2 × 1.0 mA/ft^2 = 0.5 A
- Total current required to polarize the steel in the soil zone = 2.3 + 0.5 = 2.8 A
- Current required to maintain protection of the bare steel = 469 ft^2 × 1.5 mA/ft^2 = 0.7 A
- Current required to maintain protection of the coated steel = 469 ft^2 × 0.5 mA/ft^2 = 0.2 A
- Total current required to maintain protection of the steel in the soil zone = 0.7 +0.2 = 0.9 A
- Total Current Requirements:
- Total current required to polarize the entire structure:

$$I_{pol} = 1.6 + 11.4 + 2.8$$
$$= 15.8 \text{ A}$$

- Total current required to maintain protection of the entire structure:

$$I_{prot} = 1.6 + 3.3 + 0.9$$
$$= 5.8 \text{ A}$$

-

Table 10 Current densities required for coated and uncoated steel in moving and stagnant seawater and in soil areas

Environment	Current density, mA/ft^2			
	Bare steel		Coated steel	
	To polarize	**After polarization**	**To polarize**	After polarization
Moving seawater	30-35	7-10	3-5	**1.0-1.5**
Stagnant seawater	15-25	4-7	1-3	**0.5-1.0**
Soil zone	**4-5**	**1-1.5**	**0.5-1.0**	**0.1-0.5**

The Total Current Required to Maintain Protection as the Coating Deteriorates. Calculate the expected current requirement after 20 years of service. Assume coating deterioration at the rate of 2% per year:

- Intact coating in tidal zone after 20 years = 90% initial - 40% deterioration = 50%
- Current required to maintain protection of the bare steel in the tidal zone after 20 years = 201 ft^2 × 0.50

× 35 mA/ft^2 = 3.5 A
- Current required to maintain protection of the coated steel in the tidal zone after 20 years = 201 ft^2 × 0.50 × mA/ft^2 = 0.5 A
- Intact coating in submerged zone after 20 years = 85% initial - 40% deterioration = 45%
- Current required to maintain protection of the bare steel in the submerged zone after 20 years = 1206 ft^2 × 0.55 × 10 mA/ft^2 = 6.6 A
- Current required to maintain protection of the coated steel in the submerged zone after 20 years = 1206 ft^2 × 0.45 × 1.5 Am/ft^2 = 0.8 A
- Total current required to maintain protection of the entire structure in the tidal, submerged, and soil zones after 20 years = 3.5 + 0.5 + 6.6 + 0.8 + 0.9 = 12.3 A
- Assume no coating deterioration in the soil zone.

Anode Design Calculations:

- Average total current required to maintain protection of the entire structure for 20-year life

$$= \frac{\text{Initial current (after polarization)} + \text{final current}}{2}$$

$$= \frac{5.8 + 12.3}{2} = 9.1 \text{ A}$$

- Total weight of high-purity zinc anode material required for 20-year life expectancy:

$$W = \frac{\text{CR} \times \text{L} \times \text{ATC}}{\text{E} \times \text{U}}$$

- where *W* is the weight (in pounds), CR is the consumption rate (in lb/A·yr), L is the life (in years), ATC is the average total current (in amps), E is the efficiency factor, and U is the utilization factor:

$$W = \frac{23.585 \times 20 \times 9.1}{0.90 \times 0.85} = 5611 \text{ lb}$$

-

Based on the structure description and the amount of zinc required, it can be determined that for this structure eight strings of two 390-lb (10- × 10- × 15-in.) zinc anodes (6240 lb) suspended at the locations shown in Fig. 16 should afford adequate protection for the 20-year life expectancy. The other factor to consider in a galvanic anode system is the amount of current that can be discharged from the anodes.

Resistance of the Anode Systems. The 390-lb anode measures 10 × 10 × 15 in. The outside perimeter of the anode is 40 in. The diameter of a cylindrical object whose circumference is 40 in. is 12.73 in., or 1.06 ft. The anode spacing is 25 ft.

Using the formula from the section "Resistance Calculations" for the resistance of a single anode, it can be calculated that the resistance of one 390-lb anode is:

$$R_v = \frac{0.0052\rho}{L}\left[2.3 \log \frac{8L}{d} - 1\right]$$

$$= \frac{(0.0052)(25)}{(15/12)}\left[2.3 \log \frac{(8)(15/12)}{1.06} - 1\right]$$

$$= 0.129\ \Omega$$

The resistance of the anode system is:

$$R_s =$$

$$\frac{0.0052\rho}{n\,L}\left[2.3 \log \frac{8L}{d} - 1 + \frac{2L}{S} 2.3 \log 0.656n\right]$$

where R_v is the resistance of one vertical anode (in ohms), R_s is the resistance of the anodes system (in ohms), n is the number of anodes, L is the length of anode (in feet), ρ is the water resistivity (in ohm-centimeters), d is the diameter of anode (in feet), S is the spacing between anodes (in feet):

$$R_s = \frac{(0.0052)(25)}{(8)(2)(15/12)}\left[2.3 \log \frac{(8)(2)(15/12)}{1.06} - 1 + \frac{(2)(2)(15/12)}{25} 2.3 \log 0.656(8)\right]$$

$$= 0.0147 \text{ ohm}$$

Anode system output:

$$I = \frac{E}{R}$$

where E is the driving potential, and R is the resistance of the anode system to the electrolyte.

Driving voltage of galvanic anode to polarized coated steel is of the order of 0.10 V:

$$\text{Driving potential} = 1.1 \text{ V} - 1.00 \text{ V} = 0.10 \text{ V}$$

$$I \text{ available after polarization} = \frac{0.10}{0.0147} = 6.8 \text{ A}$$

The 6.8-A output after polarization is greater than the 5.8 A required for the total current requirements given above. Therefore, the current requirement is satisfied.

To verify that life expectancy is met:

Average total current output for 20-year life

$$= \frac{6.8 + 12.3}{2} = 9.6 \text{ A}$$

Total weight of anode material required:

$$W = \frac{23.585 \times 20 \times 9.6}{0.90 \times 0.85}$$

$$= 5919 \text{ lb}$$

The total weight of the anode material used is 8 × 2 × 390 = 6240 lb. Therefore, the life expectancy is satisfied.

Example 4: Use of Impressed-Current Anodes to Protect an H-Pile Structure.

A 30-ft wide pier structure that extends 200 ft from shore is supported by 20-H-piles that are 92 ft long. The H-piles are connected in four-pile clusters by W shapes. The piles are to be driven so that 50 ft will be below the dredged mud line, 30 ft in the submerged zone, 4 ft in the tidal zone, and 8 ft in the atmospheric/splash zone (Fig. 17). The pier is located in a saltwater bay in a highly commercial and industrial area. There are commercial, industrial, chemical, and sewage pollutants. The water samples taken at three different locations show an average resistivity of 30 Ω·cm.

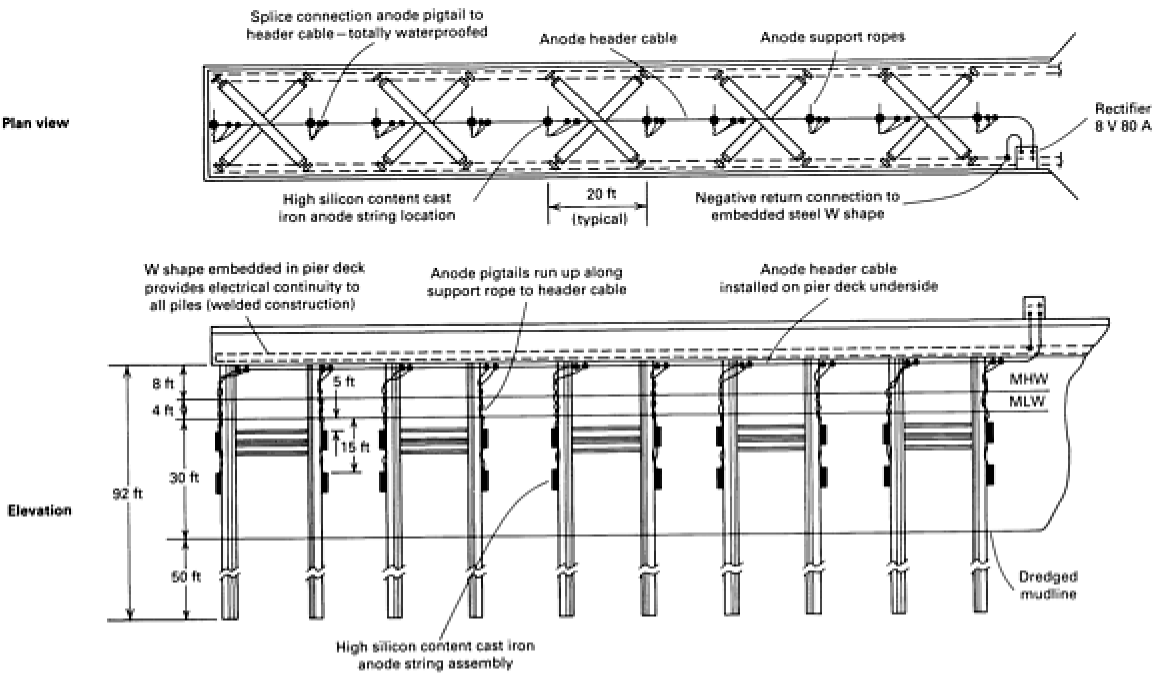

Fig. 17 Protection of H-pile steel pier structure using a protective coating and high-silicon cast iron impressed-current anodes

A decision has been made to coat the H-piles and beams with a vinyl coating of 10-mil dry-film thickness and to apply cathodic protection in the form of an impressed-current system. The cathodic protection system should be designed and a cost estimate of the coating and cathodic protection system should be made for a 20-year life expectancy.

Calculation of Steel Areas Exposed to the Specified Corrosion Zones. The 10 cross braces and the 20 vertical H-piles have a surface area of 8 ft^2 per linear foot:

- Area in Atmospheric/splash zone = $L\ n\ A$ = (8)(20)(8) = 1280 ft^2
- Area in tidal zone = $L\ n\ A$ = (4)(20)(8) = 640 ft^2
- Area in submerged zone: Piles = $L\ n\ A$ = (30)(20)(8) = 4800 ft^2
- Cross braces = $L\ n\ A$ = (30)(10)(8) = 2400 ft^2
- Total = 4800 + 2400 = 7200 ft^2
- Area in soil zone = $L\ n\ A$ = (50)(20)(8) = 8000 ft^2

where L is the length of pile or cross brace in each zone, n is the number of piles or cross braces, and A is the surface area of 1 linear foot of H-pile or cross brace.

Current Requirement Calculations. As shown in Table 10, a greater amount of current is initially required to polarize the structure and bring it to protective levels than is required to maintain these levels.

Tidal Zone:

- The total area of steel in the tidal zone is 640 ft^2. Coating damage of 5% is assumed during installation:
- Area of bare steel = 640 × 0.05 = 32 ft^2
- Area of coated steel = 640 × 0.95 = 608 ft^2
- Current required to polarize the bare steel = 32 ft^2 × 35 mA/ft^2 = 1.1 A
- Current required to polarize the coated steel = 608 ft^2 × 5 mA/ft^2 = 3.0 A
- Total current required to maintain protection of the steel during high tide = 1.1 + 3.0 = 4.1 A

Submerged Zone:

- The total area of steel in the submerged zone is 7200 ft^2. If one assumes that after installation, the coating is 95% intact, there will be 6840 ft^2 of coated steel and 360 ft^2 or bare steel. The current required to polarize this steel is as follows:
- Bare steel current requirement: = 360 ft^2 × 35 mA/ft^2 = 12.6 A
- Coated steel current requirement = 6840 ft^2 × 5 mA/ft^2 = 34.2 A
- Total current required to polarize the steel in the submerged zone = 12.6 × 34.2 = 46.8 A
- The current required to maintain protection is as follows:
- Bare steel current requirement = 360 ft^2 × 10 mA/ft^2 = 3.6 A
- Coated steel current requirement = 6840 ft^2 × 1.5 mA/ft^2 = 10.3 A
- Total current required to maintain protection of the steel in the submerged zone = 3.6 × 10.3 = 13.9 A

Soil Zone

- The total area of all piles in the soil zone is 8000 ft^2. Assuming that the coating is 40% intact, the area of coated steel will be 3200 ft^2, and the area of bare steel will be 4800 ft^2. The current required to polarize this steel is as follows:
- Bare steel current requirement = 4800 ft^2 × 5 mA/ft^2 = 24.0 A
- Coated steel current requirement = 3200 ft^2 × 1.0 mA/ft^2 = 3.2 A
- Total current required to polarize the steel in the soil zone = 24.0 + 3.2 = 27.2 A
- The current required to maintain protection is as follows:
- Bare steel current requirement = 4800 ft^2 × 1.5 mA/ft^2 = 7.2 A
- Coated steel current requirement = 3200 ft^2 × 0.5 mA/ft^2 = 1.6 A
- Total current required to maintain protection of the steel in the soil zone = 7.2 + 1.6 = 8.8 A

Total Current Requirements. Total current required to polarize the entire structure:

$$I_{pol} = 4.1 + 46.8 + 27.2 = 78.1 \text{ A}$$

Total current required to maintain protection of the entire structure:

$$I_{prot} = 4.1 + 12.9 + 8.8 = 26.8 \text{ A}$$

It must be remembered that the above current requirement calculations are for the initial period following construction of the pier. The coating can be expected to deteriorate in the post-construction years. The amount of current required to maintain cathodic protection of the structure will then increased unless an extensive maintenance program of coating repair is followed for the submerged portions.

Assuming 2% per year additional coating deterioration in the tidal zone, 1% per year in the submerged zone, and 0.5% per year in the soil zone, the final current requirements at the end of the 20-year life expectancy would be:

Tidal Zone:

- Intact coating in the tidal zone after 20 years = 95% initial - 20 × 2% deterioration = 55%
- Bare steel current requirement = 640 ft^2 × 0.45 × 35 mA/ft^2 = 10.1 A
- Coated steel current requirement = 640 ft^2 × 0.55 × 5 mA/ft^2 = 1.8 A
- Total current required to polarize the steel in the tidal zone = 10.1 × 1.8 = 11.9 A

Submerged Zone:

- Intact coating in the submerged zone after 20 years = 95% initial - 20 × 1% deterioration = 75%
- Bare steel current requirement = 7200 ft^2 × 0.25 × 10 mA/ft^2 = 18.0 A
- Coated steel current requirement = 7200 ft^2 × 0.75 × 1.5 mA/ft^2 = 8.1 A
- Total current required to maintain protection in the submerged zone = 18.0 + 8.1 = 26.1 A

Soil Zone:

- Intact coating in the soil zone after 20 years = 40% initial - 20 × 0.5% deterioration = 30%
- Bare steel current requirement = 8000 ft^2 × 0.70 × 1.5 mA/ft^2 = 8.4 A
- Coated steel current requirement = 8000 ft^2 × 0.30 × 0.5 mA/ft^2 = 1.2 A
- Total current required to maintain protection in the soil zone = 8.4 + 1.2 = 9.6 A
- Total current required to maintain protection of the entire structure at the end of the 20-year period = 11.9 + 26.1 + 9.6 = 47.6 A

Anode Design Calculations. The anode material is high-silicon content cast iron. Consumption rate is 0.75 lb/A·yr:

$$\text{Average total current required for 20-year life} = \frac{\text{Initial current} + \text{Final current}}{2} = \frac{26.8 + 47.6}{2} = 37.2 \text{ A}$$

Total weight of anode material required for 20-year life expectancy:

$$W = \frac{CR \times L \times ATC}{U}$$

where CR, ATC, and U are as given in Example 3. In impressed-current system, the efficiency factor, E, is 100% (compared to 90% for sacrificial anode systems):

$$= \frac{0.75 \text{ lb/A·yr} \times 20 \text{ yr} \times 37.2 \text{ A}}{0.50}$$

$$= 1116 \text{ lb}$$

The total number of anodes will be determined by taking into consideration the water depth, number and spacing of piles, amount of current available current distribution to the structure.

For this structure, twenty 2-in. diam × 60-in. long anodes with enlarged heads have been chosen; the anodes are to be hung in ten strings of two anodes each. The top of the upper anode is to be 5 ft below the mean low water level (MLW), and the top of the lower anode will be 15 ft below MLW. See Fig. 17 for anode locations.

Resistance of Anodes (Ground bed resistance). The resistance of one vertical anode is:

$$R_v = \frac{0.0052\rho}{L}\left[2.3 \log \frac{8L}{d} - 1\right]$$

where R_v is the anode-to-electrolyte resistance (in ohms), ρ is the electrolyte resistivity (in ohm-centimeters), L is the length of the anode (in feet), and d is the diameter of the anode (in feet):

$$R_v = \frac{(0.0052)(30)}{(60/12)}\left[2.3 \log \frac{(8)(60/12)}{(2/12)} - 1\right]$$

$$R_v = 0.140\ \Omega$$

The calculations for the resistance of several anodes in parallel are made by using the following formula:

$$R_s = \frac{0.0052\rho}{nL}\left[2.3 \log \frac{8L}{d} - 1 + \frac{2L}{S} 2.3 \log 0.656n\right]$$

where R_s is the resistance of vertical anodes in parallel to electrolyte (in ohms), and ρ, n, L, d, and S are as given previously.

Where two anodes are installed vertically in the same string, assume length, L, as equal to length of both anodes combined. From Fig. 17, the spacing is 20 ft:

$$R_s = \frac{(0.0052)(30)}{(10)(120/12)}\left[2.3 \log \frac{(8)(120/12)}{(2/12)} - 1 + \frac{(2)(120/12)}{20} 2.3 \log 0.656(10)\right]$$

$$R_s = 0.11\ \Omega$$

DC Circuit Cable Resistance. The circuit of a rectifier system consists of one or more anode header cables that run from the rectifier positive terminal to the anodes. Current from the anodes flows through the electrolyte and is collected on the structure. A negative return cable then returns this current to the rectifier negative terminal. The cable size must be large enough to carry the current flowing through it and large enough to avoid an excessive voltage drop.

For this installation, a No. 4 American Wire Gage copper wire has sufficient current-carrying capacity. The voltage drop in this wire with the rectifier at the shore end of the pier will be as follows:

$$\text{Voltage drop} = \text{Resistance of wire } (\Omega) \times \text{Current (A)}$$

where:

$$\text{Cable resistance} = \left[\frac{\text{Header cable length}}{2} + \text{Negative return length}\right] \times \text{Wire resistance/ft}$$

The header cable length is divided by 2 because the total current is not flowing through the entire length of cable. The current is being dropped off in equal amounts at equal distances. The wire unit resistance is 0.000254 Ω/ft:

$$\text{Circuit cable resistance} = \left[\frac{200\text{ ft}}{2} + 20\text{ ft}\right] \times 0.0002542\ \Omega/\text{ft} = 0.0305\ \Omega$$

$$\text{Voltage drop} = 0.0305\ \Omega \times 78.1\text{ A} = 2.38\text{ V}$$

where 78.1 A is the greatest current flow expected (polarization) from the total current requirements given previously.

Total dc Circuit Resistance. The total dc circuit resistance is the total of the following:

- Anodes-to-electrolyte resistance
- Circuit cable resistance
- Structure-to-electrolyte resistance (negligible)

Anode resistance + Cable resistance= 0.011 + 0.0305 = 0.0415 Ω

Rectifier dc outputs:

- Voltage required = Maximum current required ×
- Total circuit resistance = 78.1 A × 0.0415 Ω= 3.24 V
- Add 2 V for anode back voltage = 5.24 V
- Allow 20% for stack aging = 1.05 V
- Rectifier voltage required = 6.29 V
- Rectifier output required = 6.29 V and 78.1 A
- Closest available rectifier = 8 V dc, 80 A dc

This rating is for a single phase, 120-V air-cooled selenium rectifier.

Rectifier Efficiency:

- $$\text{Percent efficiency} = \frac{\text{dc output}}{\text{ac input}} \times 100$$
-

Corrosion Inhibitors for Oil and Gas Production

Paul J. Stone, Chevron U.S.A.

Introduction

CORROSION INHIBITORS used in the oil field can be grouped into several common types or mechanistic classes: passivating, vapor phase, cathodic, anodic, film forming, neutralizing, and reactive. These inhibitors are designed for use with carbon steel only. Inorganic inhibitors, such as sodium arsenite (Na_2HAsO_3) and ferrocyanide, have been used to inhibit carbon dioxide (CO_2) corrosion in oil wells, but the treatment frequency and effectiveness have not been satisfactory. This has led to the development of many organic chemical formulations that could almost be reduced to a single type of organic molecule: film-forming amines and their salts. These organic corrosion inhibitors can be classified as cathodic, anodic, or cathodic-anodic.

In the mid-1940s, long-chain polar compounds were shown to have inhibitive properties. This discovery dramatically altered the inhibitor practices on primary production oil wells and gas wells. It permitted operation of wells that, because of the corrosivity and volume of water produced along with the hydrocarbons, would not have been used due to economics. Perhaps entire reservoirs would have been abandoned because of the high cost of corrosion. Inhibitors also allowed the injection and production of high volumes of corrosive water resulting from the secondary-recovery concept of waterflooding.

The consensus is that organic compounds inhibit corrosion by adsorbing at the metal/solution interface. Three possible types of adsorption are associated with organic inhibitors: π-bond orbital adsorption, electrostatic adsorption, and chemisorption. A more simplistic view of the mechanism of corrosion inhibitors can be described as controlled precipitation of the inhibitor from its environment (water and hydrocarbons) onto metal surfaces.

During the past 25 years, the primary improvements in inhibitor technology have been the refinement of formulations and the development of improved methods of applying inhibitors. The methods of evaluating the performance during their use have also advanced considerably.

Varying Characteristics of Oil and Gas Wells

The varying characteristics and number of organic inhibitors are explained by the varying characteristics of oil and gas wells. In this article, oil and gas wells will be characterized as oil wells, gas wells, or water injection systems.

Oil wells, which produce liquid hydrocarbons and water, can be divided into two basic types: flowing wells, which have a natural flow of hydrocarbons and water to the surface, and artificially lifted wells, which require some form of pump. The latter type includes rod-pumped wells, which use a positive-displacement downhole pump connected to the surface by rods; gas-lifted wells, in which gas in injected at some point down the hole to lighten the fluid and cause flow; electrical submerged-pump wells, which use multistage centrifugal pumps placed near the bottom of the well; and hydraulically pumped wells, which use positive-displacement pumps driven hydraulically by oil or water from a surface motor and pump.

Gas Wells. Most gas wells flow naturally. These include dry gas wells, which produce mainly gaseous hydrocarbons, and gas-condensate wells, which produce significant quantities of liquid hydrocarbons, liquid petroleum gas (LPG), and methane at high pressures from high-temperature reservoirs.

Water injection systems are used for disposal, waterflood, or tertiary recovery.

Each of the above categories can be divided into a sweet or sour designation, which is a function of the absence or presence of hydrogen sulfide (H_2S). Corrosion is usually defined as sour when any phase of the produced fluids contains measurable H_2S. Sweet corrosion is caused by the presence of CO_2, formic acid (HCOOH), CH_3COOH, or other short-chain acids in the produced gas and/or fluids. Because corrosivity is usually related to the ratio of produced water to hydrocarbons, the volume and composition of the produced water and oil will influence the application method and performance of the inhibitor.

Influence of Well Depth and Completion Method

The industry is continuously seeking new oil and gas reserves. New finds are generally deeper and/or more inaccessible. As the depth increases in the newer wells, the bottom hole temperature increases. Bottom hole temperatures of 205 °C (400 °F) have been encountered in several deep reservoirs. High labor and equipment costs in offshore production and remote areas have caused the risk of equipment malfunction due to inhibitor failure (incorrect method of application or poor inhibitor performance) to become increasingly important. This has forced the industry to screen inhibitors carefully and to select application methods that are highly reliable. However, in the case of batch treatment, application must not be too frequent.

Factors Influencing Corrosivity of Produced Fluids

Characteristics of Fluids. Produced fluids vary from noncorrosive gases to extremely corrosive brines. The amount of water in the produced fluids may vary from 1 to 99%. Methods of monitoring corrosivity are discussed in the articles "Corrosion in Petroleum Production Operations" and "In-Service Monitoring" in this Volume.

Temperature, Pressure, and Velocity Effects. The effect of temperature increase on corrosion rate is similar to its effect on other chemical reactions. That is, the rate of reaction doubles with each 10-°C (18-°F) increase in temperature. The effect of increased pressure is to raise the solubility of acid gases, thus increasing the corrosivity of the water. Bottom hole pressures exceeding 138 MPa (20,000 psi) are occasionally encountered.

Cyclic Loading, Stress, and Wear. Corrosion inhibitors can be specially formulated to control corrosion that is accelerated by cyclic loading, stress, and wear. Methods of evaluating inhibitors for inhibition of corrosion accelerated by stress and fatigue are discussed in Ref 2, 3, 4, and 5. Because most oil wells are not perfectly vertical holes, wear of tubing by rods becomes a problem in wells that are highly deviated or crooked. Rod guides and inhibitors are sometimes effective in controlling wear and corrosion.

Erosion and Abrasion. Many wells in geologically young formations produce fine sand along with the fluids. This fine sand may remove inhibitor films, depending on the velocity of the fluids. Also, this fine sand may be a primary cause of equipment failure in artificially lifted wells. Sand control, a process of permanently preventing movement of fine sand particles from the formation, is often necessary for good corrosion inhibition.

Water Volume. Early studies by the National Association of Corrosion Engineers (NACE) and the National Gas Producers Association (NGPA) resulted in the designation of two types of corrosion: water independent and water dependent. Water-independent corrosion occurs in wells producing 0.1 t 1% H_2O. Severe corrosion begins at initial water production (Ref 6). Water-dependent corrosion develops in wells as increasing percentages of water are produced. Corrosion in this type of well may begin after several years of production. Pressure is related to corrosivity in gas wells as follows (Ref 7):

- A partial pressure of CO_2 below 48 kPa (7 psi) is considered noncorrosive
- A partial pressure of CO_2 between 48 and 207 kPa (7 and 30 psi) may indicate corrosion
- A partial pressure of CO_2 above 207 kPa (30 psi) usually indicates severe corrosion. Although this general rule is widely accepted, many exceptions have been noted

A 1953 survey of corrosive oil wells showed that no oil wells were corrosive when the water production was under 40%. Water contents from 0 to 40% usually represent well-emulsified water. Because oil is the continuous phase, the production equipment is considered to be oil-wet (Ref 8, 9, 10, 11, 12). However, recent oil production in the North Sea has shown that water contents of approximately 4% may be highly corrosive (Ref 13). As waterfloods have matured, many fields have produced sour water from the outset, although many have changed from sweet to sour during the initial water injection phase. (A waterflood is the injection of water into a field to displace hydrocarbon from the field.) Sour fluids in these mature waterfloods are generally regarded as being highly corrosive, but this notion is not borne out by the facts. There are simply more sour waterfloods that are handling large amounts of water.

Methods of Inhibitor Application

Continuous treatment of producing wells and waterflood injection systems is accomplished by a chemical-proportioning pump that operates constantly. Continuous treatment of artificially lifted wells is carried out by continuously injecting a small quantity of inhibitor into the annulus with a portion of the produced fluid. This technique is known as slip-stream flushing. After an initial treatment of several gallons of inhibitor, inhibitor is continuously injected in order to maintain an inhibitor concentration of 25 to 100 ppm in the produced fluid. The mechanical setup of continuous treatment is simple in artificially lifted wells because the annulus is open to the tubing. Gas-lifted wells prove to be an exception in that the dry gas may cause the solvent to be stripped from the inhibitor, resulting in gunking of the inhibitor and plugging of the system. A treating system of inhibiting gas-lifted wells is described in Ref 14. Continuous treatment of flowing oil and gas wells requires certain types of completion. The following completion techniques are engineered for continuous treating:

- *Dual completion* (either concentric or parallel). In this completion technique, two separate strings of tubing are run in the same hole and may or may not be the same size
- *Capillary or small-bore treating string* involves using a string of continuous, small-diameter tubing strapped to the outside of the well tubing or pipe. This type of completion provides excellent inhibitor injection control with superior results (Ref 15, 16, 17, 18). Disadvantages are the cost and the mechanical difficulties
- *Side pocket mandrel valve.* The annulus is filled with liquid inhibitor solution, and continuous injection on the surface is used to apply pressure to the annulus so that the injection valve opens. Mechanical difficulties with the valve and the stability of the inhibitor solution are disadvantages
- *Packerless completion.* No downhole valves are involved, but inhibitor solution stability must be considered (Ref 19, 20). At high bottom hole temperatures, continuous treatment is generally selected when production rates are such that the expected treatment life of batch treatments is economically prohibitive
- *A low-cost continuous method* for marginal gas wells involves perforating the tubing above the packer, filling the annulus with an inhibitor solution, and then continuously pumping inhibitor solution into the annulus at the surface (Ref 21)

Intermittent Treatment. Batch treatment of flowing gas or oils wells may be effective at low fluid production volumes. Treatment is accomplished by pumping a 10% inhibitor into hydrocarbons or water, then shutting in the well long enough for the inhibitor solution to fall to the bottom of the well. Because the liquid fluid level is unknown, the depth to which the inhibitor solution will fall is unknown; consequently, the results of the application are difficult to predict. Regular treatment intervals from 3 to 6 months can be obtained under optimum conditions in low-volume wells. A more positive approach to batch treating is full tubing displacement. This is accomplished by pumping a solution into the well and displacing the solution with water or hydrocarbon to the bottom of the well. Another approach would be to displace the inhibitor solution with an inert gas, such as nitrogen; nitrogen is less likely than water or hydrocarbon to stop the flow of the well.

Squeeze Treating. Successful squeeze treatments were first reported in 1955 in the Placido Field of Victoria County, TX (Ref 22, 23). Since that time, the method of squeezing inhibitor into the formation has been defined and refined.

Squeeze treating is applicable to all oil and gas wells with sufficient porous and permeable producing zones. It will result in essentially continuous treatment because it has been found that some inhibitors will adsorb rapidly onto sand and will desorb slowly into produced fluids from the producing sand. The inhibitors used for this technique should be very film

persistent. The most widely used technique is to mix one to two 208-L (55-gal) drums with 10 to 20 barrels of diesel oil or kerosene. The inhibitor solution is displaced to the bottom of the well, and an overflush of 200 to 500 barrels or more of oil or brine is then used to push the inhibitor into the formation. This technique often leads to continuous feedback lasting anywhere from 3 months to 2 years. The advantages of this method are that it will successfully treat wells with high fluid levels, the frequency of treatment is drastically reduced, and it is more reliable than some batch methods. Also, the entire length of the tubing is treated. However, squeeze treating is not recommended for wells with known mechanical uncertainties.

The major concern with squeeze treating is the possibility of plugging the formation by emulsion blocks or wettability reversal in the producing formation. The possible plugging effect of inhibitor squeezes on cores were studied in the laboratory, and it was reported that various sandstone formations differed in adsorption characteristics and that limestones were markedly different from sandstones (Ref 24, 25). This work was expanded upon in a field study, which is discussed in Ref 26. Tracer studies on formation squeezes were also conducted (Ref 27).

In a unique variation of the formation squeeze, the corrosion inhibitor/hydrocarbon diluent is atomized with an inert gas, such as nitrogen, and displaced down the tubing and into the formation with the same inert gas (Ref 28). Longer squeeze life and better inhibition have been claimed. The method is advantageous in wells with low bottom hole pressures because the low density of the nitrogen eases the resumption of production in such wells.

Batch Treatment of Pumping Wells. Corrosion problems in rod-pumped wells are directly related to the production volume and water content of producing wells. Severe corrosion problems can be identified by excessive rod, pump, and tubing failures. Embrittlement and pitting result in reduced rod life and fatigue failures, which are greatly accelerated by the presence of H_2S. Hydrogen sulfide and high water volumes are common to most waterfloods.

The most common way of treating rod-pumped wells consists of batch treating with a pump truck, equipped to flush the inhibitor down the annulus with produced fluids or water, followed by further flushing with the same fluids. In the 1950s and 1960s, batch treatment was accomplished without treating trucks by the use of wellhead inhibitor lubricator pots and manual flushing with produced fluids.

The methodology of batch treating involves the development of guidelines for each field. The required guidelines are volume of inhibitor per treatment, volume of flush, and treatment frequency. General rules are based on barrels of fluid produced per day (BFPD). General rules for frequency are (Ref 29, 30):

Volume of total fluid, BFPD	Frequency
0-50	**Monthly**
50-150	**Every 2 weeks**
150-350	**Weekly**
350-800	**Twice weekly**

Another set of recommended guidelines for treating frequency is given in Ref 31.

Successful batch treating of rod-pumped wells also involves the following factors:

- Circulation of high-volume wells is often necessary. In high gas-oil ratio (GOR) wells, it may be necessary to isolate the annulus for approximately 2 h after treatment to allow the inhibitor slug to fall

- Calculation of inhibitor volume based on the frequency of treatment and fluid production is an accepted procedure; inhibitor concentration is generally maintained at 25 to 35 ppm
- Determination of the correct minimum overflush
- Selection of the proper inhibitor

Automatic computer-controlled chemical injectors are available for batch treating. The cost advantages and disadvantages of computer-controlled chemical injectors are discussed in Ref 31. Corrosion fatigue in rod-pumped wells is as important as weight loss corrosion. A corrosion fatigue testing apparatus is described in Ref 32 that can be used to field test corrosion inhibitors specially formulated to prevent corrosion fatigue.

Treatment With High-Density Corrosion Inhibitors. Most liquid inhibitors have a density of 910 to 980 g/L (7.6 to 8.2 lb/gal). High-density liquid corrosion inhibitors are formulations that have been coupled with weighting agents. Their high density (1200 g/L, or 10 lb/gal) and their immiscibility with hydrocarbons and water enable them to fall through static columns of hydrocarbons. Continuous treating can be accomplished by using frequent small-volume batch treatments. Some applications for these unique inhibitors are high fluid level pumping wells and/or high- and low-pressure gas wells.

The weighting agent in high-density inhibitors is often zinc chloride ($ZnCl_2$), which may precipitate as zinc sulfide (ZnS) or zinc oxide (ZnO) when applied to some wells. The precipitation problem may become apparent in the form of plugging of downhole equipment and/or failure of the inhibitor to reach a desired point. Data on the fall rates of high-density and regular inhibitors are given in Ref 33 and 34. Other forms of weighted inhibitors, such as solid sticks, are available. More detailed information on liquid weighted inhibitors is available in Ref 35.

Miscellaneous Treatments. Slow-dissolving solids, sticks, pellets, microencapsulated droplets, and other configurations are used as vehicles for corrosion inhibitors. In addition, downhole dump bailers and concentric kill strings are used for both batch and continuous treatment.

Corrosion Problems and Inhibition in Waterfloods

Corrosion inhibition in waterfloods involves protecting surface-gathering lines and tanks used to recycle produced water, water-treating equipment, and the surface lines and downhole tubing of injection wells. The primary causes of corrosion in waterfloods are oxygen contamination and the acidity of the water. Due to the large amount of water handled, the cost of corrosion failures in repair and downtime can be substantial.

Oxygen Corrosion. Oxygen may be present in the supply water when the water source is surface or shallow ground water. Seawater is commonly used in near-shore or offshore fields and usually contains approximately 8 ppm dissolved oxygen. Anther oxygen source is small amounts of contamination into closed water-handling systems through nongas-blanketed holding tanks, open vents, or thief hatches of water holding tanks, as well as around the shaft of the suction side of centrifugal transfer pumps (Ref 36). Crude oil or diesel oil blankets on the water surface in tanks do not stop oxygen from contaminating the water. Oxygen corrosion can be controlled by removing the oxygen or by using inhibitors.

Oxygen removal by mechanical means applies mainly to high oxygen containing waters, such as seawater. Oxygen is removed by the following mechanical processes:

- Countercurrent gas-stripping towers represent the simplest and most economical method if large amounts of natural gas are available at low cost
- Vacuum tower removal is applicable where no gas is available (Ref 37)
- The water can be gas lifted from its source--for example, lifting seawater from a depth of 30 m (100 ft) by the same technology used to lift fluids in gas-lift oil wells

Usually, none of the above methods will reduce the oxygen to the required point; therefore, chemical oxygen scavengers must be used to remove the last traces.

Oxygen scavenging refers to removal of the oxygen by chemical reactions. Oxygen scavengers can reduce the oxygen content of the water to less than 10 ppb, a level that is considered insignificant from the corrosivity standpoint. The most commonly used oxygen scavengers are:

- Sulfite ion (SO_3^{2-}), which may come from sulfur dioxide (SO_2) gas generated on the site, from solutions of sodium sulfite (Na_2SO_3) or sodium bisulfite ($NaHSO_3$), or from a solution of ammonium bisulfite (NH_4HSO_3). Ammonium bisulfite is the most commonly used because of its stability in storage and its ability to exist as a highly concentrated liquid solution. Solutions containing 60 to 70% NH_4HSO_3 are commercially available
- Hydrazine, which is a practical oxygen-scavenging chemical only at elevated temperatures, such as in boilers or steam generators
- Sodium hydrosulfite ($NaHSO_2$) is recommended for scavenging oxygen, with much less polymer degradation than SO_3^{2-}, in polymer flood applications. However, $NaHSO_2$ is very unstable in solution and requires storage of a solid and solution preparation daily

The reaction of the SO_3^{2-} oxygen scavengers listed above involves a free radical mechanism that necessitates an initiating step. Very small additions (<1 ppm) of transition metal ions, such as cobalt, will catalyze the reaction. The variables affecting the rate and completeness of the SO_3^{2-} reaction are important in designing a waterflood. Sodium sulfite used in a 1- to 2-ppm stoichiometric excess plus 0.1 to 0.2 ppm cobalt chloride ($CoCl_2$) at ambient temperature often completely removes oxygen in an acceptable time period (usually a few minutes). When the rate or degree of completeness of the reaction is not satisfactory, an investigation into possible interferences with the reaction may be necessary. The most common problem is deactivation of the catalyst. All transition metals are not equally effective, and pH affects the various possible metal ions differently (Ref 38). In waters containing sulfide, the catalyst can be precipitated as an insoluble solid (Ref 39), or it can be complexed with a chelating agent, such as ethylenediamine tetraacetic acid (EDTA). In both cases, the catalyst is rendered inactive.

Water used for cyclic steam injection and steam floods must be given greater attention with regard to oxygen corrosion. Corrosion and other water treating problems in steam injection systems are discussed in Ref 40.

When removal of oxygen is not practical because of small volumes of water to be treated or other factors, two organic inhibitors are available. The first, a zinc amino methyl phosphonate, reportedly achieves excellent oxygen corrosion control in fresh to slightly brackish supply waters (Ref 41, 42, 43). The second, an organic sulfophosphate, exhibits inhibition of produced water handling systems processing sour brine contaminated with oxygen (Ref 44). The inhibitor is dispersible only in water and is said to inhibit better when H_2S and hydrocarbons are present in the water in addition to oxygen.

Corrosion by Acid Gases. The corrosive acids found in waterflood systems are usually encountered because produced water is recycled and mixed with the supply water. In a few fields, the produced water has been kept separate and theoretically should always be kept separate from the usually less problematic supply water.

Experience has shown that the presence of H_2S in injection water is much more troublesome with regard to corrosivity and handling problems than waters containing only CO_2 or short-chain acids. This is the case primarily because iron sulfide (FeS), the product of H_2S corrosion, is very insoluble. The FeS corrosion product may deposit on downstream equipment, may plug injection wells, and may cause difficulties in oil-water separation. An inhibitor has not yet been discovered to prevent the precipitation of FeS.

The corrosion inhibitors designed for acidic corrosion are usually film-forming amine salts. Water-soluble or dispersible modifications of these materials are used in waterflood applications. Experience has shown that the system must be free of oxygen contamination for these materials to be effective. Therefore, the above materials are sometimes used in conjunction with oxygen scavengers.

Film-forming ability and stability are determined by the interplay of a number of factors involving both the oleophilic hydrocarbon chain and the polar portion of the molecule. Changes in the oleophilic portion of the molecule that promote water solubility tend to decrease filming ability. The conflict between solubility and film stability is one of the basic

obstacles in formulating inhibitors for waterfloods. Water compatibility or solubility is important if the water is to be injected into a low-permeability reservoir.

The chemistry and ideas used in inhibitor molecules for producing wells have been extended or modified for use in waterfloods. Sufficient dispersibility (added to the inhibitor so that the inhibitor may be effectively transported from the injection point to the farthest injection well) must be balanced with the film-forming ability of the inhibitor. Aside from the solubility or dispersibility requirement, the same molecules can be used for waterfloods. The required concentration of inhibitor, however, is drastically increased by the absence of the hydrocarbon phase. For example, addition of a hydrocarbon phase to sour brine was found to lower the inhibitor requirement for equal inhibition from 25 to 5 ppm (Ref 45). Many other investigation and field experience show that the presence of hydrocarbons augments film formation and persistence.

Alternatives to oxygen removal and/or organic corrosion inhibitors are the use of internally coated steel pipe with either plastic or cement lining, corrosion-resistant alloys, fiberglass-reinforced plastic, or other nonmetals in place of carbon steel. Finally, inorganic inhibitors used in aerated water--for example, cooling towers and radiators--are usually not effective and are too expensive to be applied to waters on a once-through basis, as would be the case in a waterflood.

Bacteria-Induced Corrosion

Sulfate-reducing bacteria (SRB)(genus *Desulfovibrio*) reduce sulfate (SO_4^{2-}) to H_2S, often converting a noncorrosive source water into an aggressively corrosive water. Changes in the biological environment, such as temperature, velocity, pressure, shielding debris (in the bottom of tanks), deposits (organic and inorganic), and nutrients, cause bacteria to grow. The change that appears to cause the greatest increase in growth consists of transporting the water to a surface holding tank having many static areas and letting the water warm up or cool to 40 ± 6 °C (100 ± 10 °F). Sulfate-reducing bacteria also produce tubercles or biomass in conjunction with other bacteria. The SRB have in many cases produced enough H_2S to make a sweet surface system sour and have been though to be the cause of producing a reservoir change from sweet to sour. The injection of seawater into offshore fields has probably been the worst offender in introducing SRB to production equipment. Changes in temperature can increase SRB growth from zero to high levels. Additional information on this subject is available in the section "Biological Corrosion" of the article "Localized Corrosion" in this Volume.

Solutions to bacteria corrosion problems include avoiding static or dead areas in initial surface system design, keeping the system clean, and using a bactericide Cleaning the physical surface system consists of yearly removal of settled solids in surface tankage and separation vessels. Tanks left uncleaned may contain 1 to 2 m (4 to 6 ft) of solids and sludge after 5 to 10 years of operation. Surface water transmission lines are kept clean by regular pigging, which is the most effective method of controlling bacteria corrosion. The surface piping system must be designed for pig launchers and traps.

Bactericides are chemicals that kill or control microorganisms. Many of the chemicals are surface-active cationic materials and must be used with care relative to compatibility with anionic chemicals, such as scale inhibitors. The most common surface-active bactericides are dimethyl coco amine quaternized with methyl chloride; coco diamine acetate, benzoate, or adipate; 3-alkoxy*-2hydroxy-*n*-propyl trimethylammonium chloride (where * denotes a linear primary alcohol, C_{12}-C_{15}) (Ref 46); and dimethyl coco amine quaternized with 2,2-dichloro-diethyl ether. The most common nonsurface-active bactericides are formaldehyde, glutaraldehyde, acrolein, chlorine dioxide (ClO_2), chlorine, sodium hypochlorite (NaClO), isothiazolone, dibromonitrile proionamide, and sodium dimethyldithiocarbamate. The mechanisms and examples of biological corrosion are discussed in Ref 47, 48, and 49.

A method of enumerating bacteria is discussed in Ref 50. Other useful procedures include a quick field method for enumerating total bacteria and studying the effect of bactericides (Ref 51), a method of studying biofilms and the effect of bactericides on them (Ref 52), and a rating system for evaluating bacterial problems in water-floods (Ref 53).

Laboratory Testing of Corrosion Inhibitors

Many testing methods designed to simulate field conditions have been reported in the literature. However, only a few of these methods survive, and none has become the standard test.

Static Test. After several years of use, a static test was formalized based on work described in Ref 54. In the test, coupons are exposed for about 1 week in fluids with and without inhibitors and are evaluated on a weight loss basis (Ref

55). Another static inhibitor screening test consists of short-term static exposure in field fluids, followed by immersion in a copper ion solution to determine filming ability (Ref 56).

Wheel Test. One of the first written reports on the wheel test dates from 1963 (Ref 57). After 25 years of use and many series of multi-laboratory comparative inhibitor tests, no consensus has been reached on a standardized version of the wheel test. Results of round-robin testing are available in Ref 58 and 59. A wheel test procedure (not a standard) is described in Ref 60.

The wheel test is a dynamic test performed by placing synthetic or field fluids in a 7-oz beverage bottle containing a metal coupon. The bottle and its contents are purged with CO_2 or H_2S, and the bottle is capped. The bottles are then agitated for approximately 2 h by securing them to the circumference of a wheel and rotating the wheel. After the first agitation period, the coupons are transferred to a rinse bottle containing fluids with inhibitor and are agitated again. The coupons are then transferred to another bottle containing only corrosive fluids (no inhibitor) and are agitated for a longer period of time, usually 24 h. At the end of this time, the metal coupon is removed and cleaned, and weight loss is measured. The maximum temperature at which this test can be safely conducted is 80 °C (180 °F). High-temperature versions of the wheel test are discussed in Ref 61. Temperatures of 150 to 205 °C (300 to 400 °F)and pressures of several thousand pounds per square inch are achieved by the use of high-alloy pressure bonds. Agitation of the bombs is usually accomplished in the same manner as in the low-temperature wheel test. The results of one series of high-temperature wheel tests indicate a maximum corrosion rate at 105 °C (225 °F) with an unexpected decrease at 165 °C (325 °F) (Ref 62).

Monitoring Results of Inhibition in the Field

The following methods are used to monitor corrosion rates and inhibitor effectiveness:

- Coupons (NACE standards method)
- Spools, pump joints, and pony rods
- Iron counts
- Copper ion displacement
- Radioactive tracer methods
- Caliper survey
- Copra correlation (Ref 63), a quantitative assessment of deep, hot gas well corrosion
- Electrochemical methods, such as resistance measurements, PAIR (polarization admittance instantaneous rate measurements), or potentiodynamic polarization measurements (Ref 64)

Quality Control of Inhibitors

The materials used in most corrosion inhibitors are of necessity by-products of many chemical industries. Although many inhibitor formulators and manufacturers adhere to rigid specifications and procedures it is impossible to correlate product-manufacturing specifications with field performance. One report on quality control procedures used by inhibitor manufacturers showed that only 19% of the manufacturers checked performance and only 10% made compositional analyses (Ref 65).

Computerization of Inhibitor Treating Programs

Problem areas and problem wells have existed since the beginning of corrosion inhibition. Wells or batteries (geographical groups of wells) that do not respond satisfactorily to current chemical corrosion programs are defined as problem wells. Computers can effectively handle large volumes of data and, coupled with their sorting capability, can identify problem wells, changes in conditions, and other factors that influence repair costs. Computer programs can also be used as an accounting tool to monitor corrosion costs and other chemical expenses (Ref 66).

Corrosion Inhibitors for Crude Oil Refineries

Glenn L. Scattergood, Nalco Chemical Company

Introduction

THE REFINING of crude oil results in a variety of corrosive conditions. Some of these conditions, such as initial condensate corrosion, are well defined, but others, such as SO_x corrosion, are difficult to define precisely. Refinery corrosion is generally caused by a strong acid attacking the equipment surface. The most common strong acid is hydrogen chloride, although other strong acids have recently been identified. Given the general title of SO_x, these consist of sulfurous (H_2SO_3), sulfuric (H_2SO_4) thiosulfurous, and other polythionic acids.

The costs of corrosion and the savings gained through the use of appropriate corrosion inhibitors are considerable in the refinery, where conditions tend to be severe because of high flow rates, temperatures, and pressures. Four major categories of corrosion inhibitors have been identified based on the mechanism of operation: neutralizers, filming inhibitors (or barrier layer formers), scavengers, and miscellaneous types (Ref 1). The largest applications in the refinery are for neutralizers and filming inhibitors. These will be covered in detail. Scavengers and miscellaneous types will also be defined.

Inhibitor Mechanisms

Neutralizers lessen the corrosivity of the environment by decreasing hydrogen ion (H^+) concentration, which reduces the concentration of the corrosive reactant. Neutralizers function by controlling the corrosion caused by acidic materials, such as hydrogen chloride, carbon dioxide (CO_2), sulfur dioxide (SO_2), carboxylic acids, and related compounds. These materials are found in small quantities in many process streams. However, because of such separation processes as distillation, one or more of these acidic species can concentrate in specific areas and cause severe corrosion. The area most susceptible to corrosion in the refinery is the heat exchanger, where the first drops of water condense (the initial condensate). An effective neutralizer will exhibit the same distillation/condensation properties as the acid it is designed to control.

Filming inhibitors function by strong adsorption, or chemisorption, and decrease attack by forming a barrier on the metal surface that resists penetration by acid solutions. A filming inhibitor must possess a hydrocarbon portion attached to a strongly polar group. The molecules are oriented on the metal surface, with the polar group adsorbed onto the metal surface and the hydrocarbon part extending away from the surface. The hydrocarbon end will attract the molecules of the process stream to provide an additional barrier to a potentially corrosive aqueous solution.

Scavengers. Perhaps the most widely used scavenger system is employed in boilers to remove oxygen from the feedwater. Techniques such as steam stripping can be used to remove most of the dissolved oxygen from water; however, such methods become increasingly costly when the last traces of oxygen must be removed from the boiler feedwater. In these cases, chemical techniques for oxygen removal become more attractive. Hydrazine and sodium sulfite are the two most widely used scavengers in boiler systems (Ref 1).

Miscellaneous inhibitors include such materials as scale inhibitors, which minimize deposition of scale on the metal surface, and biocides, which kill living organisms that can foul equipment.

Inhibitor Composition

Neutralizing inhibitors. The primary function of a neutralizing inhibitor is to reduce the concentration of H^+ ion in the environment. A variety of neutralizers are used in many applications in the refinery. The list includes ammonia (NH_3), sodium hydroxide (NaOH), and various proprietary alkylamines and polyamines. The physical characteristics of each neutralizer determine its application. A strong alkali, such as NaOH, is an excellent neutralizer when injected into the desalted crude, but it cannot be used in overhead heat exchangers. Ammonia is an inexpensive overhead neutralizer, but it has no solubility in the initial condensate.

Filming Inhibitors. Most of the inhibitors used are of the film-forming type. Instead of reacting with or removing an active corrodent species, filming inhibitors function by creating a barrier between the metal and the environment. They consist of one or more polar groups based on nitrogen, sulfur, or oxygen that are attached to the metal surface by chemisorption or electrostatic forces (Ref 2).

Filming amine chemistry in the refinery includes amides, diamides, and imidazoline salts. Each type is known to be effective in selected environments. The amino group is the important functional and salt-forming species. For readily handled commercial products, the amide intermediate is reacted with an imidazoline salt to enhance solubility in carrier solvents and to decrease gelling or phase separation. However, both groups are effective inhibitors.

Application of Inhibitors

Neutralizers. The primary cause of corrosion in an atmospheric distillation tower overhead system is the hydrochloric acid (HCl) produced by the hydrolysis in the furnace of water-soluble magnesium chloride and calcium chloride salts found in the crude oil and escaping the desalter. Corrosion occurs when water in the system condenses, such as in the heat exchangers and connected piping. The hydrogen chloride gas dissolves in the initial condensation, forming hot HCl. To be an effective neutralizer, the inhibitor must be present when and where the acid is formed. Only a neutralizer that exhibits the same condensation profile as HCl can inhibit HCl corrosion. A neutralizer that is too volatile, such as NH_3, has no solubility in the initial condensate. A nonvolatile neutralizer, such as the commercially available polyamines, will have already condensed and taken the path through the exchangers of the condensed hydrocarbon.

To apply a neutralizer correctly to an overhead system, the point of initial condensation must be defined by a thorough study of the partial pressure relationship between the stripping steam and the hydrocarbons. The neutralizer must be

added at a point in the system such that it will completely vaporize, allowing the neutralizer to condense in accordance with its condensation profile. An initial condensate neutralizer will not allow a low-pH environment to exist inside the heat exchangers and connected piping.

Serious consideration must be given to other areas in the atmospheric distillation system that may experience water condensation. Because of localized cooling, liquid water may exist in tower-top pumps or on the top tray, where a cool reflux is returned to the tower. In these areas, small amounts of water may become concentrated with HCl, H_2SO_3, or H_2SO_4. Where these conditions exist, the problem must be addressed by use of an effective inhibitor.

A filming inhibitor should be applied to an overhead system with an understanding of the physical dynamics of the system. The filming inhibitor is capable of complete inhibition as it forms a protective barrier on equipment surfaces. Unlike neutralizers, the filmer need not contact the corrosive species to render it inactive. Therefore, filmers are much more cost effective than neutralizers.

Filming inhibitors are not volatile in an overhead system. They will follow the path of condensed hydrocarbon through the series of heat exchangers. An oil-soluble filmer has the opportunity to contact all of the equipment parts that are washed over by condensed hydrocarbon, and it is a very effective inhibitor once contact has been made. Portions of the heat exchanger are not contacted by condensed hydrocarbon and cannot be protected by filming inhibitors. The most common approach to overhead corrosion control in a refinery is to use a filmer in conjunction with a neutralizer.

The distillation tower may benefit from applying a filming inhibitor to the reflux injection, thus providing tray protection from the top of the tower to the bottom. Again, the filmer is only present where liquid hydrocarbon is available to carry it. The areas of a tower that contact only vapor, such as the underside of trays and the dome of the tower, cannot benefit from a filming inhibitor.

High-temperature corrosion (>205 °C, or 400 °F) caused by a concentration of naphthenic acids is successfully inhibited by the use of filming inhibitors that are stable at high temperatures. Naphthenic acids are cyclic carboxylic acids that are present in some crude oils and are common in lower fractions of the atmospheric and vacuum towers, such as the gas oils. Neutralization values can become quite high as the acids are distilled to their boiling points, and gas oil equipment may experience severe corrosion. This corrosion is lessened by injecting a filming inhibitor designed for naphthenic acid corrosion into the tower draws.

Monitoring Corrosion

Corrosion monitoring in the refinery is intended to provide quantitative information that will enable the service life of the process equipment to be predicted. A corrosion test program that is soundly designed, conducted, and evaluated will provide this information, but a poorly conceived program can generate information that is unless or misleading. Seven types of tests are listed below in order of decreasing reliability; each test encompasses fewer variables, and is therefore less reliable, than the one above it (Ref 3):

- Full-scale equipment
- Small side-stream equipment in an operating unit
- Equipment in a pilot unit
- Plant coupon tests
- Pilot plant coupon tests
- Laboratory tests using plant process samples
- Laboratory tests using synthetic solutions

Full-scale equipment is the only source of completely reliable information. However, it is a very slow and expensive way of determining whether a fractionating tower fabricated of a given alloy will be serviceable. Thorough, quantitative inspection data are needed to estimate corrosion rates properly on existing equipment.

Small side-stream equipment is advantageous in that inspections for corrosion evaluation can be scheduled independently of production and maintenance schedules. Small side-stream equipment is available for almost any unit in the refinery. Coupled with a continuously monitoring computer, corrosion control effectiveness is available around the clock.

For equipment in a pilot unit, the feedstock and recycle streams may differ from those in a plant unit, and operation is usually less table. An additional limitation is that a pilot plant must usually be operated under varying conditions in order to develop process data. It is seldom held at one condition long enough to develop good corrosion information.

Plant coupons are not reliable, because of the placement of the coupon. The coupon may not be in the area of most severe corrosion, or it may receive a coating of corrosion inhibitor that is not representative of the process equipment.

Control of Environmental Variables in Water Recirculating Systems

Bennett P. Boffardi, Calgon Corporation

Introduction

THE CORROSION PROCESS that occurs in industrial systems is insidious and all-embracing. This process is often difficult to discern until extensive deterioration has occurred. Corrosion robs industry of millions of dollars annually through loss or contamination of products, replacement cost and overdesign of equipment, reductions in efficiency, high maintenance expense, and waste of valuable resources. Corrosion also restrains technological progress and jeopardizes human safety.

Water, the most commonly used cooling fluid, removes unwanted heat from heat transfer surfaces. However, water is corrosive to most alloys and contributes to the buildup of insulating deposits through water-formed and water-borne foulants.

The Cooling System

An understanding of the relationship between cooling water and the buildup of deposits and corrosion of heat transfer surfaces requires an awareness of cooling system characteristics. There are basically three types of cooling systems; once-through, open recirculating, and closed recirculating systems (Fig. 1).

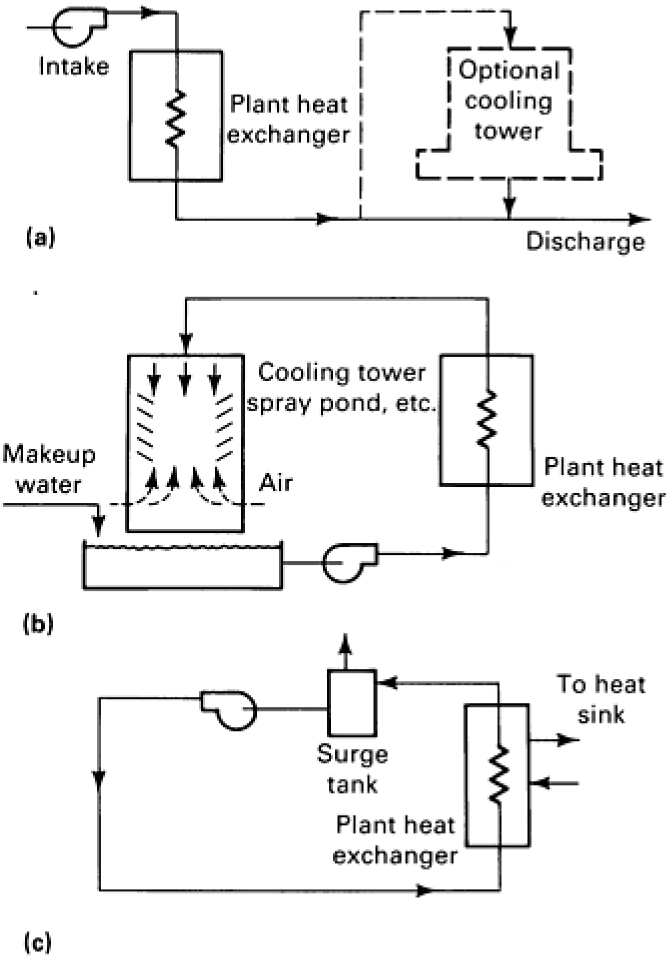

Fig. 1 Schematics of three types of cooling systems. (a) Once-through system. (b) Open recirculating system. (c) Closed recirculating system

In once-through systems, the cooling water passes through the heat transfer equipment only once before it is discharged. Large volumes of water are used with only a small temperature increase across the exchanger. The mineral content of the water remains essentially the same. Water is usually drawn from such sources as rivers, lakes, and wells.

Open recirculating systems continuously reuse the water that passes through the heat transfer equipment. Circulated water can be drawn from spray ponds or cooling tower basins. Evaporative cooling to the atmosphere dispels the unwanted heat transferred to the cooling water. The water then returns to the source and recirculates. In cooling tower operations, the water cascades over and down the tower, where evaporative heat transfer takes place. Makeup water is added to replace the evaporative losses. Additional makeup water replaces the intentionally discharged water (blowdown) to maintain an acceptable level of dissolved minerals and suspended solids in the cooling water.

Open recirculating cooling systems are oxygen saturated and may contain a high level of dissolved solids. Inlet temperatures to the heat transfer equipment are usually higher than those for once-through cooling systems. Also, there may be a larger temperature differential across the exchanger. These factors can significantly affect the buildup of deposits and deterioration of the heat transfer equipment.

Closed recirculating systems have little water loss and continuously recirculate the same water. The heat absorbed from the heat transfer equipment is dissipated to another heat sink, which is cooled by other methods. Because there are no evaporative losses, the makeup water is minimal, and the mineral content remains essentially constant. However, corrosion by-products can easily accumulate and foul heat transfer equipment because there are no methods of removing them from the system. Operating temperatures of the closed recirculating systems range from cold (as in chilled-water systems) to hot (for engine cooling jackets).

Corrosion Processes in Water-Recirculating Systems

The corrosion processes and the fouling of heat transfer equipment must be understood if long-term reliability is to be achieved. Corrosion can be defined in a very practical sense as the deterioration of metal caused by the reaction with its surrounding environment. Because water is one of the most common heat transfer fluids, it is not surprising that most of the problems associated with corrosion and deposits are water related. However, dissolved gases (such as oxygen, carbon dioxide, CO_2, ammonia, and chlorine), dissolved salts (such as calcium, magnesium, chloride, sulfate, and bicarbonate), and suspended solids make water something other than pure H_2O.

For the corrosion reactions to take place between water and the metal surface, a potential difference must exist between different areas on the surface. This causes the passage of electrical current through the metal from the area of high potential to low potential. Thus, corrosion of metals in contact with water is electrochemical in nature. The basic reactions occur at the region of lower potential, which is the anode. The dissolution reaction causes metal ions to form and go into solution. The anodic oxidation reaction can be generally represented by:

$$M \rightarrow M^{n+} + ne^-$$

where M represents the metal that has been oxidized to its ionic form having a valence of *n*+ and the release of *n* electrons. For the more common heat transfer materials, the individual reactions are:

$$Fe \rightarrow Fe^{2+} + 2e^-$$

$$Cu \rightarrow Cu^{+} + e^-$$

$$Al \rightarrow Al^{3+} + 3e^-$$

The liberated electrons that migrate through the metal to areas of higher potential are used in the reduction of other ions or oxygen in the water. These reactions occur at the cathodic site on the metal surface:

$$O_2 + 4H^+ + 4e^- \rightarrow 2H_2O$$

(Reduction of oxygen in acid solution)

$$O_2 + 2H_2O + 4e^- \rightarrow 4OH^-$$

(Reduction of oxygen in neutral or alkaline solution)

$$2H^+ + 2e^- \rightarrow H_2$$

(Hydrogen evolution)

$$Cu^{2+} + 2e^- \rightarrow Cu$$

(Metal deposition)

$$Fe^{3+} + e^- \rightarrow Fe^{2+}$$

(Reduction of metal ions)

Interaction between the products of the anodic and cathodic reactions can occur, forming solid corrosion products on the metal surface. For example, ferrous ions (Fe^{2+}) coming from the corrosion of metallic iron will react with the hydroxyl ions (OH^-) produced from the reduction of dissolved oxygen:

$$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2$$

Ferrous hydroxide ($Fe(OH)_2$) is further oxidized to form ferric hydroxide ($Fe(OH)_3$), which is unstable and subsequently transformed to hydrated ferric oxide (Fe_2O_3)--common red rust:

$$4Fe(OH)_2 + O_2 + 2H_2O \rightarrow 4Fe(OH)_3$$

$$2Fe(OH)_3 \rightarrow Fe_2O_3 + 3H_2O$$

A buildup of rust occurs at the anodic sites, forming mounds known as tubercles. Under these mounds, localized corrosion continues to accelerate (Fig. 2) (Ref 1). Not all corrosion products are detrimental. The protective oxide films on copper (cuprous oxide, Cu_2O) and aluminum (aluminum oxide, Al_2O_3) are the result of corrosion:

$$2Cu^+ + 2OH^- \rightarrow Cu_2O + H_2O$$

$$Al^{3+} + 3OH^- \rightarrow Al(OH)_3$$

$$2Al(OH)_3 \rightarrow Al_2O_3 \cdot 3H_2O$$

These films are self-limiting, inhibiting the corrosion process once they are fully developed.

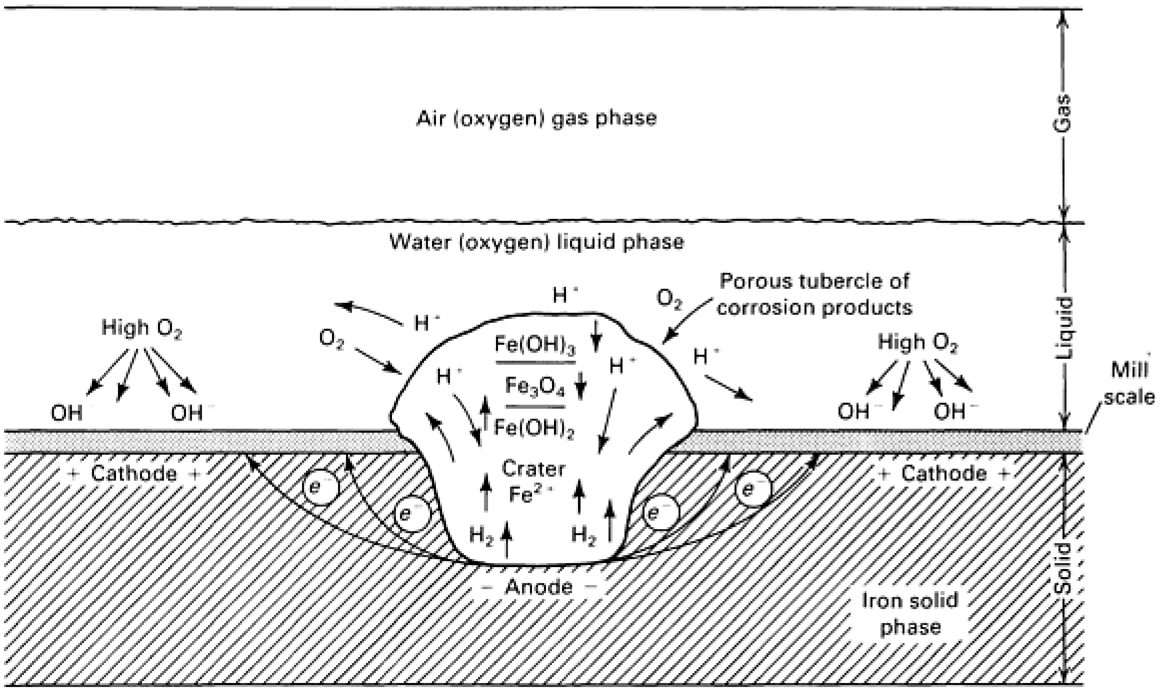

Fig. 2 Schematic of localized corrosion under a rust tubercle. Source: Ref 1

The corrosion process between water and metal surfaces can take many forms (Ref 2). The more common forms that have been observed in heat transfer equipment have the characteristics discussed in the following sections (additional information is available in the Section "Forms of Corrosion" in this Volume).

General corrosion, or uniform attack, occurs when the anodic areas on the metal surface keep shifting to different sites. This continual shifting results in relatively uniform metal removal. Because this type of corrosion can often be predicted, material loss can be taken into account.

Galvanic corrosion occurs when dissimilar materials are in contact in a conducting fluid (water). Accelerated corrosion occurs with the least resistant alloy, while the more resistant alloy is protected. The resistance of alloys can generally be described by the galvanic series, which ranks materials according to their chemical reactivity in seawater. The metals closer to the active end of the series will behave as the anode and will corrode, but those closer to the noble end will behave as the cathode and will be protected. Table 1 lists an abridged galvanic series. The intensity of attack is related to the relative surface areas of the metals in electrical contact. Large cathodic areas coupled to small anodic areas will aggravate galvanic corrosion and cause severe dissolution of the more active metal. The reverse situation--large anodic areas coupled to small cathodic areas--produces very little galvanic current.

Galvanic corrosion obviously must be considered in the design of heat transfer equipment. Alloys close to one another in the galvanic series should be used. Less obvious are the damaging effects that can occur when a dissolved noble metal is transported through the water and is capable of depositing on an active metal. For example, copper ions can plate out onto steel heat transfer tube surfaces, setting up local corrosion cells.

Erosion-corrosion is normally restricted to copper-base alloys. It occurs in areas where turbulence intensity at the metal surface is high enough to cause mechanical or electrochemical disruption of the protective film. Corrosion occurs at these sites and forms horseshoe-crescent-shaped indentations facing upstream of the water flow. The process is usually accelerated when abrasive solid particles, such as sand, are entrained in the water. Because turbulence increases with velocity, areas having higher water velocities are prone to attack. For example, turbulence intensity is much higher at tube inlets than it is several feet down the tube, resulting in the phenomenon of inlet-end erosion-corrosion.

Crevice corrosion is an electrochemical attack that is due to differences in the corrosive environment between a shielded area and its surroundings. Attack usually occurs in areas having a small volume of stagnant solution, such as at tube sheet supports, under deposits or tubercles, and at threaded joints. Corrosion is usually initiated because the oxygen concentration within the crevice is lower than that of the surrounding area. The outside area is higher in oxygen concentration and becomes the predominant cathodic region. Anodic dissolution occurs at the stagnant area. Once attack is underway, the area in the crevice or under a deposit becomes increasingly more aggressive because of pH depression and an increase in electrolyte concentration.

Pitting corrosion is one of the most insidious forms of attack. It takes place at small discrete areas where overall metal loss is negligible. The pit develops at a localized anodic site on the surface and continues to grow because of a large cathodic area surrounding the anode. High concentrations of metal chlorides often develop within the pit and hydrolyze to produce an acidic pH environment. This solution remains stagnant, having a high salt content and low oxygen concentration. The reactions within the pit become self-sustaining (autocatalytic) with very little tendency for them to be suppressed, ultimately causing penetration through the base metal. Pitting corrosion has also been associated with both crevice and galvanic corrosion. Metal deposition (copper ions plated on a steel surface) can also create sites for pitting attack.

Influence of Water Quality

The corrosivity of water is significantly influenced by concentrations of dissolved species, including gases, pH, temperature, suspended matter, and bacteria. The effects of these entities on corrosion are assumed to be independent; although this is not totally correct--interactions do exist--it is easier to visualize their contribution when they are considered separately.

Dissolved Gases

Dissolved oxygen is a major factor contributing to the natural corrosion of steel. It has been shown that oxygen is part of the overall electrochemical reactions occurring at the interface between the aqueous phase and the metal surface. Therefore, it is not surprising that steel corrosion is proportional to the oxygen content in the water. Oxygen solubility in water will vary with temperature, pressure, and electrolyte concentration. Increasing the temperature decreases oxygen solubility, but increasing the partial pressure of oxygen increases its solubility. Concentrated electrolytes decrease oxygen solubility (molar salt concentrations exist in pit cavities and crevices). For open recirculating cooling water systems, the concentration of dissolved oxygen is approximately 6 mg/L. The presence of oxygen is necessary for the formation of protective oxides on copper (Cu_2O), aluminum (Al_2O_3) and steel (γ-Fe_2O_3). In the absence of dissolved oxygen, the corrosion of steel is greatly reduced. A uniform protective film of magnetite (Fe_3O_4) is formed according to the following reaction:

$$3Fe + 4H_2O \rightarrow Fe_3O_4 + 4H_2$$

Overall, oxygen can have either a negative or a positive impact on the corrosion of steel. In aerated systems, uneven distribution of corrosion products can form on the metal surface, giving rise to localized corrosion. Under deaerated conditions, the Fe_3O_4 film isolates the base metal from the water, drastically reducing corrosion.

Carbon dioxide is more soluble than oxygen in pure water (1.3 g/L at 30 °C, or 85 °F) and will convert to carbonic acid (H_2CO_3), producing a solution having a pH of less than 6 where acid attack can predominate:

$$CO_2 + H_2O \rightleftarrows H_2CO_3 \rightleftarrows H^+ + HCO_3^-$$

Adjusting the pH of the water upward redistributes the ratio of dissolved carbonic species. Carbonic acid will dissociate to from bicarbonate ions (HCO_3^-) and subsequently carbonate ions (CO_3^{2-}). The ratio of the various components can be calculated from the pH of the system. In open recirculating cooling water systems, the pH is usually controlled within the 7 to 8.5 range. Within this range, only the CO_2/HCO_3^- ratio is important (the CO_3^{2-} concentration is negligible). Calcium ions (Ca^{2+}) in the water will react with bicarbonate species to produce calcium carbonate ($CaCO_3$). This salt has a low solubility and will precipitate onto heat transfer surfaces (see the section "Calcium Carbonate" in this article). The effect of CO_2 is most important in boiler condensate systems (see the articles "Corrosion in the Nuclear Power Industry" and "Corrosion in Fossil Fuel Power Plants" in this Volume). Here, H_2CO_3 reacts with the steel to form ferrous bicarbonate ($Fe(HCO_3)_2$), which is a highly soluble salt. Rapid general thinning of steel can occur. The addition of soluble amine inhibitors neutralizes the H_2CO_3 to suppress the corrosive attack. Copper alloys are also susceptible to increased attack in the presence of CO_2.

Chlorine is not a natural constituent of cooling waters, but is added for biological control. When dissolved in water, chlorine will convert to hypo-chlorous acid (HClO) and hydrochloric acid (HCl), which will suppress the pH:

$$Cl_2 + H_2O \rightarrow HClO + HCl$$

Acid attack on steel is a concern when the pH falls below 7. Above this pH, the deleterious effects of chlorine are reduced. Adequate biological control can be achieved if the pH is maintained at approximately 7.5. However, chlorine will accelerate the corrosion of copper alloys, even at alkaline pHs. It is one of the most aggressive species to copper alloys in cooling waters; it can induce localized attack and degrade the protective Cu_2O film.

Ammonia. Another gas that can affect heat transfer equipment is ammonia (NH_3). Although its effect on ferrous alloys is minimal, it has a drastic impact on copper-rich brasses and alloys. These alloys can experience both rapid general thinning and stress-corrosion cracking (SCC). Ammonia is originally formed from the thermal degradation of various nitrogen-containing compounds added to a boiler to reduce ferrous corrosion. It forms a soluble complex with copper that can autocatalytically deteriorate the ally in a short period of time.

Temperature

As previously stated, corrosion is an electrochemical phenomenon. It is not surprising that an increase in temperature will cause an increase in corrosion rates. Temperature plays a dual role with respect to oxygen corrosion. Increasing the temperature will reduce oxygen solubility. In open systems, in which oxygen can be released from the system, corrosion will increase up to a maximum at 80 °C (175 °F) where the oxygen solubility is 3 mg/L. Beyond this temperature, the reduced oxygen content limits the oxygen reduction reaction, preventing occurrence of the iron dissolution process. Thus, the corrosion rate of carbon steel decreases, and at boiling water conditions, the temperature effect is similar to room temperature with a high oxygen content. For closed systems, in which oxygen cannot escape, corrosion continues to increase linearly with temperature. The other physicochemical properties affected by temperature are the diffusion of oxygen to the metal surface, the viscosity of water, and solution conductivity. Increasing the temperature will increase the rate of oxygen diffusion to the metal surface, thus increasing corrosion rate because more oxygen is available for the cathodic reduction process. The viscosity will decrease with increasing temperature, which will aid oxygen diffusion. Ionic mobility will also increase with temperature, increasing the overall conductivity of water.

An unusual temperature effect can occur with copper alloys (Ref 3). Temperature differences of at least 65 °C (115 °F) between the ends of copper conduits will cause the cold end to be cathodic to the hot end. Copper ions will migrate to the

cold end and dissolve (corrode) at the hot end. At the cathode, copper ions will plate out, but at the anode, the surface will become rough and will pit. This effect is known as thermogalvanic attack.

One other effect of temperature should be noted, although it is not related to corrosion. An increase in temperature will decrease the solubility of many sparingly soluble inorganic salts. The solubility of $CaCO_3$ and calcium sulfate ($CaSO_4$) will decrease with an increase in temperature, precipitating and forming a thick barrier deposit at the hottest areas.

Suspended Solids

Suspended matter, such as clays, silt, and corrosion products, is always present in open recirculating cooling water systems. Particulates scrubbed from the air add to the suspended solids loading. These materials are usually soft and nonabrasive. They are capable of depositing in low-flow areas, forming a physical barrier, and preventing oxygen from reaching the metal/solution interface. This buildup will contribute to the formation of differential aeration cells (crevice corrosion) and will promote localized attack.

Effect of pH

The normal pH range for an open recirculating cooling water system is 6.5 to 9. Closed systems operate at a pH of 8.5 to 9; in boilers, the pH of the water is often 11. These pH values are the bulk pH of the water, but the actual pH at the metal surface can be different, depending on prevailing surface reactions. Oxygen reduction will produce OH^- ions, raising the pH, but under-deposit corrosion products can depress the pH.

When the bulk water pH is moderately acidic (pH 5), uniform corrosion is the predominant form of attack, which increases with decreasing pH. In mineral acid (pH 4 or below), the protective oxide film dissolves, exposing bare metal surfaces. Corrosion is further accelerated when dissolved oxygen is reduced at the metal surface at low pH. Both hydrogen evolution and oxygen reduction become the prevalent cathodic reactions. As the pH increases above 4, iron oxides precipitate from solution to form deposits. Uniform corrosion gradually decreases, but under-deposit attack begins because of the formation of Fe_2O_3 adhering to the surface. These deposits impede the diffusion of oxygen to the metal surface. As the pH increases, the nature of the iron oxide deposits changes from loosely adherent at pH 6 to hard and tenacious at pHs above 8. Although the corrosion of steel in aerated waters decreases within the normal operating pH range of 6.5 to 9, the rates are sufficiently high that chemical treatments must be added to these systems to bring the rates within a manageable level of less than 0.13 mm/yr (5 mils/yr).

Copper alloys are not as sensitive to pH as carbon steel is. Acid pHs will accelerate general corrosion. As the pH increases, uniform corrosion decreases significantly. However, general thinning is not as severe a problem as the formation of cupric ions (Cu^{2+}), which can cathodically deposit on steel and create active sites for pitting attack.

Aside from the effect of pH on corrosion, increasing the pH waters having moderate levels of calcium and alkaline values can result in the precipitation of $CaCo_3$. The deposition of this alkaline scale can impede the diffusion of oxygen to the metal surface in addition to forming a heat transfer barrier.

Dissolved Salts

Dissolved constituents in water can have a variety of effects, both individually and through their interactions. The effects include increased corrosion in addition to scale and deposit formation. Increasing the dissolved solids content of the waters increases its conductivity. Galvanic effects due to the coupling of dissimilar metals are extended in waters having a higher salt content compared to waters of low conductivity.

Hardness ions (calcium and magnesium) and HCO_3^- ions are inhibitive and will suppress corrosion, but chloride (Cl^-) and sulfate (SO_4^{2-}) ions are antagonistic and will increase the rate of some forms of corrosion. The aggressiveness of water can be reduced by increasing the concentration of hardness ions. Most waters used for cooling have pHs in the vicinity of neutral or above. This environment is very conductive to the formation of a protective film of $CaCO_3$ even when the water is below the saturation level for this salt. The actual mechanism that occurs at the water/metal surface interface is more involved than simple deposition of deposit. It is quite probable that $CaCO_3$ formation is due to electrochemical changes at the metal surface. The pH at the surface is usually higher than that of the bulk water because of an increase in OH^- ion concentration, a reaction product of oxygen reduction.

The overall aggressiveness of water is related to its hardness and alkalinity. Soft waters which are low in calcium, are more corrosive than hard waters. Laboratory studies using three different waters of various compositions have shown that increased calcium concentration reduces general corrosion (Ref 4), as illustrate in Fig. 3.

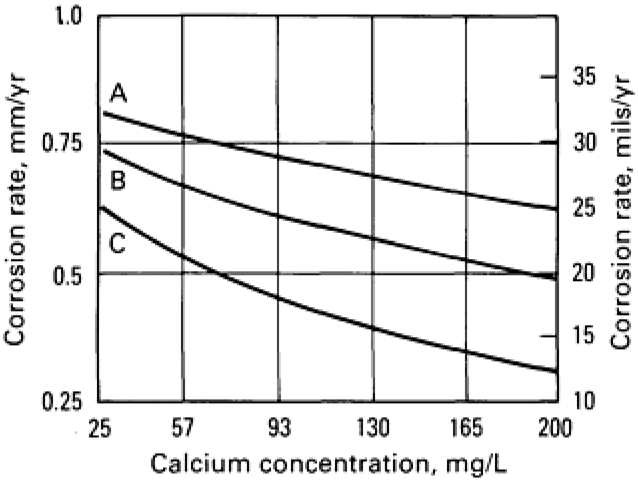

Fig. 3 Corrosion rate versus calcium concentration in three different waters. A, HCO_3^- = 38 mg/L, Cl^- = 78 mg/L, SO_4^{2-} = 78 mg/L; B, HCO_3^- = 100 mg/L, Cl^- = 224 mg/L, SO_4^{2-} = 224 mg/L; C, HCO_3^- = 266 mg/L, Cl^- = 644 mg/L, SO_4^{2-} = 644 mg/L

The HCO_3^- ion is the predominate alkaline species in natural waters within the 6.5 to 9 pH range. Alone, it is a mild inhibitive species. Its reaction with Ca^{2+} ions is quite obvious, producing bulk precipitation of $CaCO_3$ once saturation is reached. Localized corrosion cells normally develop under the deposits. Increasing the bicarbonate concentration beyond that required for $CaCO_3$ saturation can be aggressive to steel due to the formation of a nonprotective iron carbonate ($FeCO_3$) film.

Copper alloys are also attacked by high HCO_3^- concentrations. Greenish-blue nodules that consist of basic copper salts usually form at active pit sites.

Chloride and SO_4^{2-} ions are known to have a deleterious effect on steel. Much of the antagonistic nature of Cl^- ions is due to their ability to adsorb on the metal surface and interfere with the formation of passive films. Pitting is the most common form of attack. The small exposed area where Cl^- ions have adsorbed are anodic to the large cathodic passive oxide surface. High current densities are generated at the Cl^- site. Once corrosion begins, hydrolysis of the metal ions from the anodic reaction causes a decrease in pH, which discourages film repair and accelerates attack. The level of Cl^- ions needed to initiate attack can be as low as a few milligrams per liter for some stainless steels in high-purity waters. The more susceptible an alloy is to general attack, the less effect there is from Cl^- ions. Carbon steel will corrode in chloride-containing waters primarily from uniform corrosion rather than localized attack.

Copper alloys are subject to degradation by Cl^- ions that modify the Cu_2O structure. The small, negatively charged Cl^- ion can migrate through the Cu_2O film to areas of high positive charge density (Cu_2O is a *p*-type semiconductor). Substitution of a monovalent charged chloride species for a divalent charged oxygen species can occur. To maintain electroneutrality, cuprous ions (Cu^+) are ejected (dissolved) into the aqueous phase. The loss of Cu^+ ions is, by definition, corrosion.

Sulfate ions are somewhat more elusive in their effect on corrosion. These ions do not appear to have the film-piercing properties of Cl^- ions. In fact, there is evidence that SO_4^{2-} ions may inhibit corrosion of some stainless steels (Ref 5).

Other ions found in cooling waters that have an effect on corrosion are manganese, sulfide (S^{2-}), phosphate (PO_4^{3-}), and nitrate (NO_3^-). Sodium (Na^+) and potassium (K^+) ions are considered neutral species and have no discernible effect. Manganese is found in both well and surface waters and can cathodically deposit on stainless steels and copper-base alloys. Attack usually occurs under these deposits. Sulfide ions from Putrefaction of organic matter, sulfate-reducing bacteria, or pollution will attack copper-base alloy and steels.

The Cu_2O film becomes nonprotective through a substitution of S^{2-} ions for the oxygen ion, accelerating corrosion. Attack occurs on steel through the formation of ferrous sulfide (FeS). Deep pits will develop in both alloys. Phosphate ions can act as an accelerator or as an inhibitor for steel corrosion, depending on its concentration. At low concentrations. PO_4^{3-} ions will cause pits to develop on the surface of the metal. Higher concentrations of 15 to 20 mg/L reverse this role, and the ion contributes to the stabilization of γ-Fe_2O_3. Nitrate ions can be reduced on steel surfaces, producing nitrites, NH_3, and OH^- ions. Nitrite ions (NO_2^-) are inhibitory to copper and steel alloys, but NH_3 will attack copper.

Scale Deposition

Water-formed deposits, commonly referred to as scale, can be defined as a crystalline growth of an adherent layer (barrier) of insoluble salt or oxide on a heat exchanger surface. The rate of formation is a complicated function of many variables, including temperature, concentration of scale-forming species, pH, water quality, and hydrodynamic conditions. The normal solubilities of scales increase with temperature, but few, for example, $CaCO_3$ and $CaSO_4$, have the reverse trend. Unfortunately, these scales are commonly found in cooling water systems.

Calcium carbonate is perhaps the most commonly found scale in cooling water systems. Calcium and bicarbonate alkalinity are both needed to form this extremely tenacious scale (alkalinity is the concentration of HCO_3^-, CO_3^{2-}, and OH^- ions present in the water). An increase in heat and/or pH will cause the HCO_3^-, ions to decompose to CO_2 and $CaCO_3$:

$$Ca(HCO_3)_2 \rightarrow CaCO_3 \downarrow + CO_2 \uparrow + H_2O$$

The greatest concentration of $CaCO_3$ will occur at the hottest areas along the heat transfer surfaces.

Many methods have been proposed to predict the formation of $CaCO_3$. However, they are all based on the thermodynamic equilibria of H_2CO_3 and are alkalinity corrected for temperature and dissolved solids (ionic strength). The more commonly used equations or indices are the Ryznar Stability Index (RSI) (Ref 6) and the Langelier Saturation Index (LSI) (Ref 7). The LSI is defined as:

$$LSI = pH - pH_s \qquad \textbf{(Eq 1)}$$

where pH is the actual measured value in the water, and pH_s is the pH of saturation calculated from the expression:

$$pH_s = (pK'_2 - pK'_{sp}) + pCa + pAlk \qquad \textbf{(Eq 2)}$$

where K'_2 is the apparent second dissociation constant of H_2CO_3, K'_{sp} is the apparent solubility product of $CaCO_3$, pCa is $-\log_{10}(Ca^{2+})$ in moles per liter, and pAlk = $-\log_{10}$ [total alkalinity] in equivalents per liter. The complexity of Eq 1 and 2 has been reduced to nomographs (Ref 8). The RSI is an empirical expression:

$$RSI = 2pH_s - pH \qquad \textbf{(Eq 3)}$$

where pH and pH_s have the same meaning as previously described. Interpretations of LSI and RSI values are listed in Table 2.

Table 2 Prediction of water characteristics by LSI and RSI

Index		Tendency of water
LSI	**RSI**	
2.0	<4	**Heavy scale forming, nonaggressive**
0.5	5-6	**Slightly scale forming and mildly aggressive**
0	6-6.5	**Balanced or at $CaCO_3$ saturation**
-0.5	6.5-7	**Nonscaling and slightly aggressive**
-2.0	**>8**	**Undersaturated, very aggressive**

These indices indicate only the tendency for $CaCO_3$ to deposit, not the rate or capacity for deposition. Also, these values do not take into account the tendency for $CaCO_3$ to supersaturate, its rate of formation, or whether the water contains any inhibitor to prevent deposition.

Calcium carbonate formation can be controlled by adding acids or specific chemicals tailored to inhibit its formation or modify the crystal lattice. Sulfuric acid (H_2SO_4), which is inexpensive, is most often used. Other acids, such as HCl, citric, or sulfamic acid (NH_2SO_3H), are also suitable. Acid addition produces salts that are more soluble than $CaCO_3$. These salts can reach saturation and must be controlled to prevent precipitation on heat transfer surfaces:

$$Ca(HCO_3)_2 + H_2SO_4 \rightarrow CaSO_4 \downarrow + 2CO_2 + 2H_2$$

Calcium carbonate precipitation can also be inhibited by chemical treatment. A cost-effective group of materials is the polymeric inorganic phosphates. This class of compounds includes the salts of pyrophosphate, tripolyphosphate, and hexametaphosphate. Approximately 1 mg/L of active material can stabilize 44 times the $CaCO_3$ equilibrium saturation. This concentration is well below the stoichiometric values required for complexing calcium hardness and is termed threshold treatment. At these concentrations, the polyphosphates inhibit the crystallization of $CaCO_3$ crystallites by suppressing both nucleation and crystal growth. The polyphosphates are partly adsorbed on the surface of the growing crystals and partly included in incipient crystal nuclei. A disadvantage of the polyphosphates is their ability to hydrolyze or revert to PO_4^{3-} ions, which have no scale-inhibiting properties (see the section "Calcium Phosphate" in this article).

Other phosphate compounds found to be effective belong to the class known as phosphonates. Two of the more common compounds are AMP (nitrilo tris (methylene phosphonic acid)) and HEDP (1-hydroxyethylidine-1, 1-diphosphonic acid). Threshold treatment inhibitor concentrations range from 0.25 to 0.5 mg/L, although higher concentrations are often used. The compounds AMP and HEDP have greater hydrolytic stability than the polyphosphates. It should be noted that AMP will degrade in the presence of Cl^- to PO_4^{3-} ions. The addition of zinc ions (Zn^{2+}) significantly stabilizes the AMP molecule while still maintaining its control over $CaCO_3$ scale. Although HEDP is less affected by Cl^- ion than AMP, at least 50% of the HEDP is degraded to PO_4^{3-} at residual chlorine concentrations of 0.2 to 0.5 mg/L (Ref 9).

Organic polymers have also been found to be effective $CaCO_3$ inhibitors. These include polycarboxylates, such as polyacrylates, polymethacrylates, polymaleates, and their copolymers. Treatment levels are higher than the phosphorus-bearing materials, usually in the range of 2 to 4 mg/L. The molecular weights of these polymers should range from 1000 to 10,000 amu for effective scale control.

The polymers adsorb onto the $CaCO_3$ crystal structure, limiting the growth of $CaCO_3$ and ultimately limiting scale formation. These polymers are more frequently considered dispersants. They retard $CaCO_3$ scale by maintaining small particles of distorted crystalline material in suspension.

Bifunctional compounds are a recent development for $CaCO_3$ control. Phosphinocarboxylic acids contain both organic phosphorus and carboxylic acid groups (Ref 10). Simple molecules combining both the phosphono and carboxylic groups have also emerged and are very effective $CaCO_3$ inhibitors (Ref 9). However, these bifunctional compounds may be more expensive than the traditional low molecular weight polymers, polyphosphates, or phosphonates.

Calcium sulfate can exist in various forms in cooling water systems, the most common form being gypsum ($CaSO_4 \cdot 2H_2O$). The hemihydrate and anhydrous forms are much less common. Their solubilities as a function of temperature are shown in Fig. 4. Because $CaSO_4 \cdot 2H_2O$ is more soluble than $CaCO_3$ by at least a factor of 50, it will precipitate only after the latter scale has been formed, within the normal pH range of 7 to 9. This phenomenon provides the basis for H_2SO_4 addition to control $CaCO_3$ in recirculating cooling water systems. The normal upper limit for calcium and sulfate concentration in the absence of an inhibitor is expressed by:

$$[Ca^{2+}] \cdot [SO_4^{2-}] = 500,000 \qquad \textbf{(Eq 4)}$$

where the bracketed values are the ionic concentrations expressed in milligrams per liter.

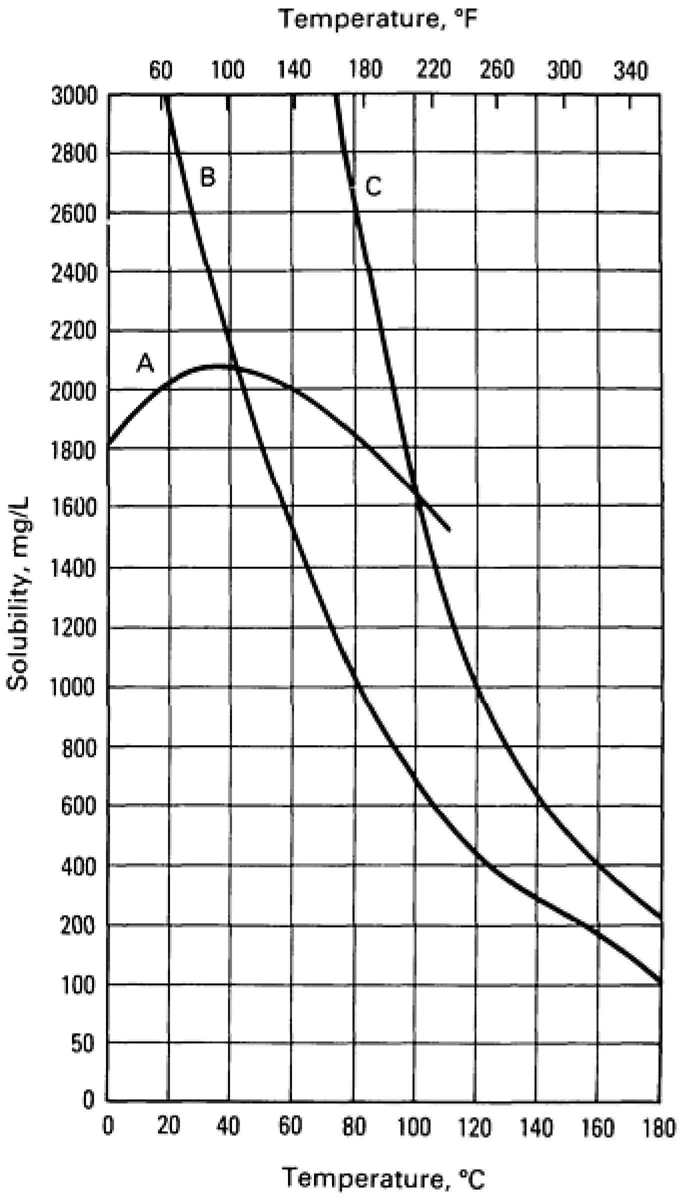

Fig. 4 Solubility of three forms of $CaSO_4$ versus water temperature. A, $CaSO_4 \cdot 2H_2O$; B, anhydrous $CaSO_4$; C, hemihydrate ($CaSO_4 \cdot \frac{1}{2} H_2O$). Source: Ref 11

Calcium sulfate scale can be most effectively controlled with polyacrylates (Ref 12), their copolymers, and phosphinocarboxylates (Ref 10). As with $CaCO_3$, excellent calcium scale control is achieved with polymers having low molecular weights in the range of 1000 to 10,000 amu. Concentrations of 1 to 2 mg/L can increase $CaSO_4$ solubility by a factor of 20. This is similar to maintaining the $[Ca] \cdot [SO_4] > 10^7$ compared to 500,000 in the absence of chemical treatment. These polycarboxylates are stable over a wide range of pH and temperature. The basic mode of inhibition is through a combination of threshold crystal distortion and dispersancy mechanism that prevents or delays precipitation.

Another chemical that controls $CaSO_4$ precipitation efficiently is the phosphonate AMP. In fact, the family of aminophosphonates has been found to be extremely effective. The level of AMP needed is approximately 0.5 mg/L.

Calcium phosphate ($Ca_3(PO_4)_2$) scale has become more common in recirculating cooling water systems. Increasing pH, calcium concentration, and phosphate addition from chemical treatment have provided the potential for this deposit to form on heat transfer surfaces. Other water sources have also contributed to the increased level of phosphate. Makeup

waters obtained from agricultural runoff and partly treated sewage can have high levels of PO_4^{3-} ions (at least 10 mg/L).

The solubility of $Ca_3(PO_4)_2$ decreases with increasing pH. It is essentially unaffected over normal temperature ranges (about 25 to 75 °C, or 75 to 165 °F). These deposits are usually amorphous and eventually transform to a more crystalline hydroxyapatite--$Ca_5(PO_4)OH$. Because of the low solubility of $Ca_3(PO_4)_2$ (about 10^{-30}), deposits can easily form in waters containing 5 mg/L of PO_4^{3-} ions and 300 mg/L of Ca^{2+} ions at pH 7 to 7.5. The scale-forming tendency of $Ca_3(PO_4)_2$ is a complex function of pH, calcium hardness, PO_4^{3-} concentration, ionic strength, and temperature. Rule-of-thumb relationships between these variables do not exist. Also, in the 0absence of any phosphate deposit, the PO_4^{3-} ions can contribute to the corrosion inhibition of carbon steel.

Calcium phosphate is an extremely difficult scale to inhibit. Intensive research has brought forth new chemistry to control this tenacious deposit. These new inhibitors include acrylic acid-hydroxypropylacrylate copolymer (Ref 13), styrene sulfonic acid-maleic acid copolymer, acrylic acid-sulfonic acid copolymer (Ref 14), and phosphino/acrylic acid-organo-sulfonic acid copolymer. They function by markedly modifying the morphology and size of $Ca_3(PO_4)_2$ deposit while also acting as a dispersant to prevent adherence of $Ca_3(PO_4)_2$ to heat transfer surfaces. Normally concentrations of these copolymers are 10 to 15 mg/L under conditions of moderate calcium hardness (about 500 mg/L as $CaCO_3$) and 10 mg/L of PO_4^{3-} ions at pH 8 to 8.5. Increasing any of these parameters will require an increase in polymer concentration.

Silicate Scales. Calcium silicate ($CaSiO_3$) and magnesium silicate ($MgSiO_3$) scales tend to develop under more alkaline cooling water conditions, in which the pH is approximately 8.5 or greater. These scales are very tenacious, dense, and difficult to remove from heat transfer surfaces. Although the solubility of silica (SiO_2) increases with pH, the solubility of the alkaline silicate decreases with increasing pH.

An upper limit for SiO_2 concentration is 150 mg/L in the recirculating water, although other factors affect this value. Magnesium silicate can precipitate on heat transfer surfaces with magnesium concentrations as low as 50 mg/L and 150 mg/L SiO_2. A rule-of-thumb pseudosolubility product of $[Mg] \cdot [SiO_2] \leq 8400$ has been developed (bracketed values are in milligrams per liter). The addition of chemical treatment as a preventive measure is essentially nonexistent. The most effective method of control is to keep the SiO_2 concentration in the recirculating cooling water below the 150-mg/L limit.

Fouling Deposits. Water-borne deposits, commonly known as foulants, are loose, porous, insoluble materials suspended in water. They include such diverse substances as particulate matter scrubbed from the air; migrated corrosion products; silt, clays, and sand suspended in make-up water; organic contaminants (oils); biological matter; floc carryover from clarifiers; and such extraneous materials as leaves, twigs, and wood fibers from cooling towers. Fouling interferes with the flow of cooling water as compared to the reduction in heat transfer caused by barrier scales. However, fouling can reduce heat transfer efficiency because of plugging of the exchanger. Thus, adequate water flow through the tubes is essential.

High flow rates (1.5 to 2.5 m/s, or 5 to 8 ft/s) can sweep away ordinary deposits, but low flow rates (less than 0.6 m/s, or 2 ft/s) cause the suspended foulants to drop out and deposit. Regions of low velocity include shell-side coolers, compressor jackets, water boxes, and cooling tower basins.

Mechanical methods can be used to reduce fouling. In once-through cooling systems, coarse filters (bar screens, trash tracks, traveling screens) are used to remove large debris. Fine filtration is not practical. This is not the case with open recirculating systems. When the makeup water contains an appreciable concentration of suspended matter, it is advantageous to use side-stream filtration. In general, passing a few percent of the recirculating water through the side-stream filter will reduce the suspended solids loading 80 to 90%.

Another effective mechanical method used to control foulants is to pass scrapers, brushes, or balls through the heat exchanger tubes, wiping them free of deposits. The technique is most frequently used in power utility surface condensers or other critical exchangers.

Chemical treatment has also been found to be an effective control method. Synthetic polymers are the chemicals more commonly used to disperse foulants. Polyacrylates, polymaleates, partially hydrolyzed polyacrylamides, and their co-polymers constitute the majority of dispersant chemicals. The most important aspect of these materials is their molecular

weights. An effective dispersant has a molecular weight of 1000 to 10,000 amu--the same range as far scale control. Concentrations of a few milligrams per liter are required in open recirculating systems, but lower levels are normally used in once-through systems.

Natural dispersants, such as tannins, lignin sulfonate, and carboxymethyl cellulose, are occasionally used, but they are not as effective as the synthetic polymers. The natural materials require higher concentrations to produce good dispersion of foulants, may not be cost effective, and may contribute to foaming. The synthetic polymers are not as easily degraded by biological organisms as the natural polymers are.

Increasing the molecular weight of the synthetic polymers into the million range changes the characteristics of the treatment from dispersion to flocculation. These high molecular weight polymers consist of polyacrylamides, polyamines, or polyacrylates and their various copolymers. Fouling is controlled by agglomeration of the suspended solids into nonadherent larger particles. To settle deposits, the polymers are usually added to concentrations of 0.2 to 0.5 mg/L to clarifiers or thickeners. Similar concentrations are used in open recirculating systems. However, the deposit will accumulate in low-flow or stagnant areas in the recirculating systems. Normally, heat transfer will not be seriously reduced, because of the low bulk density of these deposits. Buildup of sludge in the cooling tower basins will necessitate periodic cleaning.

Biological Fouling. The presence and growth of living matter is commonly referred to as biofouling. Biofouling can interfere with the flow of water through heat exchangers and other conduits. This inhibits heat transfer and contributes to corrosion and general deterioration of the entire cooling system.

Recirculating cooling water systems are ideal incubators for promoting the growth and proliferation of microorganisms. Water saturated with oxygen, exposed to sunlight, maintained at a temperature of 30 to 60 °C (85 to 140 °F), and having a pH of 6 to 9 ensure abundant nutrients and appropriate environment for life-sustaining growth. Although biofouling interferes with heat transfer, it does so in a manner quite different from that of inert deposits.

The buildup of a biofilm is initiated with the adsorption of organic material on the metal surface from the bulk water. Transport of microbial particles to the surface is due to the turbulent flow. The microorganisms can attach to the surface, with growth occurring through the assimilation of nutrients. Eventually, some of the biofilm is sheared away and reentrained in the flowing water to repeat the process of biofilm development. These steps are shown schematically in Fig. 5.

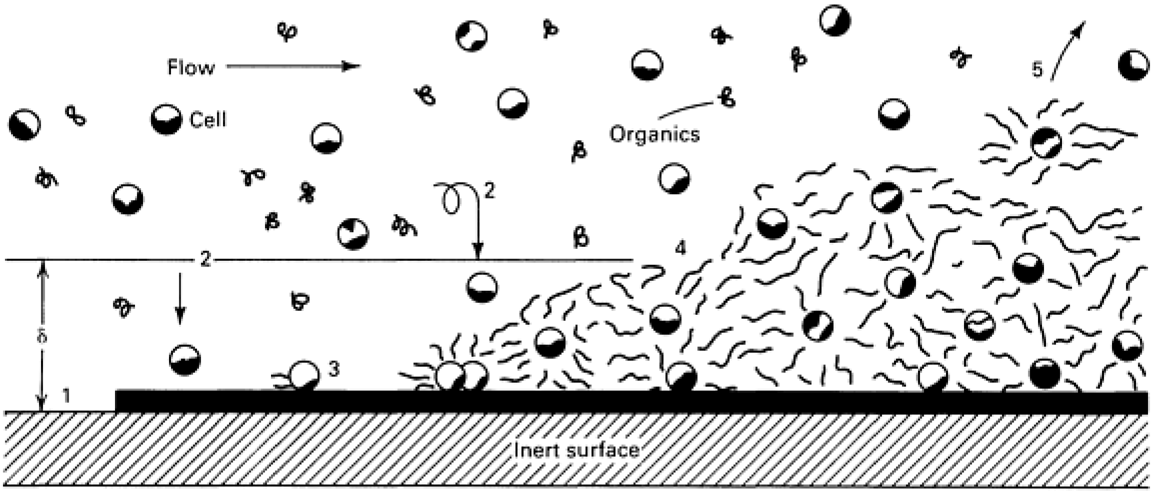

Fig. 5 Steps in biofilm formation. Formation is initiated when small organic molecules become attached to an inert surface (1) and microbiological cells are adsorbed onto the resulting layer (2). The cells send out hairlike exopolymers to feed on organic matter (3), adding to the coating (4). Flowing water detaches some of the formation (5), producing an equilibrium layer δ. Source: Ref 15

The biofilm can cause losses in heat transfer because of its insulating properties. Kinetic energy is absorbed from the flowing water through the ripple surface. Increased pumping energy is required to overcome the frictional resistance of the biofilm. Even though the film is 95 to 98% H_2O, the pressure decrease produced by a 500-μm thick film is greater than would be expected.

Three major classes of microorganisms are associated with recirculated cooling water systems: algae, fungi, and bacteria. Algae can range from very simple single-cell (unicellular) plants to multicellular species. The latter include diverse forms and shapes, including slimy masses composed of several cells or long strands (filaments) of algae. All algae contain colored pigments, the most important of which is chlorophyll. Algae usually flourish on wetted surfaces exposed to oxygen and sunlight, such as cooling exposed lumber, mist eliminators, screens, and distribution trays.

Their impact on metal corrosion can be severe. The large slime mass contributes to crevice corrosion and pitting. Massive growth can inhibit proper water distribution by plugging screens, restricting flow, and interfering with pump suction.

Fungi are similar to algae, but not contain chlorophyll. The major forms of interest are yeast and molds. They require moisture and air but not sunlight and exist on nutrients found in water or substances to which they are attached, for example, bacteria and algae. Mold fungi are filamentous in forms, but most yeast are unicellular. Fungi consume wood components, causing serious surface deterioration and internal decay (wood rot).

Bacteria are unicellular microscopic plantlike organisms that are similar to algae but lack chlorophyll. They exist in three basic forms: rodshaped (bacillus), spherical (coccus), and spiral (spirillus). The nutrients required for growth must be in solution, which necessitates a certain amount of moisture for their environment. Some bacteria require other carbon forms in addition to CO_2 in order to produce carbohydrates for food. Therefore, water or wet environments high in organic content are suitable for the proliferation of bacteria slime. Heat exchangers are ideal incubators for this biomass, which can significantly reduce heat transfer efficiency and aggravate underdeposit corrosion attack.

The presence of oxygen is not required by all species of bacteria. Aerobic bacteria require free oxygen for growth, but anaerobic bacteria grow in the absence of oxygen.

Acidic waters produced by some forms of bacteria will directly attack metal surfaces. One species that is quite common is sulfate-reducing bacteria. These organisms are anaerobic and convert dissolved sulfur compounds, that is, SO_4^{2-}, to hydrogen sulfide (H_2S). Carbon steel, stainless steel, and copper-base alloys can be severely corroded by H_2S. *Desulfovibrio desulfuricans* is the most prevailing sulfate-reducing species. It exists mainly under deposits devoid of oxygen. The form of corrosive attack on carbon steel by this bacteria is quite distinctive; it is recognizable by the smooth disk-shaped concentric rings formed on the metal surface. Corrosion rates as high as 2.5 mm/yr (100 mils/yr) can occur under optimum growth conditions. The following general reactions occur:

$$10H^+ + SO_4^{2-} + 4Fe \rightarrow 4Fe^{2+} + H_2S + 4H_2O$$
$$H_2S + Fe^{2+} \rightarrow FeS + 2H^+$$

The formation of black iron sulfide deposits in conjunction with a rotten egg odor are also characteristic of attack by sulfate-reducing bacteria.

The aerobic sulfur bacteria *Thiobacillus* can oxidize sulfur, sulfides, or sulfates to H_2SO_4. Localized pH depression as low as 1 can occur, causing severe general thinning of steels where these organisms contact the metal. *Thiobacillus* and *Desulfovibrio* bacteria can both exist simultaneously in close proximity. The anaerobic sulfate-reducers can survive beneath the aerobic sulfur bacteria deposits.

Another organism common to cooling water systems is the nitrifying bacteria, which can oxidize NH_3 to nitrate. This is accompanied by a decrease in pH and occurs according to the reaction:

$$NH_3 + 2O_2 \rightarrow HNO_3 + H_2O$$

Rapid general thinning can occur with copper-base alloys and steels. Nitrite-base steel corrosion inhibitors can be rendered ineffective because of their oxidation to nitrate by this species of bacteria.

Several other groups of bacteria exist in cooling water environments. Iron-depositing bacteria can oxidize water-soluble Fe^{2+} ions to insoluble Fe_2O_3, which will subsequently deposit on the inside of piping, reduce flow, and aggravate crevice corrosion. Slime-forming bacteria form dense, sticky biomasses that impede water flow and contribute to fouling by sustaining the growth of other organisms.

The most practical and efficient method of controlling microbiological activity in cooling waters is through the use of biocides (Ref 16). These chemicals have the ability to kill the organisms or inhibit their growth and reproductive cycles. Biocides perform their function in various ways. Some biocides alter the permeability of the microbe cell wall, thus interfering with their vital life processes. Others damage the cell by interfering with the normal flow of nutrients and discharge of waste (Table 3).

Table 3 Microbiocides used in cooling water systems

Microbiocide	**Effectiveness**[a]			Comments
	Bacteria	**Fungi**	**Algae**	
Chlorine	E	S	E	**Oxidizing; reacts with -NH_2 groups: effective at neutral pH; loses effectiveness at high pH. Use concentration: 0.1-0.2 mg/L continuous free residual; 0.5-1.0 mg/L intermittent free residual**
Chlorine dioxide	E	G	G	**Oxidizing; pH insensitive; can be used in presence of -NH_2 groups. Use concentration: 0.1-1 mg/L intermittent free residual**
Bromine	E	S	E	**Oxidizing; substitute for Cl_2 and ClO_2; effective over broad pH range. Use concentration: 0.05-0.1 mg/L continuous free residual; 0.2 to 0.4 mg/L intermittent free residual**
Organo-bromide (DBNPA)	E	NA	S	**Nonoxidizing; pH range 6-8.5. Use concentration: 0.5-24 mg/L intermittent feed**
Methylene bisthiocyanate	E	S	S	**Nonoxidizing; hydrolyzes above pH 8. Use concentration: 1.5-8 mg/L intermittent feed**
Isothiazolinone	E	G	E	**Nonoxidizing; pH insensitive; deactivated by HS^- and - NH_2 groups. Use concentration: 0.9-13 mg/L intermittent feed**
Quarternary ammonium salts	E	G	E	**Nonoxidizing; tendency to foam; surface active; ineffective in highly oil- or organic-fouled systems. Use concentration: 8-35 mg/L intermittent feed**
Organo-tin/quarternary ammonium salts	E	G	E	**Nonoxidizing; tendency to foam; functions best in alkaline pH. Use concentration; 7-50 mg/L**
Glutaraldehyde	**E**	**E**	**E**	**Nonoxidizing; deactivated by - NH_2 groups; effective over broad pH range. Use concentration: 10-75 mg/L intermittent feed**

(a) E, excellent; G, good; S, slight; NA, not applicable

Biocides can be either oxidizing or nonoxidizing toxicants. Chlorine is the most prevalent industrial oxidizing biocide. It rapidly hydrolyzes in water to form HClO and HCl:

$$Cl_2 + H_2O \rightarrow HClO + HCl$$

The HClO is the active species and dissociates as a function of pH:

$$HClO \rightarrow H^+ + ClO^-$$

At pH 7.5, equal concentrations of HClO and hypochlorous ions (ClO^-) exist. Above this pH, ClO^- predominates, with essentially total ionization at pH 9.5. Therefore, chlorine becomes less effective in the more alkaline environments. Generally, the pH range of 6.5 to 7.5 is considered practical when chlorine is used as a biocide. Lower pHs will accelerate corrosion. Continuous treatment levels of 0.1 to 0.2 mg/L are common, but intermittent treatment requires levels of 0.5 to 1.0 mg/L. Chlorine is both an excellent algicide and bactericide. However, *Desulfovibrio* can develop a strong resistance, requiring an increase in chlorine concentration or a change to an alternate biocide. Other sources of chlorine are salts of HClO, such as sodium hypochlorite (NaClO) and calcium hypochlorite ($CA(ClO)_2$). Both of these salts function in much the same way as chlorine gas.

Another oxidizing biocide is chlorine dioxide (ClO_2). This gas does not form HClO in water, but exists solely as ClO_2 in solution. It is used more extensively in the pulp and paper industry for bleaching than as a biocide. However, ClO_2 is extensively used in cooling waters contaminated with NH_3 or phenols due to the low demand for reaction with these species.

Brominated compounds that form hypobromous acid (HBrO) are very effective over a broader pH range than HClO. At pH 7.5, 50% of the HClO is present, but over 90% of the HBrO is present. Increasing the pH to 8.7 reduces the HClO concentration to 10%, but 50% of the HBrO remains.

Nonoxidizing biocides can be more effective than oxidizing biocides because of their overall control of algae, fungi, and bacteria. They also have greater persistence, with many of them being pH independent.

An organo-bromine broad spectrum nonoxidizing toxicant is 2,2-dibromo-3-nitrilopropionamide (DBNPA). This molecule is an extremely potent bactericide and is only slightly effective as an algicide. It has little fungicide activity. The toxicity of DBNPA decreases with an increase in alkaline pH.

Organo-sulfur compounds include a wide variety of different biocides of which methylene bisthiocyanate (MBT) is the most common. Their mode of activity is through the inhibition of cell growth by preventing the transfer of energy or life-sustaining chemical reactions from occurring within the cell. Methylene bisthiocyanate is effective in controlling algae, fungi, and bacteria, most notably *Desulfovibrio.* A shortcoming of methylene bisthiocyanate is its pH sensitivity and rapid hydrolysis in the alkaline pH range. Therefore, methylene bisthiocyanate is not recommended for use in cooling water systems having and pH above 8.

Under broader alkaline conditions, sulfur-base biocides, such as bistrichloromethylsulfone and tetrahydro-3,5-dimethyl-2H-1,3,5-thiadiazine-2-thione, are more appropriate. The former is active in the pH range of 6.5 to 8, and the latter in more alkaline cooling water systems.

Isothiazolinone is a relatively new sulfur-containing biocide. It is very effective in controlling algae and bacteria. Isothiazolinone can be used over a broad pH range with no decrease in activity.

Quaternary ammonium salts are generally most effective against algae and bacteria in alkaline pH range. The quaternary compounds cause cell death by reducing the permeability of the cell wall, preventing the typical intake of nutrients necessary to sustain life. Because of their surface-active nature, these compounds are easily rendered ineffective in systems heavily fouled with dirt, oil, and debris.

Organic tin compounds, such as bistributyl-tin oxide are very effective against algae and fungi. They function best in the alkaline pH range and provide synergistic biocidal activity when combined with quarternary ammonium salts.

Glutaraldehyde (1,5-pentanedial) is an effective broad-spectrum biocide capable of controlling slime-forming and sulfate-reducing bacteria, fungi, and algae (Ref 17). It functions over broad pH and temperature ranges and is compatible with chlorine. Glutaraldehyde is deactivated is systems containing NH_3 and other primary amines, that is $-NH_2$ groups.

Corrosion Control

Aqueous corrosion has been shown to consist of electrochemical processes (see the section "Corrosion Processes in Water Recirculating Systems" in this article). The detrimental effects of these processes in cooling water environments can be significantly reduced by various methods, such as designing systems with more corrosion-resistant materials, applying protective coatings (paints, epoxy), and using sacrificial anodes (cathodic protection) and chemical treatments.

For chemical treatment or corrosion inhibitor programs to be effective, they must protect all exposed metal from corrosive attack, must be effective at low concentration, must not cause deposits on the metal surface, must remain effective under broad range of pH, temperature, water quality, and heat flux, must prevent scale formation and disperse deposits, and must have minimal toxicological effect when discharged. Economics should also be considered when assessing the merits of a chemical treatment program. In once-through cooling systems, protection must be achieved with a few milligrams per liter, or the cost may be prohibitive. For these types of systems, use of more corrosion-resistant alloys is often a more economical approach to corrosion control. With respect to open recirculating cooling systems, chemical addition to the makeup water can be in the range of 10 to 50 mg/L (active). Cost is not as prohibitive, because of the recycling of the water system, which also includes the inhibitor. Closed recirculating cooling water systems require high active treatment levels (in the range of several thousand milligrams per liter). These systems have very small water losses.

Inhibitors can be broadly classified according to the rate process being controlled. Anodic inhibitors suppress anodic reactions; that is, the rate of metal ions being transferred into the aqueous environment is reduced. Cathodic inhibitors impede the cathodic reaction--for example, oxygen reduction reaction. Mixed inhibitors hinder both reactions.

Inorganic inhibitors usually affect the anodic process. Rapid suppression of general corrosion occurs. However, when these inhibitors are below a critical concentration, they can stimulate localized pitting attack and therefore must be used with caution.

Cathodic inhibitors reduce corrosion primarily by interfering with oxygen reduction reaction. This family of inhibitors decreases general corrosion and does not stimulate pitting attack. When the anodic and cathodic reactions are both affected by the chemical treatment, a mixed mode of inhibitor is in effect.

The performance of an inhibitor can be assessed by its effectiveness in reducing the corrosion rate. This is generally expressed as a rate of thinning or penetration in microns per year or mils per year.

The current approach to cooling water treatment is toward the more alkaline or high-pH conditions. This was not always the case. Historically, acid treatment was widely used to prevent scale deposition on heat transfer surfaces. The system pH was slightly acidic (pH 6.5 to 7.0), and corrosion was controlled by using highly effective anodic inhibitors, the most effective being chromates.

Anodic Inhibitors

Chromates are highly effective in protecting ferrous and many nonferrous alloys against corrosion. The protective film is formed on ferrous metals through the oxidation of iron to form a mixed oxide (Cr_2O_3 + Fe_2O_3) (Ref 18).

There is critical chromate concentration that is necessary for protection, because this inhibitor is sensitive to aggressive ions, such as Cl^- and SO_4^{2-}. Below this minimum, severe pitting attack can occur even though uniform corrosion is low. Above the minimum chromate concentration, local attack is arrested, producing excellent overall protection. Normal control concentrations of chromate for proper steel protection require a high initial dosage of 500 to 1000 mg/L to meet the Cl^- and SO_4^{2-} demands, followed by a reduction in concentration to a maintenance level of 200 to 250 mg/L. There is no discernible change in corrosion protection within normal bulk water temperatures (38 to 65 °C, or 100 to 150 °F) and pH ranges (6 to 11).

When chromates are used at low concentrations of approximately 15 to 25 mg/L, their mode of inhibition is cathodic (Ref 19). Steel protection is provided in conjunction with the dissolved oxygen in the water to produce the protective oxide layer of γ-Fe_2O_3. The reduction product of chromate--Cr_2O_3--does not become part of the protective oxide. The pH range remains the same as for high concentration--pH 6 to 11. Low levels of chromate are insensitive to electrolyte concentration.

Nitrites. Sodium nitrite ($NaNO_2$) is an anodic inhibitor and requires a critical concentration for the protection of steel. Nitrites are extensively used as inhibitors in closed recirculating systems. The level of inhibitor depends on the aggressive species in solution. Sulfate ions interfere with nitrite protection to a greater extent than Cl^- ions. Treatment level should be at least the concentration of $NaNO_2$ required to produce a weight ratio of 1 with aggressive ion concentrations ($[NaNO_2]/[NaCl + Na_2SO_4] = 1$). This concentration is normally in the range of 500 to 750 mg/L at pH above 7.5. Nitrite may contribute to pitting of carbon steel if the concentration falls below this critical level.

Nitrites are easily oxidized to nitrates in open recirculating cooling water systems and therefore are not suitable. However, when formulated with borax, nitrites are excellent corrosion inhibitors for closed systems. The borax buffers the water to a pH above 8.5. Dosage levels for the borax-nitrite systems are 1500 to 2000 mg/L, with a nitrite concentration near 800 mg/L. It should be noted that NO_2^- ions are nutrients for some species of bacteria, which can oxidize the NO_2^- ions and render the treatment ineffective, producing slime deposits and a low pH. Biocides (isothiazolinone) are often used in conjunction with borax-nitrite programs for optimum protection.

Molybdates have been available for corrosion protection for over 50 years, but have never been widely used. Molybdates are classified as anodic inhibitors. In waters having moderate Cl^- concentration (200 mg/L), the level of sodium molybdate (Na_2MoO_4) needed for protection is at least 1000 mg/L. In dilute electrolytes, the concentration can be reduced to 150 mg/L. Normal treatment practices consist of combinations of molybdates with other inhibitors to produce synergistic treatments. This reduces the high level of molybdate ions (MoO_4^{2-}) needed when used alone. Combinations with zinc salts; phosphonates (AMP and HEDP); inorganic phosphates; nitrites; and carboxylates, such as long-chain acrylates and azoles (benzo- or tolyltriazoles), have been shown to be effective in controlling corrosion of multimetal systems (Ref 20).

Sodium molybdate is a nonoxidizing inhibitor and requires a suitable oxidizing agent to augment the inhibitor and to impart a protective film. In aerated systems, the most abundant oxidizer is oxygen. Any of the above combinations are applicable except nitrites (see the section "Nitrites" in this article). A wide range of ratios have been used in specific formulations. A typical treatment consists of MoO_4, HEDP, zinc, and benzotriazole in a 3:3:1:1 weight ratio (Ref 20).

The use of molybdates in closed systems requires an oxidizing salt, such as $NaNO_2$. The optimum composition for the Na_2MoO_4: $NaNO_2$ system consists of a 60:40 weight ratio of the two salts (Ref 20).

Molybdate treatments have minimal pH dependency and can be used over a pH range of 5.5 to 8.5. They are sensitive to electrolyte concentration and are adversely affected by aggressive ions, such as Cl^- and SO_4^{2-}, when used alone. Temperature dependency is minimal. Molybdate treatments are known to inhibit both pitting and differential aeration attack. The precipitation of calcium molybdate ($Ca(MoO_4)$) is a concern in waters with moderate-to-high calcium hardness.

The mechanism by which molybdates inhibit the corrosion of ferrous metals is uncertain and complex. Simplistically, when iron corrodes, MoO_4^{2-} ions, in conjunction with other anions, adsorb to form a nonprotective complex with Fe^{2+} ions. Because of dissolved oxygen or other oxidizers in the water, some of the Fe^{2+} ions are oxidized to the ferric (Fe^{3+}) state, and the ferrous-molybdate is transformed to ferric-molybdate, which is both insoluble and protective in neutral and alkaline waters.

Phosphates. Sodium phosphate (Na_3PO_4) is an anodic inhibitor and is effective in the presence of oxygen. Its protective properties toward steel are a function of pH. The monosubstituted phosphate (MH_2PO_4, where M is a metal) is the least protective, but the trisubstituted phosphate (M_3PO_4) is the most protective. Use of phosphate as a corrosion inhibitor should be relegated to more alkaline environments (pH > 8).

In open recirculating waters, phosphate treatment levels should be 15 to 20 mg/L. At lower concentrations of a few milligrams per liter, PO_4^{3-} ions will cause pitting attack. The oxygen content of the system is primarily responsible for the ability of the phosphate to inhibit steel (Ref 21). The dissolved oxygen produces a defective thin film of γ-Fe_2O_3. The PO_4^{3-} fill in the voids and accelerate film growth. These plugs prevent any further diffusion of Fe^{2+} ions from the metal surface. The primary reactant responsible for steel inhibition is oxygen, which forms the thin oxide film.

Inhibition by PO_4^{3-} ions is sensitive to electrolyte concentration; Cl^- ions can promote pitting attack. Because the protective oxide film contains voids and other inclusions, Cl^- ions are easily adsorbed to soluble complexes. Hydrolysis of these complexes produces acid domains, which leads to localized acidic attack. Film breakdown is a function of the aggressive ion concentration, but film repair will depend on PO_4^{3-} level and oxygen concentration.

Overall, inhibition by PO_4^{3-} ions is sensitive to water quality and pH. There is minimal temperature sensitivity. One word of caution regarding PO_4^{3-} ions as steel corrosion inhibitors: With waters of high calcium hardness, the potential for deposit formation increases with hardness, phosphate level, pH, and temperature. These deposits will stimulate crevice (underdeposit) corrosion. The need for an inhibitor to prevent calcium deposits becomes exceedingly more important as cooling waters increase in cycles of concentration and pH (see the section "Scale Deposition" in this article).

Cathodic Inhibitors

Cathodic inhibitors suppress the corrosion rate by reducing the effectiveness of the cathodic process. They do not cause intense local attack and are generally considered to be safe inhibitors. Cathodic inhibitors are not as effective as the anodic inhibitors.

Precipitating inhibitors fall under the domain of a cathodic inhibitor. They produce insoluble films on the cathode under conditions of locally high pH and isolate the cathode from the solution. Calcium bicarbonate ($Ca(HCO_3)_2$) will react with the alkaline medium at the cathode to form $CaCO_3$. The increase in alkalinity is due to the oxygen reduction process, generating OH^- ions:

$$Ca(HCO_3)_2 + OH^- \rightarrow CaCO_3 + HCO_3^- + H_2O$$

At the appropriate pH, $CaCO_3$ will precipitate to form a hard, smooth deposit that prevents oxygen from diffusing onto the metal surface. The tendency of a water to form a $CaCO_3$ deposit is given by the LSI (see the section "Scale Deposition" in this article).

Zinc ions are used to achieve a general reduction in corrosion by precipitating as zinc hydroxide ($Zn(OH)_2$) at the cathode due to locally elevated pH. Zinc is usually combined with chromates, phosphonates, or polyphosphates. The durability of $Zn(OH)_2$ is tenuous at best. Although not normally used alone in cooling systems, zinc is synergistic when combined with other inhibitors as part of a multicomponent treatment program.

Zinc causes rapid development of a protective film over the metal surface. Above pH 7.5, the solubility of zinc is rapidly reduced to a few tenths of 1 mg/L. Its solubility can be significantly enhanced when combined with phosphonates or with some of the polymers used for $Ca_3(PO_4)_2$ control.

Polyphosphates are widely used cathodic inhibitors. They have been in use for more than 40 years and are among the most economical of all inhibitor treatments. Sodium salts of the polyphosphates are normally used for corrosion control. They exist as linear polymers having the general structure shown in Fig. 6. The lower members of the series having x equal to or less than 2 are crystalline in nature, that is, x = 0, orthophosphate; x = 1, pyrophosphate; x = 2, tripolyphosphate. Higher members of the series are glassy and have no definitive structure.

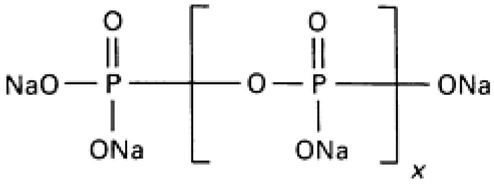

Fig. 6 General structure of sodium polyphosphate. *x* = 0, sodium phosphate; *x* = 1, sodium pyrophosphate; *x* = 2, sodium tripolyphosphate; *x* = 12 to 14, sodium polyphosphate

Varying the ratio of *n* Na_2O: *m* P_2O_5 will produce species of different chain lengths and physicochemical properties, even though the inhibitive action of these polyphosphates is not significantly altered. The pH of the environment directly affects the protective properties of the phosphates. Orthophosphate inhibits corrosion in a more alkaline environment than pyrophosphate does. The crystalline phosphates protect steel at higher pHs than the glassy phosphates, which function better near neutral pH. Normal concentrations in recirculating waters are 15 to 20 mg/L. The pH should be maintained in the range of 6.5 to 7.5 if steel and copper alloys are both part of the system metallurgy.

The polyphosphates are relatively insensitive to electrolyte concentrations, but do require an increase in dosage level with an increase in water corrosivity. They are effective inhibitors in controlling galvanic attack between two dissimilar metals (Ref 22), but do not prevent deposition of cathodic species on the more active metal, that is, copper deposition on steel.

Divalent metal ions, and Ca^{2+} in particular, are needed with the polyphosphates for effective inhibition of steel. The ratio of Ca^{2+} ion concentration to polyphosphate concentration should be at least 0.2, and preferably 0.5. The protective film develops through the formation of a positively charged colloidal complex that migrates to the cathode, forming an amorphous protective barrier. The cationic complex is accounted for by assuming that the calcium intercalates the polyphosphate chains. The colloidal particles are the result of numerous cationic complexes loosely knit one to another through the Ca^{2+} ions. The polyphosphates will revert to PO_4^{3-} ions, which is a potential scale in the presence of Ca^{2+} ions and alkaline pH (see the section "Scale Deposition" in this article).

The phosphonates differ from the polyphosphates by a direct bond formation between the phosphorus and carbon atoms, rather than an oxygen-phosphorus bond in the polyphosphate. This linkage creates greater hydrolytic stability, which reduces the problem of reversion common to the polyphosphates. Two classes of materials are extensively used: AMP and HEDP. Their structures are shown in Fig. 7 and 8. When used alone, both compounds are marginally good steel inhibitors, especially at high pH (pH 8.0). They protect ferrous metals through a mixed mode of inhibition. Incipient local attack occurs but is rapidly arrested. Normal treatment levels are in the range of 15 to 20 mg/L.

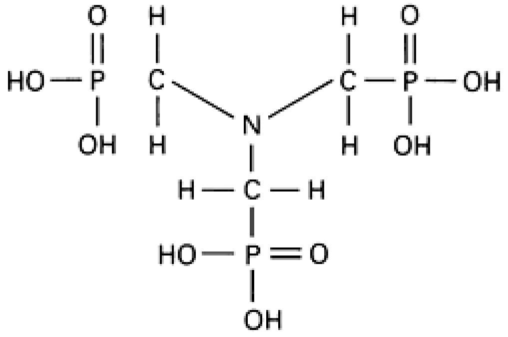

Fig. 7 Structure of AMP

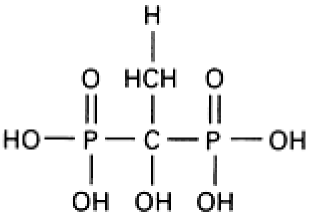

Fig. 8 Structure of HEDP

The hydrolytic stability of the phosphonates eliminates the problem of $Ca_3(PO_4)_2$ deposition in moderately to highly alkaline waters. However, AMP will degrade in the presence of chloride, producing PO_4^{3-} ions, and therefore should not be fed concurrently. The phosphonates form very stable complexes with a variety of metal ions and thus accelerate their corrosion. Increased attack occurs on nonferrous alloys, especially the copper-base alloys. The

addition of zinc significantly suppresses this antagonistic attack. Calcium phosphonate deposits will form in moderate-hardness high-alkaline waters, that is, 400 to 500 mg/L calcium hardness at pH 8 to 8.5. These deposits can be controlled with some of the new polymers available for $Ca_3(PO_4)_2$ control.

The phosphonates are sensitive to overall water quality. The protection afforded to carbon steel decreases with increasing aggressive ion concentration. Sensitivity to temperature is also exhibited. The major difference between AMP and HEDP is that the latter resists oxidation to a greater extent and can therefore be used in the presence of chlorine.

Multicomponent Systems. Cooling water formulations containing mixtures of inhibitors usually offer increased protection to ferrous metals. Such mixtures are synergistic in their action. Many combinations have been developed to achieve enhanced protection under a wide variety of plant operating conditions. Heavy-metal formulations containing zinc and/or chromate have been widely used in industry, where environmentally acceptable, particularly for severe corrosion problems. Nonheavy-metal treatment programs (no zinc or chromium) are receiving increased attention because of government discharge restraints. Complex blends of PO_4^{3-}, polyphosphate, phosphonate, copper corrosion inhibitor (see the section"Copper Inhibitors" in this article), and $Ca_3(PO_4)_2$ dispersants are probably the most widely used multicomponent inhibitors.

Zinc chromate ($ZnCrO_4$) is one of the most effective multicomponent treatments. It inhibits carbon steel corrosion by stifling the oxygen reduction reaction and is therefore classified as a cathodic inhibitor. Both components of this formulation--low-level zinc and low-level chromate--are also cathodic inhibitors. As little as 5% of either component will show significant synergistic action to ferrous metals, although at least 20% of each ingredient appears to be optimum (Ref 23). Both zinc and chromate exist as individual species in solution without the formation of a specific compound or intermediate.

The effect of zinc addition (5 to 10 mg/L as Zn^{2+} ion) to low-level chromate (up to 20 mg/L of CrO_4^{2-}) is synergistic and significantly reduces local attack. This formulation has broad applicability to multimetal systems. It is capable of protecting copper-base metals, aluminum alloys, and galvanized steel. The protection afforded by $ZnCrO_4$ to these multimetal systems is the reduction of general attack and the prevention of galvanic attack due to the reduction of noble metal ions on more active base metal.

Normal concentrations are approximately 10 mg/L of each constituent. The treatment program is insensitive to normal operating temperatures and overall water aggressiveness. Therefore, $ZnCrO_4$ has broad application to a multitude of water compositions and levels of aggressiveness in addition to a wide range of operating temperatures. The pH of the system can range from 5.5 to 7.5, with a pH of 7 being most acceptable. Even after major upsets due to pH excursions, the protective film is rapidly reestablished. However, there are some disadvantages to this treatment. Zinc chromate has no threshold-inhibitive effect on hardness scales. It lacks dispersion action to keep the metal surfaces free of deposits and debris, and pH excursion above 7.5 will cause precipitation of zinc to form insoluble basic zinc salts.

Zinc Chromate/Phosphonate. The disadvantages of $ZnCrO_4$ formulation are circumvented by the addition of such a phosphonate as AMP. Approximately 5 mg/L of the phosphonate supplements the $ZnCrO_4$ program to provide threshold treatment to prevent $CaCO_3$ and $CaSO_4$ scales. It can extend the pH range up to 9 because of the increased stability the phosphonate gives Zn^{2+} ions. The phosphonate adds detergent power to the system, flushes away suspended solids, and helps keep the metal surface clean.

Zinc chromate is not a nutrient for biological growth; this simplifies biological control. The Zn^{2+} ions, which are stabilized at high pH, also improve the resistances to phosphonate degradation. All of the advantages of $ZnCrO_4$ are maintained: rapid film formation, insensitivity to electrolyte concentration, and insensitivity to temperature.

Zinc Polyphosphate. The addition of zinc to the polyphosphates does not appreciably change the general nature of the polyphosphates. This system retains its insensitivity to electrolyte concentration, its threshold inhibition of $CaCO_3$ and $CaSO_4$, its ability to protect ferrous and nonferrous metals, and its detergent properties. Zinc polyphosphate inhibitors also enable multivalent metal ions to form positively charged colloidal complexes.

Zinc increases the rate at which the protective film is formed on the metal surfaces (Ref 24). This rapid protective film formation improves the general corrosion protection to the system. It is also synergistic in combination with polyphosphates. The amount of treatment needed using a zinc/polyphosphate inhibitor combination is less than that required for the polyphosphates alone.

The mode of inhibition is cathodic, similar to the polyphosphates in calcium-containing waters. The zinc accelerates film formation, restraining attack until a thin, tenacious, durable film is developed. The deposition of zinc phosphate ($Zn_3(PO_4)_2$) does not seem to be involved in the inhibition process.

Approximately 10 to 20% Zn is usually incorporated into the polyphosphate for synergism. Beyond this level, little improvement is observed. Maintenance concentrations are usually 10 mg/L as polyphosphate. Good practice requires a dosage of two to three times the maintenance level as a pretreatment to the system for a short period of time, that is, less than 1 week. A pH range of 6.8 to 7.2 is required for good control. This limitation in pH is necessary to prevent excessive attack on copper-base alloys (the lower the pH, the greater the attack on copper). Sensitivity to bulk water temperatures is minimal.

Zinc Phosphonates. The combination of zinc with phosphonates provides significantly improved protection compared to phosphonates alone. The addition of zinc makes this formulation synergistic in its protection to carbon steel.

Good corrosion control is attained by using 20 to 80% Zn, with 30 to 60% being optimum (Ref 25). Overall treatment levels are 8 to 10 mg/L phosphonate with 2 to 3 mg/L Zn^{2+} ions. The need for zinc becomes paramount in the presence of copper-base alloys. When used alone, the phosphonates are aggressive to copper and form a strong copper-phosphonate complex. Zinc negates this antagonistic effect by forming a stronger and more stable complex, significantly reducing attack on the alloys. The effectiveness of the zinc-phosphonate combination is due to increased cathodic protection. The zinc effectively counter-acts the anodic character of the phosphonates through the formation of a phosphonate-zinc complex, which is cathodic compared to the phosphonates alone.

Due to this complex, broad pH application becomes possible. The zinc phosphonate treatment can be used over a pH range of 6.5 to 9. Zinc is held in solution at these more alkaline pH levels, and protection actually improves with an increase in pH.

Little sensitivity is shown with increased salt or electrolyte concentration, and temperature effects are minimal. Thus, the zinc-phosphonate systems can be used over a wide range of water quality, at high bulk water temperatures (70 to 75 °C, or 160 to 170 °F), and with pH levels up to 9.0.

Degradation of phosphonates to PO_4^{3-} ions by chlorine is significantly reduced with a phosphonate/zinc system, and the latter can be used in chlorine environments because of diminished chlorine demand. The zinc stabilizes the complex, preventing the deterioration of the carbon-phosphorus bond in the oxidizing environment.

Nonheavy-Metal Systems. Many combinations of building blocks are currently being used in nonheavy-metal formulations. Some of the systems in use include combinations of the phosphonates, AMP/HEDP; polyphosphate/phosphonate mixtures, polyphosphate/HEDP; polyphosphate or phosphonate/orthophosphate; and polyphosphate or HEDP/PO_4^{3-}. These systems are synergistic in protecting carbon steel. They combine the many advantages of the individual components, including:

- Complex formation with calcium and numerous polyvalent metal cations required to form the protective film over the metal surface. The polyphosphates still form the colloidal species for cathodic protection, and the phosphonate serves as a cathodic polarizer
- Threshold inhibition of slightly soluble inorganic salts, such as $CaCO_3$ and $CaSO_4$
- Detergent and dispersive action on surface deposits

Most nonheavy-metal treatments for carbon steel function best in more alkaline or elevated-pH systems. Waters are less corrosive but more prone to form scale or deposit. Therefore, good scale control is absolutely necessary. These treatments are generally not as effective as heavy-metal formulations. However, because of the less corrosive nature of the recirculating cooling system, good overall protection can be achieved. More care and attention are required to operate these nonheavy-metal treatments because they are less tolerant of system upsets and function under more contained ranges of water corrosivity, pH, and temperature.

The AMP/HEDP nonheavy-metal inhibitor pair is classified as a cathodic inhibitor. A critical AMP/HEDP ratio of 1.5:1 is needed for optimum carbon steel protection (Ref 26). Performance improves with pH and should be used in systems

having a pH of at least 7.5. The combined phosphonate program is not as sensitive to temperature as the individual components, nor is it adversely affected by high levels of Cl^- and SO_4^{2-} ions.

Normal treatment levels of at least 15 mg/L total phosphonate can be used to achieve good protection (<75 μm/yr, or 3 mils/yr). Adequate pretreatment of at least two to three times normal concentration for 1 week is required before reducing the concentration to a maintenance level. With good pH control, normal treatment levels can be reduced and still achieve the desired corrosion protection. Concern over attack on copper-base alloys still exists such that the addition of a specific copper inhibitor is highly recommended.

Polyphosphate/HEDP. The second nonheavy-metal system--polyphosphate/HEDP--is also cathodic in nature while being synergistic in protecting carbon steel. Approximately 40 to 80% by weight of the polyphosphate is needed for good protection of carbon steel. Corrosion control of approximately 50 μm/yr (2 mils/yr) can be achieved with 15 mg/L total phosphate content. The sensitivity of polyphosphate/HEDP to pH is minimal over the range of pH 6 to 8. Temperature sensitivity is minor. Good corrosion control is achieved at bulk water temperatures exceeding 60 °C (140 °F). As with the AMP/HEDP system, sensitivity to water aggressiveness is not a major concern. The antagonistic effects of Cl^- and SO_4^{2-} ions are subdued by this treatment program.

Treatment levels are approximately 15 to 20 mg/L, which can be reduced if the system is pretreated at two to three times maintenance concentration for at least 1 week. Attack on copper-base alloys is reduced compared to the AMP/HEDP system; however, as with the combined phosphonate system, there is a need for a specific copper inhibitor. Concern over reversion still exists, because the polyphosphates are subject to hydrolysis. The PO_4^{3-} ions generated will improve the overall corrosion protection, assuming $Ca_3(PO_4)_2$ precipitation is controlled.

The polyphosphate/PO_4 combination functions in a mixed mode. The cathodic portion comes from either the polyphosphate or phosphonate (HEDP), while the anodic portion derives from the PO_4^{3-} ion. The addition of PO_4^{3-} improves protection to carbon steel through a synergistic interaction with either polyphosphate (Ref 14) or phosphonate. The level of polyphosphate or phosphonate is not critical and can range from 20 to 80%. The corrosion rate of carbon steel can be easily controlled to 25 μm/yr (1 mil/yr) with 15 to 18 mg/L total phosphate.

This system is applicable over a broad pH range of 6.0 to 8.5. There is little sensitivity to pH. The lack of sensitivity to pH refers only to corrosion control, and the inhibitors remain active in solution. The formation of a $Ca_3(PO_4)_2$ precipitate is prevented by the addition of an appropriate additive that inhibits its growth and adherence to the metal surface.

Sensitivity to temperature is also minimal. The inhibitor pair has applicability to very hot systems having bulk water temperatures as high as 70 °C (160 °F). Reversion of the polyphosphate molecules to PO_4^{3-} will be accelerated at the higher temperature, but will also enhance overall protection due to the inhibitive activity of its product (PO_4^{3-} ion).

The system is moderately sensitive to aggressive ions, specifically Cl^-, that can promote pitting attack. Because PO_4^{3-} is an anodic inhibitor, there is a critical concentration that must be maintained that is a function of the electrolyte. Treatments containing polyphosphate will revert to PO_4^{3-}, and a sufficient amount of a $Ca_3(PO_4)_2$ inhibitor should be present to suppress its formation.

Attack on copper-base alloys is not a major concern when polyphosphates are used. However, the phosphonate can be aggressive to copper-base alloys. The addition of a specific copper inhibitor is recommended.

Copper Inhibitors

Most of the steel inhibitors that have been discussed exert some degree of control over corrosion of copper-base alloys. However, system upsets, such as pH excursions and process leaks, can dissolve copper into the cooling water, where it can interfere with steel protection. Concentrations of at least 0.1 mg/L can deposit on steel conduits, accelerating localized attack. Ancillary inhibitors are available that are very effective in controlling corrosion of copper-base alloys and preventing galvanic deposition or dissolved copper onto ferrous metals.

Three specific inhibitors have been extensively used: mercaptobenzothiazole (MBT), benzotriazole, and tolyltriazole. Mercaptobenzothiazole is an extremely effective inhibitor for copper-base alloys. Its inhibitive properties are attributed to formation of an adherent protective film on the metal oxide surface. The inhibitor reacts with the metal surface to form a chemisorbed barrier. The initial corrosion product of Cu^+ ions reacts with the MBT molecule to form a 3-dimensional complex of Cu(1)MBT. Rate of film growth is rapid, reaching a self-limiting thickness within a short period of time.

Mercaptobenzothiazole is susceptible to oxidizing agents, such as air, chlorine, and ultraviolet light from sunlight, that can degrade the molecule into a disulfide having no inhibitory properties. This degradation occurs only to the molecule in solution, not the complex on the metal surface. Because of the sensitivity of MBT toward chlorine, the inhibitor should be used only if no chlorine residual is present. Thus, MBT should not be added to open recirculating cooling water systems, in which continuous chlorination is often practiced.

Cupric ions can be effectively inhibited from cathodically depositing onto more active metals, such as steel and aluminum, by reacting with MBT in a 1:2 molar ratio. In the absence of complicating factors, such as copper concentrations exceeding 0.1 mg/L in the cooling water or a chlorine residual, the concentration of MBT required for good copper inhibition is approximately 4 mg/L. A feeding procedure based on 3 mg/L, followed by 1 mg/L addition 12 h later, has been very successful.

Benzotriazole and tolyltriazole function similarly in controlling copper corrosion. Structurally, tolyltriazole differs from benzotriazole in that the former has a methyl group attached to the benzene ring. Both materials behave similarly in cooling waters, reacting with the metal surface to produce a three-dimensional chemisorbed layer.

The azoles are classified as cathodic inhibitors because they adsorb at cathodic sites and interfere with the oxygen reduction reaction. These molecules are more resistant to oxidation than MBT. In the presence of chlorine, 1-chlorobenzotriazole (or 1-chlorotolyltriazole) is probably formed, having minimal inhibitory properties. Upon dissipation of residual chlorine, the chloro-compound reverts back to the active azole. Chlorination does not affect the integrity of the complex on the metal surface.

The azoles can deactivate dissolved copper in cooling water systems and prevent its deposition onto steel or other active metals. A 2:1 molar ratio of inhibitor to copper ions is required, similar to the MBT reaction.

The concentration of azoles necessary for copper inhibition is approximately 1 to 2 mg/L in the absence of any residual chlorine. The optimum practice is to pretreat the system with two to three times normal concentration for 1 to 2 days, then control at a maintenance dosage. Under chlorination conditions, the azole should be fed after the dissipation of residual chlorine. If continuous chlorination is practiced and cannot be changed to intermittent practice, the level of treatment should be increased to 4 to 5 mg/L. In the presence of continuous chlorination, overall copper corrosion protection will be less than with intermittent chlorination.

Surface Modification

R.D. Granata, Lehigh University; P.G. Moore, Naval Research Laboratory

Introduction

SURFACE MODIFICATION is the alteration of surface composition or structure by the use of energy or particle beams. Elements may be added to influence the surface characteristics of the substrate by the formation of alloys, metastable alloys or phases, or amorphous layers. Surface-modified layers are distinguished from conversion or coating layers by their greater similarity to metallurgical alloying versus chemically reacted, adhered, or physically bonded layers. However, surface structures are produced that differ significantly from those obtained by conventional metallurgical processes. This latter characteristic further distinguishes surface modification from other conventional processes, such as amalgamation or thermal diffusion. Two different modification methods will be discussed. The first, ion implantation, is the introduction of ionized species (usually elements, for example, Ti^+) into the substrate using kilovolt to megavolt ion accelerating potentials. The second method, laser processing, is high-power laser melting with or without mixing of materials precoated on the substrate, followed by rapid melt quenching.

The advantages of the surface modification approach to promoting corrosion resistance include (Ref 1):

- Alteration of the surface without sacrifice of bulk properties
- Conservation of scarce, critical, or expensive alloying elements
- Production of novel surface alloys (unattainable by conventional metallurgical techniques) with superior properties
- Avoidance of coating adhesion problems

The disadvantages of the surface modification techniques include:

- Processing materials having deep or hidden contours
- Cost of processing equipment
- Substrate sensitivity to high energy input (for example, thermal instability)
- The thinness (susceptibility to damage) of the coatings

Ion implantation and laser processing will be discussed separately in the following sections.

Ion Implantation

Surface modification by ion implantation is a technique that was derived from the semiconductor industry. Specimens for corrosion research were initially prepared by using high-energy research instrumentation or commercial semiconductor implanters. Equipment for surface modification of metal parts by batch processing has been built, and production capabilities of the equipment are being evaluated. Ion implantation is reaching a stage of development in which specific advantages are being recognized and exploited for enhancing the corrosion and wear resistance of critical metal parts (Ref 2). For wear resistance, ion implantation has been used for the hardening and friction reduction of metal surfaces (Ref 3). Related techniques are also used in conjunction with ion implantation to increase the ratio of material introduced into the substrate per unit area, to provide appropriate mixtures of materials, or to overcome other difficulties involved in surface modification by ion implantation alone. These techniques include:

- *Ion beam sputtering:* An ion beam of argon or xenon directed at a target sputters material from the target to a substrate; the sputtered material arrives at the substrate with enough energy to promote good adhesion of the coating to substrate
- *Ion beam mixing:* Deposited layers (electroplating, sputtering) tens or hundreds of nanometers thick are mixed and bonded to the substrate by an argon or xenon ion beam
- *Plasma ion deposition:* Ion beams are used to create coatings having special phases, especially ion beam formed carbon coatings in the diamond phase or ion beam formed boron nitride coatings
- *Ion beam assisted deposition:* Ion beams are combined with physical vapor deposition

Materials Processing and Product Characteristics. The ion implantation technique consists of introducing the target (substrate material) into the implanter vacuum chamber, vaporizing and ionizing the implant species, and electrostatically accelerating the ionized species into the target. Figure 1 shows schematics of research and semiconductor production ion implantation devices. A production-type implanter for materials surface modification that has recently come on-line is shown in Fig. 2.

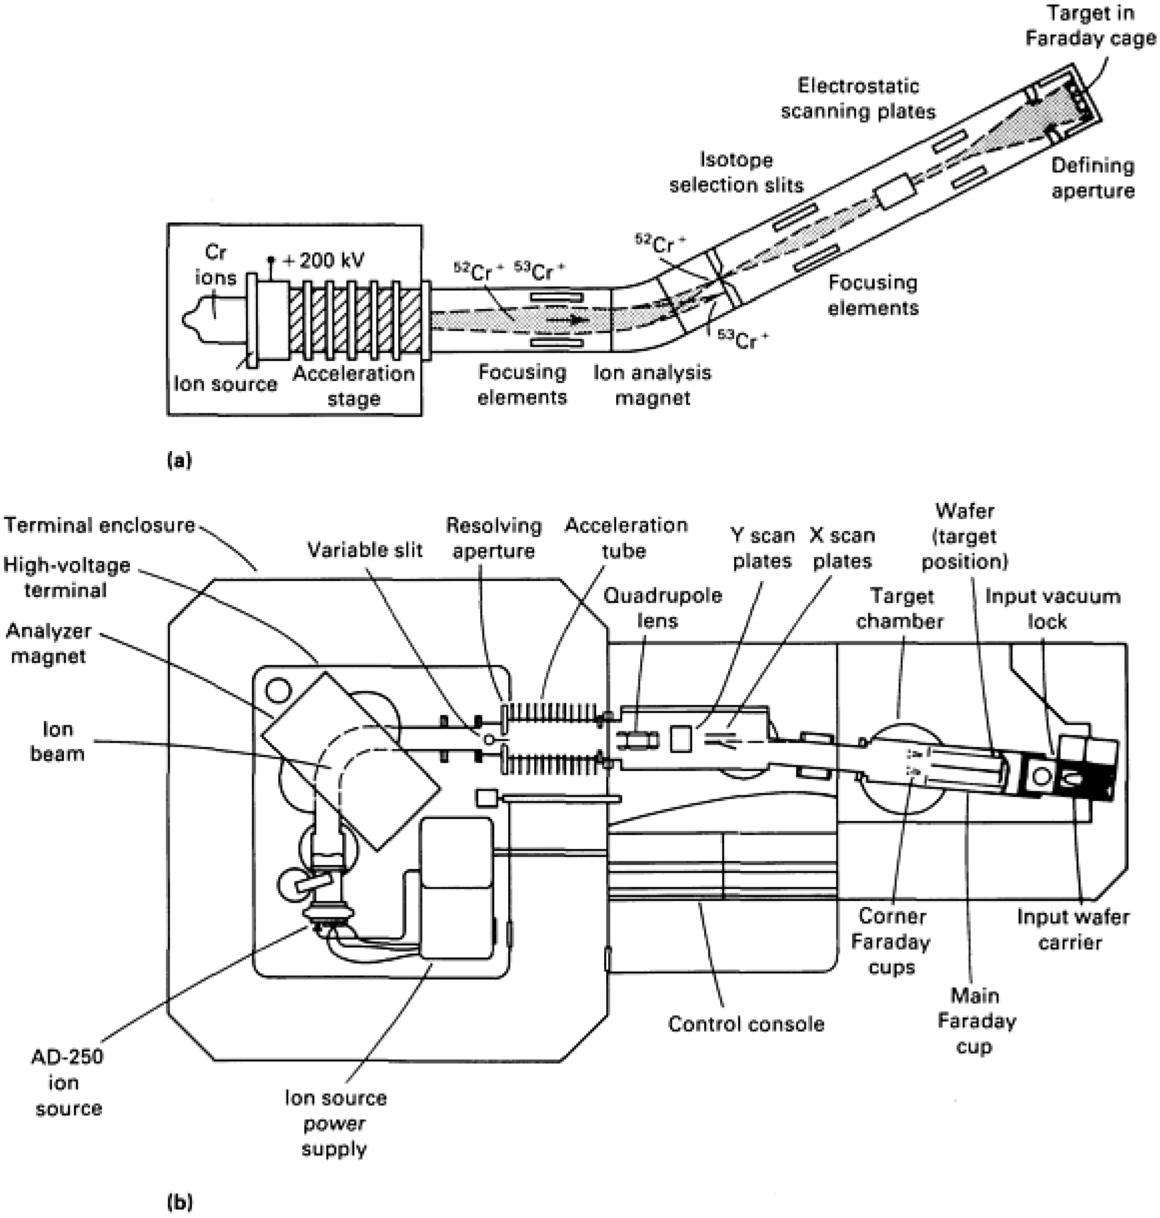

Fig. 1 Schematics of research-type ion implantation system (a) and a production-type semiconductor implanter (b)

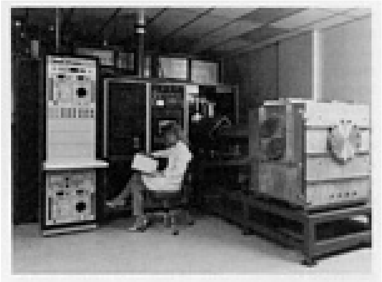

Fig. 2 Commercial ion implanter for materials modification. Courtesy of Spire Corporation

The implant species may be most any element that can be vaporized and ionized in a vacuum chamber. The material used to generate the implant species is usually in the form of a chloride salt of a metal, a gaseous compound, or the pure

element. Solid materials are heated to provide an adequate vapor pressure of the implant species. The vaporized material is ionized and accelerated toward the target. Magnetic fields separate various mass/charge ratios and enable the selection of specific implant species. A selected species impacts the target material and is implanted within, producing a surface-modified substrate. The depth to which the species is implanted depends on the accelerating voltage and the atomic numbers of the implant versus target species (Ref 4). Commonly used acceleration voltages are 20 to 200 keV. The typical average implantation depth (range) is 10 to 100 nm. The distribution of implanted species versus range is roughly Gaussian.

Figure 3 shows a diagram illustrating calculated concentration profiles of cobalt, aluminum, and boron implanted in iron at 50 keV to a dose of 10^{17} ion/cm^2 (6.45 × 10^{17} ion/in.^{2}). Implantation causes removal (sputtering) of the surface layers, but the thickness of the sputtered layer is generally less than the implantation thickness. Sputtering rates of elements differ and depend on such factors as substrate composition, chemical bonding, metallurgical structure, beam energy, and angle of the incident beam. In some cases, sputtering rate becomes equal to the implantation rate; an equilibrium is achieved (saturation), and no net addition of ions to the substrate occurs. Maximum concentrations of implanted species may be as high as 50 at.%.

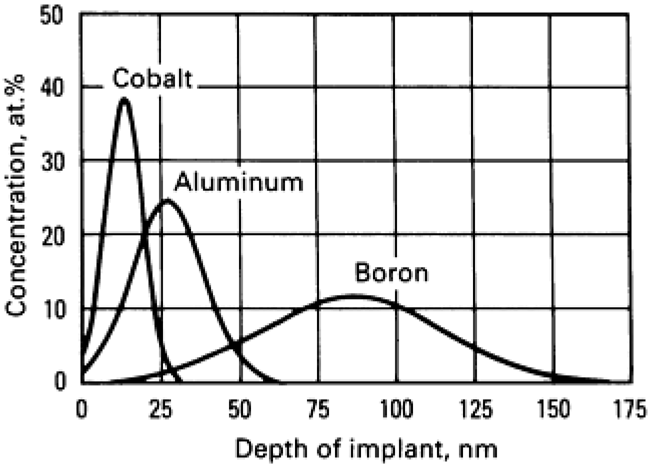

Fig. 3 Concentration profiles for cobalt, aluminum, and boron implants in iron approximated using methods described in Ref 4. Energy: 50 kV. Dose: 10^{17} ion/cm^2 (6.45 × 10^{17} ion/in.^{2})

The advantages of the ion implantation surface modification process include (Ref 1):

- No sacrifice of bulk properties
- Solid-solubility limit can be exceeded
- Alloy preparation is independent of diffusion constants
- No coating adhesion problems, because there is no interface
- No significant change in sample dimensions
- Depth concentration distribution is controllable
- Composition can be changed without affecting grain sizes
- Precise location of implanted area(s)
- Clean vacuum process
- Allows screening of the effects of changes in alloy composition

The implantation process can be viewed as a means of changing the material properties of an item only at the surface. An item can be fabricated from a material having desirable bulk properties (machinable, low-cost) and can be modified to provide the requisite surface properties (corrosion resistance, wearability). However, the disadvantages of the process must be kept in mind:

- The ion beam cannot process deep or hidden contours (±30° incidence)
- Processing equipment may be too costly
- The substrate may be excessively heated by high energy input; for example, the typical energy flux of 2 W/cm^2 (13 W/in.^{2}) can heat a substrate 500 °C (930 °F)
- Inclusions in substrate material may bridge the depth of the surface-modified region, producing sites with undesirable properties
- Treatment depth may be inadequate for some applications, resulting in galvanic effects with localized corrosion or in implant layer removal by abrasion or erosion

Problems associated with thermal effects and sample handling have been discussed and technical solutions proposed (Ref 4, 5, 6). For example, nitrogen-implanted surfaces must be kept below 200 °C (390 °F), the temperature at which outward diffusion of nitrogen occurs. Many sample types have been implanted while keeping their surface temperatures below 100 °C (212 °F) by using heat sinks and by modifying processing conditions.

Dry Corrosion Properties. Dry corrosion or thermal oxidation in the absence of a liquid phase is primarily governed by the transport processes in the oxide and the ability of the oxide to resist spalling and breakdown or abrasion and erosion. The ion implantation process has provided a means for studying and modifying the surface layers active in dry corrosion. Interesting results have been obtained with implanted materials, as in the following five examples.

First, in one study, the effects of the implanted material were found to persist to a much greater depth than the thickness of the implanted layer (Ref 7). Oxide layer growths of more than 100 times the implant depth showed the persistence of the implanted element effects. An Ni-20Cr alloy developed a complete, protective Cr_2O_3 scale more rapidly when implanted with cerium, yttrium, calcium, or aluminum, but implanted zirconium or chromium had no effect. Scale adherence was increased by ion implantation with cerium, yttrium, calcium, or zirconium. For yttrium-implanted Ni-20Cr, the weight change was approximately 25% that of unimplanted material after 24 h at 1000 °C (1830 °F) in 101-kPa (1-atm) oxygen.

Second, a stainless steel implanted with 10^{17} ion/cm^2 (6.45 × 10^{17} ion/in.^{2}) of yttrium gave no observable spalling of the oxide after over 6,500 h versus unimplanted material, which spalled more than 2 mg/cm^2 (Ref 8). Third, implantation of aluminum into an Fe-Cr-1.4Al alloy increased the surface aluminum concentration to 10% and promoted the formation of a thick, protective, pure Al_2O_3 scale (Ref 9).

Fourth, high doses of silicon ion implanted into low silicon containing substrates did not provide the desired corrosion resistance associated with their conventional high-silicon counterpart materials. However, ion beam mixing of deposited silicon films with argon at 500 °C (930 °F) produced silicon-rich films on iron or titanium that are thicker than those obtained by ion implantation alone (Ref 10). These thick silicon layers should provide enhanced corrosion resistance. Attempts are being made to produce highly oxidation-resistant $MoSi_2$ by ion beam mixing of molybdenum and silicon layers (Ref 11). Lastly, zirconium was implanted with such elements as iron, cobalt, or nickel to help relieve internal stresses within the oxide film that result in the break-away oxidation associated with protective oxide fracture (Ref 12).

Wet Corrosion Properties. There are two approaches to using ion implantation for increasing the corrosion resistance of substrates; the first is to enhance passivation characteristics, and the second is to create novel materials. In the first approach, implantation creates a surface composition based on conventional metallurgical experience that reacts to form a passive layer. In the second approach, implantation creates a surface composition and a structure that are difficult, impossible, or impractical to achieve by conventional metallurgy.

The two main problems in applying ion implantation methods for creating corrosion-resistant surfaces are producing a surface layer that has a corrosion rate low enough to prevent penetration to the base material during the designed lifetime of the item and producing a surface that is self-repairing. The first problem is approached by introducing elements that enhance corrosion resistance, as in conventional metallurgy--for example, chromium (Ref 13) or molybdenum (Ref 14) in ferrous metals. Another approach is to create combinations of elements in the surface layers that cannot be produced by conventional metallurgical methods--for example, tantalum in iron (Ref 15) or phosphorus in iron-chromium alloys (Ref 16). Tantalum forms intermetallic compounds with iron, but conventional alloys with sufficiently high tantalum content are not readily produced. Other examples are chemically resistant amorphous layers produced, for example, on iron-chromium implanted with phosphorus, carbon, silicon, or boron. These materials passivate spontaneously in hot 25% hydrochloric acid (HCl) (Ref 16).

The second problem is approached by the introduction of elements that are not soluble in or removed by the environment, for example, palladium in titanium. Titanium passivation is strongly promoted by palladium and can be alloyed with it to provide lasting self-passivation properties in acidic media. However, palladium is required only at the interface as a catalyst for the hydrogen reduction reaction and is not readily soluble. Thus, it may be more cost-effective to modify the surface by implantation than to use palladium in the bulk alloy. The palladium-assisted passivation of titanium is a persistent effect with research specimens (Ref 17).

Substantial efforts have been made in the search for effective applications of ion implantation for enhancing corrosion resistance (Ref 18, 19, 20, 21, 22, 23, 24). The greatest difficulty lies in the thinness of the implanted layer; corrosion-resistant layers must not be entirely consumed or damaged. Many research efforts have attempted to mimic conventional alloy compositions. However, the corrosion rates of conventional alloy systems are usually too high relative to the thinness of the implanted layer. The most successful approaches have involved detailed knowledge of a specific material and environmental corrosion conditions or have created unconventional materials. The palladium-implanted titanium, tantalum-implanted iron, and phosphorus or boron implanted in iron-chromium systems described above are good examples. Another example of adapting ion implantation to a specific application is its use for interfacial reactions. Implantation of aluminum or titanium in 1010 steel significantly decreased the cathodic delamination rates of organic coatings from the implanted substrates (Ref 25).

Wear resistance enhancement by ion implantation is included in the discussion of surface-modified corrosion-resistant surfaces because erosion, cavitation, and fretting corrosion are important forms of corrosion. Ion implantation has been shown to have a major effect on wear resistance properties. The combined effects of ion implantation on corrosion and wear resistance are particularly well suited in applications in which bearings or sliding surfaces are subjected to intermittent use or experience long periods of storage.

Wear resistance is a property that has shown significant improvement for some substrates after surface modification by ion implantation. Activity in this area has been increasing at research laboratories, and specialized equipment has been developed for commercialization. Some of the work on the development of wear-resistant ion-implanted materials is focusing on quantification and lifetime predictions.

Adhesion and abrasion are the most specific wear mechanisms, with corrosive and surface fracture related mechanisms making contributions in certain cases. In adhesive wear, surfaces under sufficient local pressure deform plastically and weld at the contact points. When the surfaces separate, the contact point welds break, resulting in the formation of debris and in surface roughening. The oxidized debris causes most of the subsequent wear. Abrasive wear is simply the cutting of one surface by another edged or pointed surface. Abrasive wear decreases as the hardness of the cut surface approaches that of the cutting surface. Abrasion is dramatically lower when both material hardnesses are equal. Adhesive and abrasive wear as well as tribomechanical properties for ion-implanted materials are discussed in Ref 26 and 27, respectively.

There are many examples of ion implantation studies for increasing the wear resistance of materials. Many studies have used nitrogen-implanted steel because of the readily available high-current nitrogen beams and because direct comparison to thermal nitriding processes is possible. Increases of the order of two to three times in the microhardness of steels due to nitrogen implantation have been reported (Ref 28). However, large reductions in wear rate often result from relatively small increases in microhardness. Extrusion dies for TiO_2-pigmented plastics fabricated from low-carbon steel often wear rapidly, yet nitrogen implantation increases the die lifetime by up to ten times. This modification suggests that the microhardness of the steel has been raised above that of TiO_2 (Ref 26). Extended tool life has been demonstrated for plastic molding machines with estimated ion implantation costs as low as 10% of the ordinary part costs (Ref 3). Nitrogen implantation of a titanium alloy (Ti-6Al4V) has been found to decrease the wear rate by more than two orders of magnitude (Ref 29). Data suggest that wear rates have been reduced by almost three orders or magnitude in a titanium alloy designed for hip joint prostheses (Ref 26).

Wear reduction can be attributed to factors other than microhardness. The residual carbon films introduced during implantation of other elements may decrease the occurrence of adhesive wear by providing lower friction coefficients. Implantation of titanium or tantalum usually results in the coimplantation or inward diffusion of carbonaceous matter present in the vacuum system. In the case of titanium-implanted steel, the wear reduction has been attributed to the formation of an amorphous iron-titanium-carbon film. Other systems are being studied--for example, tin-implanted iron, yttrium, and nitrogen in chromium steels and nitrogen implantation in cobalt-cemented carbide. It has been suggested that deep-penetrating interstitially active elements, such as nitrogen, be used to ion beam mix thin coatings of oxide-modifying materials into substrates for synergistic wear reduction (Ref 26). However, another opinion is that implanted

ions do not migrate below the surface. Four mechanisms have been identified as contributing to the reduction of sliding wear of ion implanted metals (Ref 27):

- Production of low-friction surfaces by altering surface chemistry
- Modification of microstructure to harden the surface
- Stabilization of microstructure against deleterious work-hardening effects
- Introduction of residual (compressive) stresses to combat fracture

Impact wear with and without sliding wear was also studied for various materials implanted with nitrogen (Ref 30). The materials used in this study were:

- *Soft:* aluminum alloy 2024, aluminum alloy 7075, and oxygen-free high-conductivity copper (CDA C10100)
- *Medium:* cartridge brass (CDA C26000) Cu10Sn, aluminum bronze (Cu-18Al), and sintered iron (Fe-5Cu-lC)
- *Hard:* AISI 1018 carbon steel and AISI type 304 stainless steel

Impact wear improved significantly, but the combination of impact and sliding wear showed only a very small effect. Interestingly, one of the materials, cartridge brass, showed no significant improvement.

Critical Evaluation of Product Utility. Numerous examples have been given to define application areas that may benefit from the use of implantation techniques for materials processing. The advantages and disadvantages relate to the small dimension of implantation depth (nanometers). Significant niches are being created for materials processed by ion implantation and related techniques. These surface modification techniques for industrial applications are perhaps best appraised by considering the information presented in Table 1.

Table 1 Successful applications of ion implantation for industrial exploitation

Application	**Material**	Typical results
Orthopedic implants (artificial hip and knee joints)	Ti-6Al-4V	**Significant (400 times) lifetime increase in laboratory tests**
Bearings (precision bearings for aircraft)	M50 tool steel, 440C stainless steel, or 52100 bearing steel	**Improved protection against corrosion, sliding wear, and rolling-contact fatigue**
Extrusion tools (spinnerettes, nozzles, and dies)	Various alloys	**Four to six times normal performance**
Punching and stamping tools (pellet punches for nuclear fuel, scoring dies for cans)	**D2 tool steel**	**Three to five times normal life and better end products**

Laser Surface Processing

Lasers with continuous outputs of 0.5 to 10 kW can be used to modify the metallurgical structure of a surface and to tailor the surface properties without adversely affecting the bulk properties. The surface modification can take the following three forms. The first is transformation hardening, in which a surface is heated so that thermal diffusion and solid-state transformations can take place (Ref 31, 32, and 33). The second is surface melting, which results in a refinement of the structure due to the rapid quenching from the melt (Ref 32, 33, 34, 35, 36, 37). The third is surface alloying, in which

alloying elements are added to the melt pool to change the composition of the surface (Ref 38, 39, 40, 41, 42, 43, and 44). The novel structures produced by laser surface melting and alloying can exhibit improved electrochemical behavior.

Materials Processing

The processing parameters necessary for laser surface processing depend on the type of modification to be done (for example, transformation hardening or surface alloying) and the properties of the material that are being treated (for example, thermal diffusivity, heat capacity, and transformation temperatures). Figure 4 shows typical ranges of conditions for various processes. The laser power, power density, and interaction time are the primary variables. Other variables, such as the composition of the atmosphere during treatment or the rate of material addition, are determined by the details of the processing--for example, the necessity of shielding against oxidation and the desired thickness, composition, and structure of the surface layer.

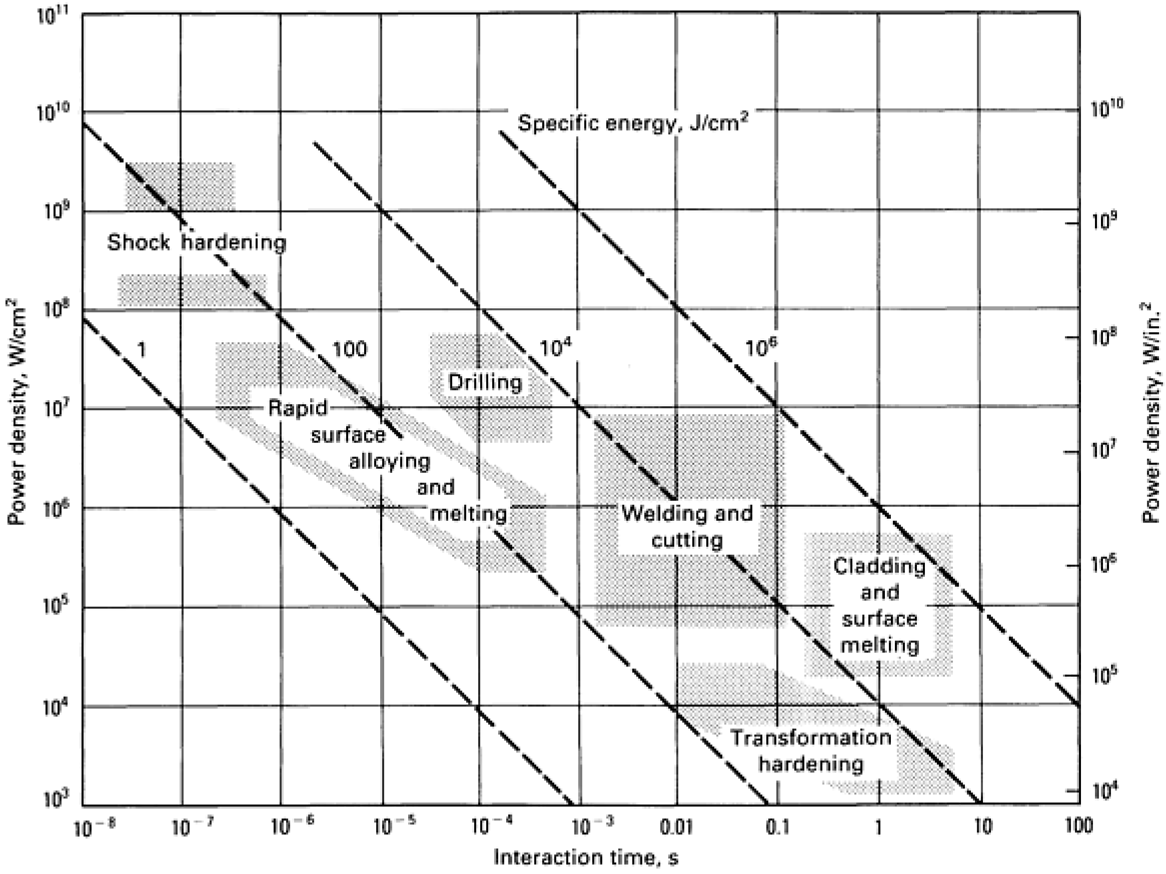

Fig. 4 Interaction times and power densities necessary for various laser surface modification processes

The laser beam modified layer can range in thickness from 0.01 to 5 mm (0.4 to 200 mils), depending on the processing variables, although thicknesses of 0.05 to 1 mm (2 to 40 mils) are more common. The longer the interaction time of the laser beam with the material, the deeper the processed layer will be. Of the processes shown in Fig. 4, the areas labeled "Cladding and surface melting" and "Transformation hardening" delineate process parameters that typically affect the material to depths from 0.5 to 5 mm (20 to 200 mils) and result in metallurgical structures similar to welded structures. The parameters designated "Rapid surface alloying and melting" affect a surface layer only 0.02 to 0.6 mm (0.8 to 24 mils) thick, but result in quench rates to 10^7 K/s and therefore allow for the production of novel metallurgical structures and alloys.

The procedure for laser beam surface modification is shown in Fig. 5. A high-power laser beam is brought to a focus near the surface of the workpiece. After a melt pool is established, the laser beam can be rastered across the surface, melting a strip of material with each sweep, until the entire surface has been processed. The processing is performed in an inert gas

atmosphere or vacuum to protect the metal from oxidation. In practice, it is more convenient to move the workpiece rather than the laser beam.

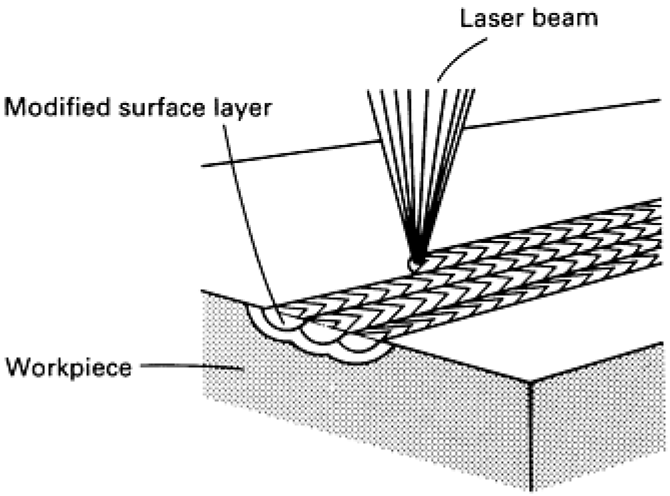

Fig. 5 Schematic of the procedure for the laser processing of metals

Figure 6 shows a schematic of an apparatus for processing laboratory specimens. The specimen is passed through the laser beam by the rotation of the turntable, and the entire apparatus is translated a fraction of a melt width between passes to process a larger area. The process is varied by changing the power level of the laser beam, the power density (or spot diameter), or the sweep speed. The effects of these variables on the depth of melting for three materials are shown in Fig. 7. As can be seen, the melt depth can be varied by an order of magnitude simply by changing the sweep speed. The width of the melt pass is determined primarily by the diameter of the laser spot and the thermal properties of the material and is very slightly dependent on the sweep speed. The rate at which a surface can be processed is typically about 1 cm^2/s (0.16 $in.^2/s$) for a variety of conditions and materials.

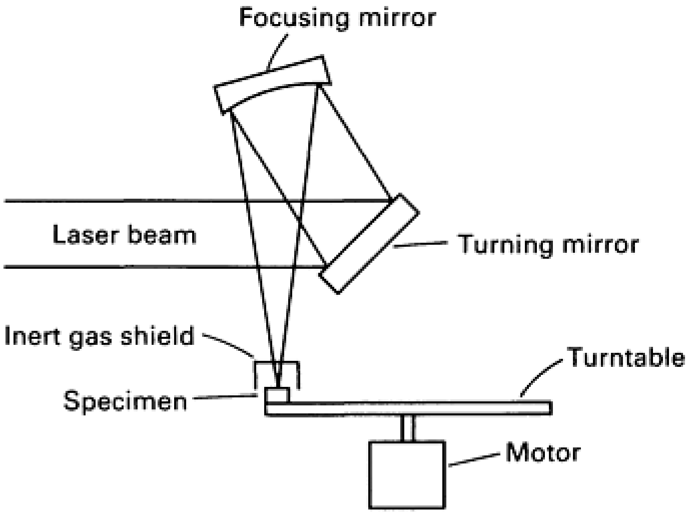

Fig. 6 Schematic of an apparatus for laser processing

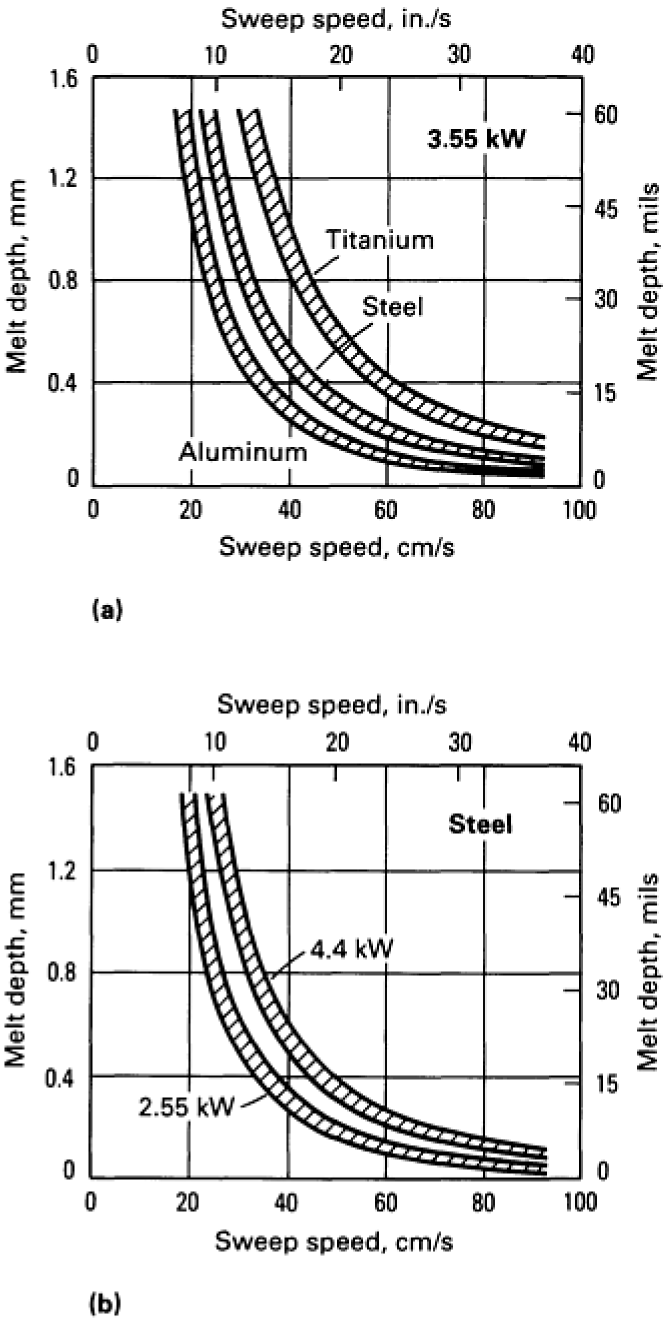

Fig. 7 Effects of laser-processing conditions on melt depth. (a) For three materials at one power level. (b) For steel at two power levels

Product Characteristics

Solidification Effects. The heat flow characteristics of such processing can reasonably be described by one-dimensional heat flow in which the rate at which energy enters the surface is balanced by the rate at which heat is conducted away by the cool substrate (Ref 45). A number of studies have been devoted to characterizing the temperature profiles that result from the laser and electron beam processing of materials (Ref 31, 33, and 46). The character of the temperature profiles experienced by material at various depths below the surface of the metal is shown in Fig. 8. The three reference temperatures indicated represent the liquidus and solidus as well as a solid-state transformation temperature. As the laser beam sweeps across the surface of a metal sample, the surface begins to heat. When the melting temperature of the material is exceeded, a melt front is established and moves from the free surface of the sample toward the bulk. Shortly after the beam is turned off (or has moved away), the melt front slows and then stops. It then moves back toward the free surface as a solidification front. The unique characteristics of this solidification front are the high

cooling rates (such as 10^7 K/s) and the steep temperature gradient (such as 10^5 K/cm). These characteristics promote the formation of metastable compositions and structures.

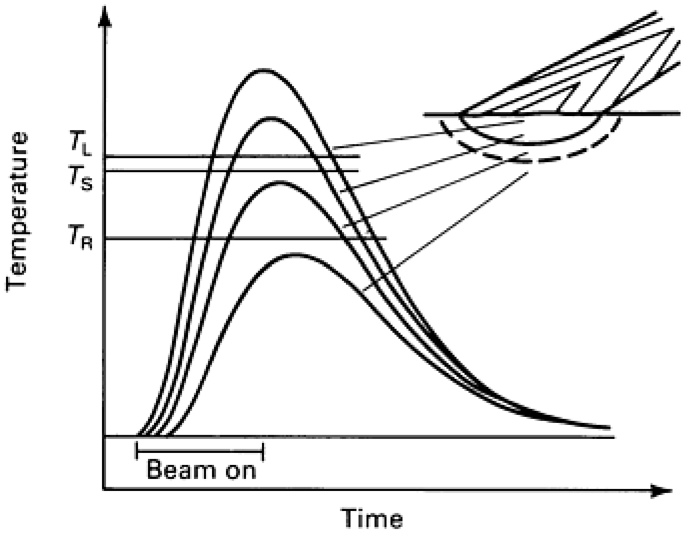

Fig. 8 View of laser-melted surface and temperature profiles experienced at different points on the surface during laser melting. Liquids (T_L), solidus (T_S), and solid-state transformation (T_R) temperatures are indicated.

Because of this steep temperature gradient, there is only a thin layer of metal that is cool enough to solidify. The material above this layer is above the liquidus temperature, and the material below this layer has already solidified. There is a strong epitaxial character to the resolidification as a result of the steep temperature gradients (Ref 47, 48). This is illustrated in Fig. 9. The two effects that complete during the solidification are the regrowth of grains from the substrate and the heterogeneous nucleation and growth of new grains in this thin layer of chilled metal. For most alloys, grains from the substrate will grow into the chilled zone, and any grains that may have nucleated within the melt pool will either redissolve or be transported by the melt front to the free surface. As an example of this, Fig. 10 shows a β-titanium alloy that has been laser processed.

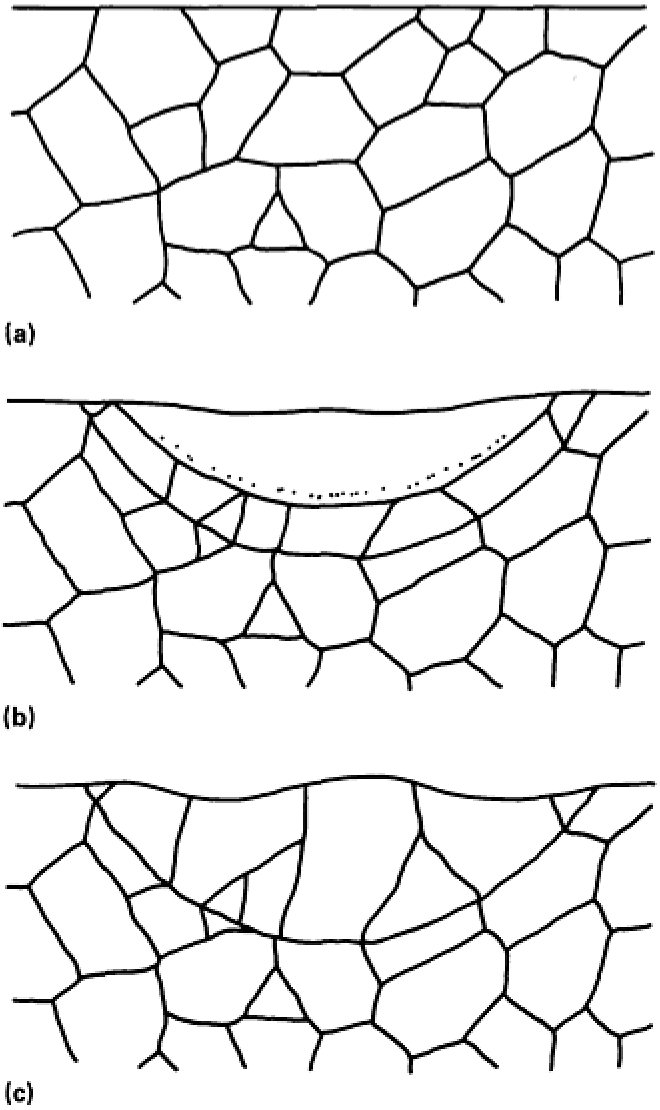

Fig. 9 Origins of epitaxial resolidification as a result of laser processing. (a) Before laser melting. (b) During resolidification. (c) After quenching

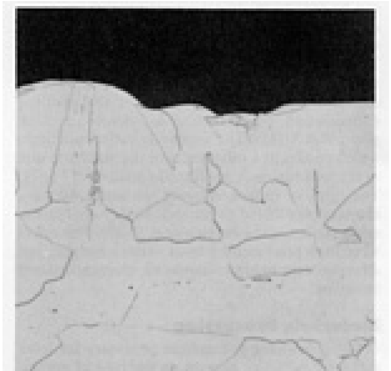

Fig. 10 Planar resolidification of a β-titanium alloy

The epitaxial solidification can have a striking effect on the grain size of the surface layer and on the crystallographic texture. Because some crystal planes grow faster than others--for example, (100) for cubic crystals and (1010) for hexagonal close-packed crystals--those substrate grains having a large component of these orientations in the direction of the temperature gradient will grow at the expense of less favorably oriented grains. As these grains grow, they will tend to squeeze out less favorably oriented grains. This affects the crystallographic texture in two ways. First, there is a higher probability for grains at the free surface to be oriented with the fast-growing direction normal to the free surface, and second, low-angle grain boundaries will occur with a higher frequency than in the substrate. As shown Fig. 11, when the grain size of the metal before processing is small compared to the depth of melting, there is a coarsening of the grain size, and the texture effects are more pronounced. Examples of these effects are shown in Fig. 9 for a large-grain material and in Fig. 12 for a fine-grain material.

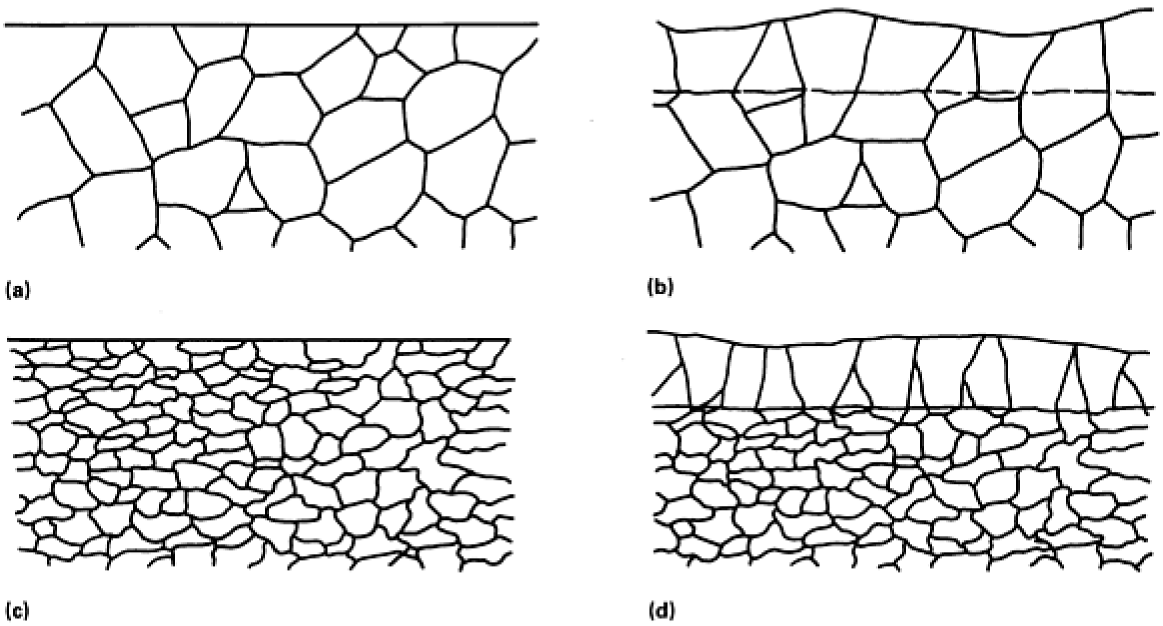

Fig. 11 Effect of epitaxial resolidification on grain size for a material with large original grain size (a and b) and a material with small original grain size (c and d) compared to the melt depth. (a) and (c) Before processing. (b) and (d) After processing

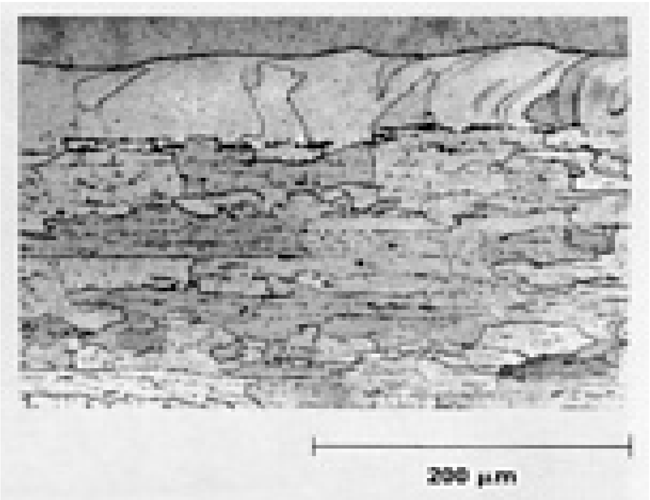

Fig. 12 Coarsening of grain size in a ferritic stainless steel by laser melting

During the solidification process, there is generally a redistribution of solute atoms away from the solidification front so that the interface can remain as close to equilibrium as possible (Ref 49). After an initial transient, this partitioning results in the geometrical destabilization of the solidification front, and dendritic solidification results. For a single-crystal alloy that undergoes rapid surface melting, the dendritic character of the resulting melt is shown in Fig. 13. This effect was documented by the laser melting of single crystals of a nickel-base superalloy (Ref 47). The high-temperature gradient affects the character of the dendritic growth in two ways. First, it restrains crystal growth to the directions of the fast-growing crystal planes as described above, and second, it minimizes the amount of segregation because of the short times allowed for lateral diffusion. An example of the dendritic character of laser-processed material is shown in Fig. 14. The diameter of the dendrites can be used to estimate the cooling rates experienced by the material as it resolidified. Higher cooling rates result in less lateral diffusion and smaller dendrites, while lower cooling rates result in more lateral diffusion and larger diameters.

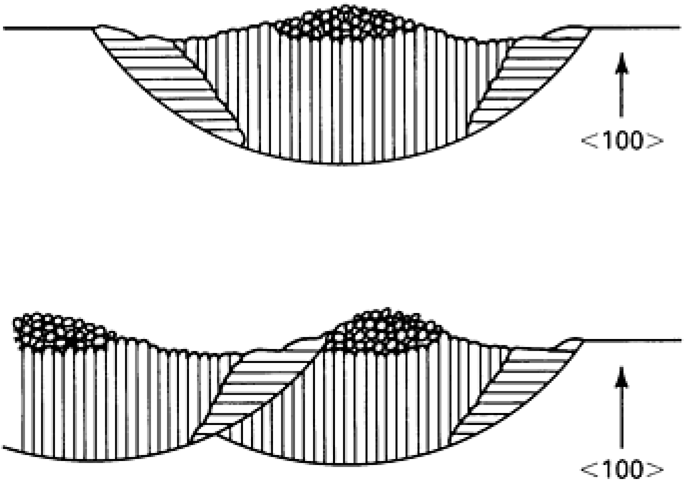

Fig. 13 Dendritic solidification of cubic single crystals. The high-temperature gradient resulting from laser melting causes dendrites to grow in the preferred <100> direction.

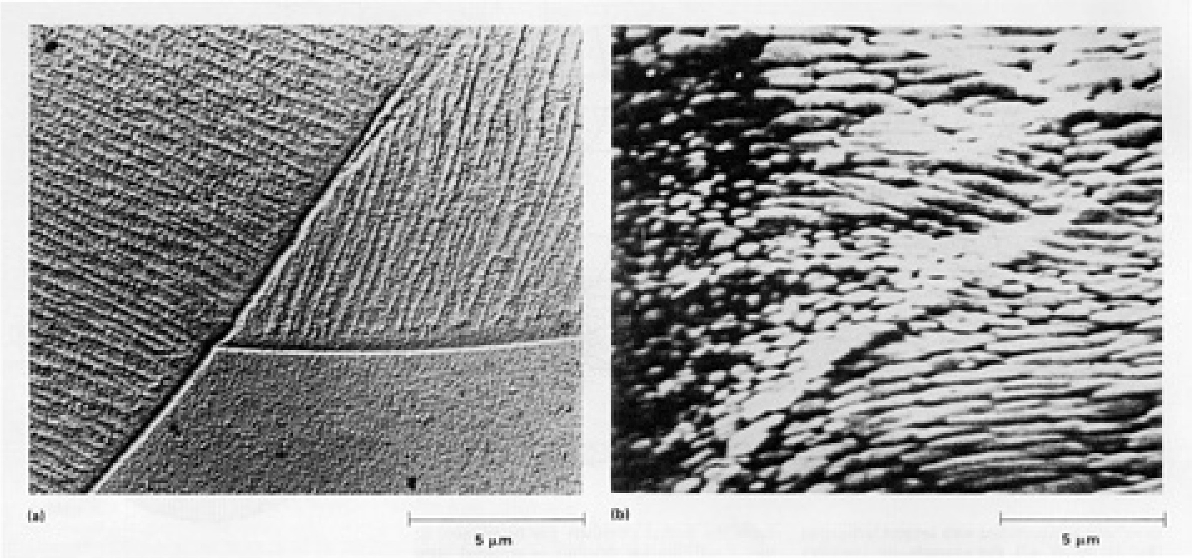

Fig. 14 Dendritic solidification in laser surface melted type 304 stainless steel. (a) Surface replica of a polished-and-etched cross section. (b) SEM micrograph of the free surface

To the extent that equilibrium cannot be maintained at the solidification front by partitioning as described in the previous paragraph, more than the equilibrium amount of solute atoms will be incorporated into the solidification structure. An

increase in the cooling or solidification rates results in still greater deviations from the equilibrium concentrations (Ref 50, 51). In systems that exhibit solubility at all compositions, for example, the aluminum-manganese system, the solubility limits can be extended. Deviations from equilibrium can also result in the formation of metastable crystal structures when the system has several phases with comparable free energies of formation (Ref 52, 53). Amorphous or glassy surface layers can be produced by laser processing only when the system has several energetically and structurally similar crystalline phases; thus, atoms attaching to the solidification front will have a variety of closely spaced lattice sites with similar energies to choose from. This confuses the long-range order and destroys the crystalline character of the solid.

Changing the Chemical Composition. In addition to the structural modifications described in the previous section, the composition of the surface layer can also be changed to form surface alloys whose compositions can be tailored to suit surface requirements. Changes in composition have been accomplished with several techniques (Ref 31, 39, 41, 42). For example, the specimen can be coated before laser processing with a thin layer of the desired alloying element or elements. Such coatings have been applied by vacuum deposition, electroplating, spraying, or the use of a slurry. The alloying elements can also be introduced directly into the melt pool during processing in the form of wire or as an injected powder. When the composition is changed, care must be taken to ensure that the alloying elements are distributed uniformly in the surface layer. Three mechanisms have been identified for facilitating the mixing of components: liquid-state diffusion, convection currents within the melt pool, and agitation of the melt pool by a laser-sustained plasma (Ref 42). A uniform composition can generally be obtained by processing two or more times, as shown in Fig. 15. The first set of passes disperses the alloying elements to the desired depth and determines the overall composition of the surface alloy. Subsequent passes (using processing conditions selected to obtain slightly shallower melt depths) further homogenize the surface.

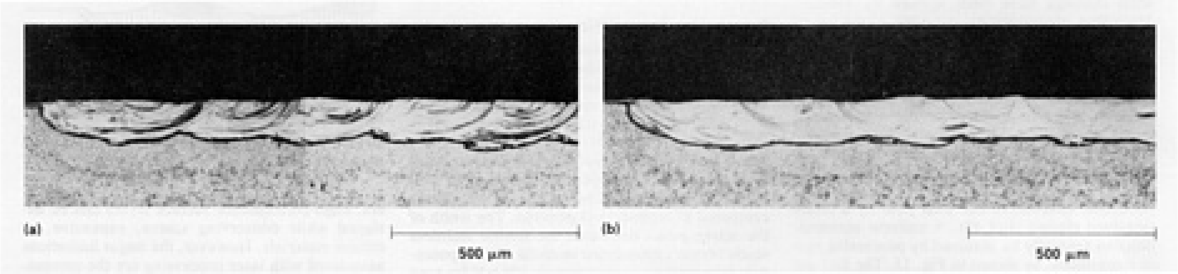

Fig. 15 Laser surface alloying of molybdenum into Ti-6Al-4V showing the effectiveness of multiple passes in homogenizing the chemical composition. (a) Single pass. (b) Double pass

Effects of Microstructure on Properties. The microstructural changes that result from laser processing can take several forms: a redistribution of major alloy components, a redistribution of any second phases or precipitates, a change in the crystalline character of the surface, or a change in the composition. The melting process results in a leveling of any large-scale composition variations, but the solidification transients can also result in a surface that is enriched in one or more of the alloy components. The high cooling rates during solidification and the accompanying extension of solid-solubility limits often result in either the elimination of second phases or a fine distribution of second phases or precipitates. Alloying may be necessary to take advantage of the higher solubility limits. The steep temperature gradients present during processing generally result in epitaxial resolidification, which introduces some crystallographic texture of the surface grains and grain boundaries (Ref 54). The modification of composition holds the most promise for improving electrochemical behavior because the surface chemistry can be adjusted so that a solidification structure is obtained upon quenching that exhibits more corrosion resistance than the base alloy (Ref 55).

Corrosion Properties

The corrosion resistance of laser-processed materials has been studied by several research groups. For example, laser beam processing was used in one study to melt and rapidly solidify AISI type 304 stainless steel and ferritic Fe-13Cr-*x*Mo (*x* = 0, 2, 3.5, or 5) stainless steels (Ref 56). The critical current density for the passivation of laser-processed type 304 stainless steel in 1 *N* sulfuric acid decreased two orders of magnitude compared to unprocessed material. The width of the active peaks decreased for ferritic stainless steels versus unprocessed material. Pitting potentials increased by

approximately 150 mV for type 304 stainless steel and 5% Mo ferritic stainless steel. Ferritic steels with 0, 2, or 3.5% Mo showed decreases in the pitting potentials.

In another case, the corrosion behavior of iron-aluminum bronzes was studied electrochemically in 5% H_2SO_4 (Ref 57). Substantial beneficial effects were observed and attributed to homogenization of the complex microstructure.

Lastly, laser surface alloying was performed to incorporate chromium in SAE 1018 steel and molybdenum in type 304 stainless steel (Ref 58). The SAE 1018-Cr materials passivated similarly to corresponding bulk alloys (5 to 80% Cr). The 304-3Mo material was similar in pitting resistance to type 316 stainless steel. The 304-9Mo material was superior to type 316 stainless steel and showed no pitting up to oxygen evolution potentials. Table 2 shows some of the results for the 304-Mo materials. Plasma-sprayed titanium coatings on steel were consolidated by laser processing to remove residual porosity, which is the major obstacle to enhanced corrosion resistance (Ref 59).

Table 2 Effect of laser surface alloying with molybdenum on pitting potentials of austenitic stainless steels in 0.1 *M* NaCl

Sample	**Composition, %**			Pitting potential (E_{pit}) (V vs SCE)
	Cr	**Ni**	**Mo**	
Type 304	18-20	8-10	0	**0.300**
Type 316	16-18	10-14	2-3	**0.550**
304-Mo	18.9	9.1	3.7	**0.500**

Critical Evaluation of Product Utility

Laser processing provides unique opportunities for producing corrosion-resistant surface layers. High-performance surface layers can be designed while conserving scarce, expensive, or critical materials. However, the major limitations associated with laser processing are the compatibility of substrates with thermal conduction requirements and the current restriction to planar substrates.

Classification of Hydrogen Processes

The specific types of hydrogen damage have been categorized in order to enhance the understanding of the factors that affect this behavior in alloys and to provide a basis for development and analysis of theories regarding different hydrogen damage mechanisms (Ref 78). Table 3 presents one of these classifications schemes, describing the materials that are susceptible to the various forms of damage, the source of hydrogen, typical conditions for the occurrence of failure, and the initiation site. The mechanisms for each of these failure modes will also be described briefly. The first three classes are grouped together and designated hydrogen embrittlement because these are the failure modes that typically exemplify classical hydrogen embrittlement.

Table 3 Classifications of processes of hydrogen degradation of metals

	Hydrogen embrittlement			Hydrogen attack	Blistering	Shatter cracks, flakes, fisheyes	Micro-perforation	Degradation in flow properties	Metal hydride formation
	Hydrogen environment embrittlement	**Hydrogen stress cracking**	**Loss in tensile ductility**						
Typical materials	Steels, nickel-base alloys, metastable stainless steel, titanium alloys	Carbon and low-alloy steels	Steels, nickel-base alloys, Be-Cu bronze, aluminum alloys	Carbon and low-alloy steels	Steels, copper, aluminum	Steels (forgings and castings)	Steels (compressors)	Iron, steels, nickel-base alloys	V, Nb, Ta, Ti, Zr, U
Usual source of hydrogen (not exclusive)	Gaseous H_2	Thermal processing, electrolysis, corrosion	Gaseous hydrogen, internal hydrogen from electrochemical charging	Gaseous	Hydrogen sulfide corrosion, electrolytic charging, gaseous	Water vapor reacting with molten steel	Gaseous hydrogen	Gaseous or internal hydrogen	Internal hydrogen from melt; corrosion, electrolytic charging, welding
Typical conditions	10^{-6} to 10^{8} N/m^2 (10^{-10} to 10^{4} psi) gas pressure	0.1 to 10 ppm total hydrogen content	0.1 to 10 ppm total hydrogen content range of gas pressure exposure	Up to 10^{8} N/m^2 (15 ksi) at 200-595 °C (400-1100 °F)	Hydrogen activity equivalent to 0.2 to 1 × 10^{8} N/m^2 (3-15 ksi) at 0-150 °C (30-300 °F)	Precipitation of dissolved ingot cooling	2 to 8 × 10^{8} N/m^2 (30-125 ksi) at 20-100 °C (70-200 °F)	1-10 ppm hydrogen content (iron at 20 °C, or 70 °F) up to 10^{8} N/m^2 (15 ksi) gaseous hydrogen (various metals, T >0.5 melting point)	10^{5} to 10^{8} N/m^2 (15-15,000 psi) gas pressure hydrogen activity must exceed solubility limit near 20 °C (70 °F)
	Observed at -100 to 700 °C (-150 to 1290 °F); most severe near 20 °C (70 °F)	Observed at -100 to 100 °C (-150 to 212 °F); most severe near 20 °C (70 °F)	Observed at -100 to 700 °C (-150 to 1290 °F)	. . .	. . .	. . .	. . .	. . .	. . .
	Strain rate important; embrittlement more severe at low strain	Strain rate important; embrittlement more severe at	Occurs in absence of effect on yield stress; strain rate	. . .	. . .	. . .	. . .	. . .	. . .

	rate; generally more severe in notched or precracked specimens	low strain rate; always more severe in notched or precracked specimens	important						
Failure initiation	Surface or internal initiation; incubation period not observed	Internal crack initiation	Surface and/or internal effect	Surface (decarburization); internal carbide interfaces (methane bubble formation)	Internal defect	Internal defect	Unknown	. . .	Internal defect
Mechanisms	Surface or subsurface processes	Internal diffusion to stress concentration	Surface or subsurface processes	Carbon diffusion (decarburization); hydrogen diffusion; nucleation and growth (bubble formation)	Hydrogen diffusion; nucleation and growth of bubble; steam formation	Hydrogen diffusion to voids	Unknown	Adsorption to dislocations; solid-solution effects	Hydride precipitation

Source: Ref 78

Hydrogen environment embrittlement occurs during the plastic deformation of alloys in contact with hydrogen-bearing gases or a corrosion reaction and is therefore strain rate dependent. The degradation of the mechanical properties of ferritic steels, nickel-base alloys, titanium alloys, and metastable austenitic stainless steels is greatest when the strain rate is low and the hydrogen pressure and purity are high.

Hydrogen stress cracking, often referred to as hydrogen-induced cracking or static fatigue, is characterized by the brittle fracture of a normally ductile alloy under sustained load in the presence of hydrogen. Most often, fracture occurs at sustained loads below the yield strength of the material. This cracking mechanism depends on the hydrogen fugacity, strength level of the material, heat treatment/microstructure, applied stress, and temperature. For many steels, a threshold stress exists below which hydrogen stress cracking does not occur. This threshold is a function of the strength level of the steel and the specific hydrogen-bearing environment. Therefore, threshold stress or stress intensity for hydrogen stress cracking is not considered a material property. Generally, the threshold stress decreases as the yield strength and tensile strength of an alloy increase. Hydrogen stress cracking is associated with absorption of hydrogen and a delayed time to failure (incubation time) during which hydrogen diffuses into regions of high triaxial stress. Hydrogen stress cracking may promote one mode of fracture in an alloy rather than another form normally observed in benign environments. Thus, all modes of cracking have been observed in most commercial alloy systems; however, hydrogen stress cracking usually produces sharp singular cracks in contrast to the extensive branching observed for SCC. The catastrophic cracking of steels in hydrogen sulfide (H_2S) environments referred to as sulfide stress cracking is a special case of hydrogen stress cracking.

Loss in tensile ductility was one of the earliest recognized forms of hydrogen damage. Significant decreases in elongation and reduction in area are observed for steels, stainless steels, nickel-base alloys, aluminum alloys, and titanium alloys exposed to hydrogen. This mode of failure is most often observed in lower-strength alloys, and the extent of loss in tensile ductility is a function of hydrogen content of the material. Loss in tensile ductility behavior is strain rate sensitive and becomes more pronounced as the strain rate decreases.

Hydrogen attack is a high-temperature form of hydrogen damage that occurs in carbon and low-alloy steels exposed to high-pressure hydrogen at high temperatures for extended time. Hydrogen enters the steel and reacts with carbon either in solution or as carbides to form methane gas; this may result in the formation of cracks and fissures or may simply decarburize the steel, resulting in a loss in strength of the alloy. This form of damage is temperature dependent, with a threshold temperature of approximately 200 °C (400 °F).

Blistering occurs predominantly in low-strength alloys when atomic hydrogen diffuses to internal defects, such as laminations or nonmetallic inclusions, and then precipitates as molecular hydrogen (H_2). The pressure of molecular hydrogen can attain such high values that localized plastic deformation of the alloy occurs, forming a blister that often ruptures. Blisters are frequently found in low-strength steels that have been exposed to aggressive corrosive environments (such as H_2S) or cleaned by pickling.

Shatter cracks, flakes, and fish eyes are features common to hydrogen damage in forgings, weldments, and castings. They are attributed to hydrogen pickup during melting operations when the melt has a higher solubility for hydrogen than the solid alloy. During cooling from the melt, hydrogen diffuses to and precipitates in voids and discontinuities, producing the features that result from the decreased solubility of hydrogen in the solid metal. In many aspects, these features are comparable to blistering, and this could be considered a special case of that class.

Microperforation by high-pressure hydrogen occurs at extremely high pressures of hydrogen near room temperature. Microperforation occurs predominately in steels. This form of hydrogen damage manifests itself as a network of small fissures that allow permeation of the alloy by gases and liquids.

Degradation in flow properties in hydrogen environments has been found at ambient temperatures for iron and steel and at elevated temperature for several alloy systems. The steady-state creep rate under constant load has been observed to increase in the presence of hydrogen for some nickel-base alloys.

Hydride formation produces embrittlement in magnesium, tantalum, niobium, vanadium, uranium, thorium, zirconium, titanium, and their alloys, as well as many other less common metals and alloys. The degradation of mechanical properties and the cracking of these metals and their alloys are attributable to the precipitation of metal hydride phases. Hydrogen pickup often results from welding, heat treating, charging from corrosion processes, or during melting of the alloy. Hydride formation is enhanced for some metal-hydrogen systems by the application of stress--the so-called stress-induced hydride formation. Alloy systems that form hydrides are generally ductile at high (>300 K) and low

(<100 K) temperatures at which they fracture by ductile rupture. This temperature dependence is comparable to that observed for the hydrogen embrittlement of ferrous and nickel alloys. Some of these alloys are also susceptible to failure in hydrogen by mechanisms other than hydriding. Some evidence exists that nickel and aluminum alloys may also form a highly unstable hydride that could contribute to hydrogen damage of these alloys; however, this possibility has not been confirmed.

Theories for Hydrogen Damage

As may be appreciated from the numerous classes of hydrogen damage, there are many explanations or theories for these various forms of degradation. The preeminent theories for hydrogen damage are based on pressure, surface adsorption, decohesion, enhanced plastic flow, hydrogen attack, and hydride formation. Although many other theories have been presented, most are variations on these basic models.

The pressure theory of hydrogen damage, or more specifically, hydrogen embrittlement, is one of the oldest models for hydrogen damage (Ref 79). This theory attributes hydrogen embrittlement to the diffusion of atomic hydrogen into the metal and its eventual accumulation at voids or other internal surfaces in the alloy. As the concentration of hydrogen increases at these microstructural discontinuities, a high internal pressure is created that enhances void growth or initiates cracking. This model, although apparently reasonable for blistering and possibly appropriate for some aspects of loss in tensile ductility, does not explain many of the factors observed for classes of failure such as hydrogen stress cracking. However, it is a well-recognized phenomenon that charging hydrogen into steel or nickel alloys at high fugacity, either with high-pressure hydrogen gas or under extreme electro-chemical charging, can create a significant density of voids and irreversible damage to the alloy consistent with a pressure-dependent model.

The surface adsorption theory suggests that hydrogen adsorbs on the free surfaces created adjacent to the crack tip, decreasing the surface free energy and thus the work of fracture (Ref 80). Reduction in the work of fracture would thus enhance crack propagation at stress levels below those typically experienced for a particular alloy in a benign environment. There are many arguments against this model. The principal criticism is that it greatly underestimates the work of fracture and does not account for the discontinuous crack growth that has been observed for hydrogen cracking.

Decohesion describes the effect of hydrogen on the cohesive force between atoms of the alloy matrix (Ref 81, 82). Sufficiently high hydrogen concentrations that accumulate ahead of a crack tip are assumed to lower the maximum cohesive force between metal atoms such that the local maximum tensile stress perpendicular to the plane of the crack then becomes equivalent to or greater than the lattice cohesive force and fracture results.

Enhanced plastic flow is associated with hydrogen dislocation interactions and is primarily based on fractographic observations (Ref 83). This approach proposes that atomic hydrogen enhances dislocation motion, generally screw dislocations, and the creation of dislocations at surfaces and/or crack tips, leading to softening of the material on a localized scale. Although this behavior has been observed in certain steels, hardening by hydrogen has also been found. Careful high-resolution electron microscopy of what appears to be brittle cleavage or intergranular fracture surfaces has revealed evidence of crack tip plasticity in support of this mechanism.

Hydride formation is the degradation of Group Vb metals (niobium, vanadium, and tantalum) and zirconium, titanium, and magnesium in hydrogen environments by the formation of a brittle metal hydride at the crack tip. When sufficient hydrogen is available in the alloy, a metal hydride precipitates. Cracking of the hydride occurs, followed by crack arrest in the more ductile matrix or continued crack growth between hydrides by ductile rupture. Because hydride formation is enhanced by the application of stress, the stress field ahead of the crack tip may induce precipitation of additional hydrides that cleave. Thus, in some alloys, brittle crack propagation occurs by repeated precipitation of hydrides ahead of the crack tip, cleavage of these hydrides, and precipitation of new hydrides and so on until fracture is complete (Ref 84).

Hydrogen attack is one of the better understood mechanisms of hydrogen damage, but is specific to a single class of damage by hydrogen at high temperature (Ref 85). Hydrogen attack may take two forms of damage: surface decarburization or internal decarburization. However, the mechanism is the same for both forms. At elevated temperatures, hydrogen diffuses into the steel or reacts at the surface with carbon in solid solution or that which has dissociated from carbides to form a hydrocarbon--typically methane. This chemical reaction is easily described thermodynamically, which sets this form of damage apart for the more complex forms of hydrogen damage. As expected, damage is dependent on temperature and hydrogen partial pressure. Surface decarburization occurs at temperatures above 540 °C (1000 °F) and internal decarburization at temperatures from 200 °C (400 °F) upward.

Hydrogen Trapping. Although numerous models exist, none adequately explains the behavior exhibited by alloys in different hydrogen-bearing systems. Until a universal theory is developed, one must rely on the phenomenological behavior between the more prominent alloy systems to understand hydrogen damage. One of the principal factors that determines the hydrogen damage susceptibility of ferrous alloys is a phenomenon referred to as trapping (Ref 86). Diffusion studies of iron and steels have shown an initial retardation in diffusion rate or lag time for hydrogen diffusion through these alloys before a steady-state diffusivity compatible with that expected theoretically is achieved. This lag time is generally considered to be related to the filling of traps by hydrogen. In fact, the apparent diffusivity of hydrogen in steels shows a precipitous decrease with increasing concentration of particles (traps), as shown in Fig. 37.

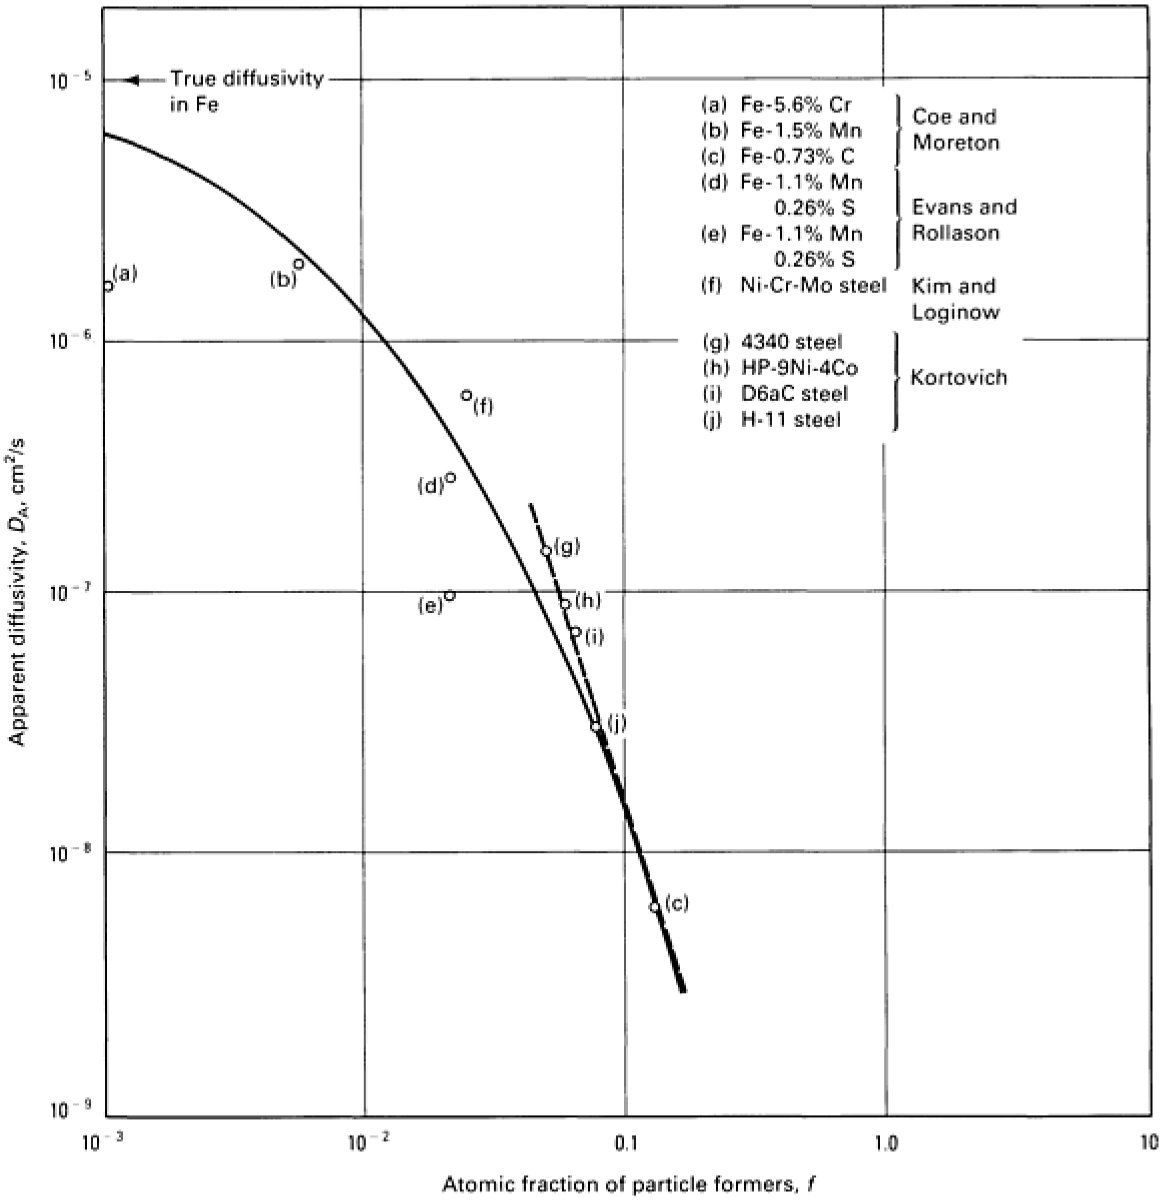

Fig. 37 Decrease in apparent hydrogen diffusivity with increased fraction of precipitate particles. Source: Ref 87

Hydrogen trapping may be considered the binding of hydrogen atoms to impurities, structural defects, or microstructural constituents in the alloy. Binding may be attributed to local electric fields and stress fields, temperature gradients, chemical potential gradients, or physical trapping. These hydrogen traps may be mobile (dislocations, stacking faults) or stationary (grain boundaries, carbide particles, individual solute atoms). They may also be reversible or irreversible traps. Short-duration trapping of hydrogen in which the occupancy time is limited is referred to as reversible. A long residency time for hydrogen characterized by a high binding energy is termed irreversible trapping. Table 4 presents a classification

of hydrogen traps in steel. The concept and investigation of trapping have been developed primarily for steels; however, it may not be restricted to this system. Face-centered cubic alloys show a similar trapping behavior, although at a somewhat reduced efficiency for trapping compared to steels.

Table 4 Classification of hydrogen traps in steels according to size

Trap class	**Example of trap**		**Interaction energy**[a]**, eV**	**Character if known**	Influence diameter, D_i
	Elements at the left of iron	**Elements with a negative** ϵ_H^i [b]			
Point	. . .	Ni	(0.083)	Most probably reversible	**A few interatomic spacings**
	Mn	Mn	(0.09)		
	Cr	Cr	(0.10)		
	V	V	(0.16)		
	. . .	Ce	(0.16)		
	. . .	Nb	(0.16)	Reversible	
	Ti	Ti (vacancy)	0.27		
	Sc	O	(0.71)	Getting more irreversible	
	Ca	Ta	(0.98)		
	K	Ia	(0.98)		
	. . .	Nd	(1.34)		
Linear	Dislocations		0.31	Reversible	**3 nm for an edge dislocation**
			0.25 (average values)	Reversible	
	Intersection of three grain boundaries		. . .	Depends on coherency	. . .
Planar or bimensional	Particle/matrix interfaces				

bimensional	TIC (incoherent)	0.98	Irreversible, gets more reversible as the particle is more coherent	**Diameter of the particle, or a little more as coherency increases**
	Fe_3C MnS	0.8-0.98		
	Grain boundaries	0.27	Reversible	**Same as dislocation**
		Average value 0.55-0.61 (high angle)	Reversible or irreversible	
	Twins	. . .	Reversible	**A few interatomic spacings**
	Internal surfaces (voids)	. . .	. . .	**. . .**
Volume	Voids	>0.22	. . .	**Dimension of the defect**
	Cracks	. . .	. . .	
	Particles	**Depends on exothermicity of the dissolution of H by the particle**	**. . .**

(a) Values of interaction energies are either experimental or are calculated (when between parentheses) at room temperature.

(b) ϵ_H^i is the interaction coefficient. A negative ϵ_H^i means hydrogen is attracted.

Hydrogen Damage in Iron-Base Alloys

Pure Irons. Hydrogen damage may occur in relatively pure irons, such as Ferrovac, Plastiron, and Armco Iron, producing either transgranular or intergranular fracture, depending on the presence of impurities and solutes (carbon, oxygen, and nitrogen) at the grain boundaries and the heat treatment. Hydrogen can also lower the yield strength and flow stress of high-purity iron around room temperature or lead to hardening. Although the yield strength is reduced for impure iron, the flow stress may be increased under conditions of low hydrogen fugacity.

Ferrous Alloys. Many factors affect the behavior of ferrous alloys in hydrogen-bearing environments. Hydrogen concentration, temperature, heat treatment/microstructure, stress level (applied and yield stress), solution composition, and environment are the primary factors involved in determining susceptibility to hydrogen embrittlement. Figure 38 shows the effect of hydrogen concentration on the time to failure for a high-strength steel. The longer the baking time, the lower the residual hydrogen in the steel matrix. In general, increasing the concentration of hydrogen in an alloy will reduce time to failure and the stress level at which failure will occur.

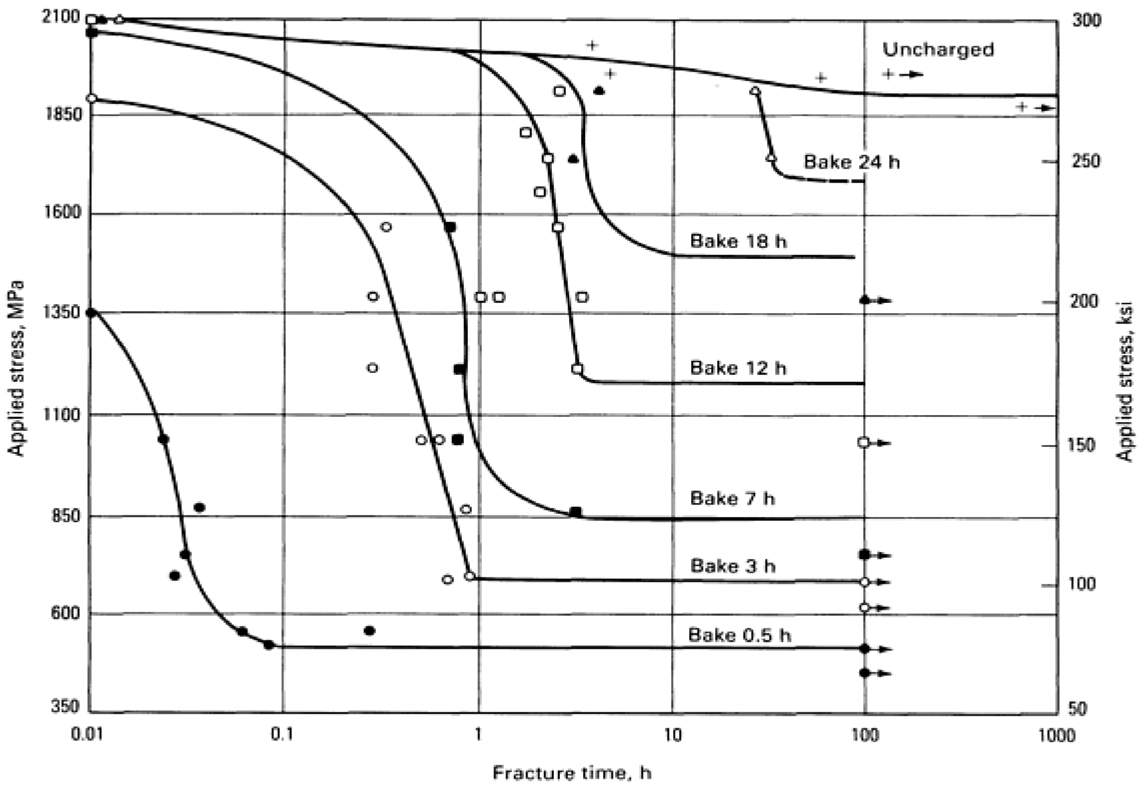

Fig. 38 Static fatigue curves for various hydrogen concentrations obtained by different baking times at 570 °C (300 °F). Sharp-notch high-strength steel specimens; normal notch strength: 2070 MPa (300 ksi). Source: Ref 81

Hydrogen concentration in the alloy is a function of the fugacity or the approximate concentration of hydrogen at the surface exposed to the environment. Therefore, hydrogen embrittlement will be controlled by the hydrogen gas pressure or pH of the environment as well as constituents within the environment that may accelerate or inhibit the entry of hydrogen into the alloy. Elements such as sulfur, phosphorus, antimony, tin, and arsenic and their compounds have been found to inhibit the hydrogen recombination reaction in aqueous solutions, thus increasing the charging of atomic hydrogen into the alloy. In contrast, small amounts of oxygen in gaseous hydrogen environments have demonstrated an inhibitive effect on crack growth of high-strength steels subject to hydrogen cracking.

Figure 39 shows the dependence of both the threshold stress intensity and the crack growth rate of high-strength AISI 4130 steel on hydrogen pressure. Increasing the hydrogen pressure reduces the threshold stress intensity for crack initiation and increases the crack growth rate for a specific stress intensity value.

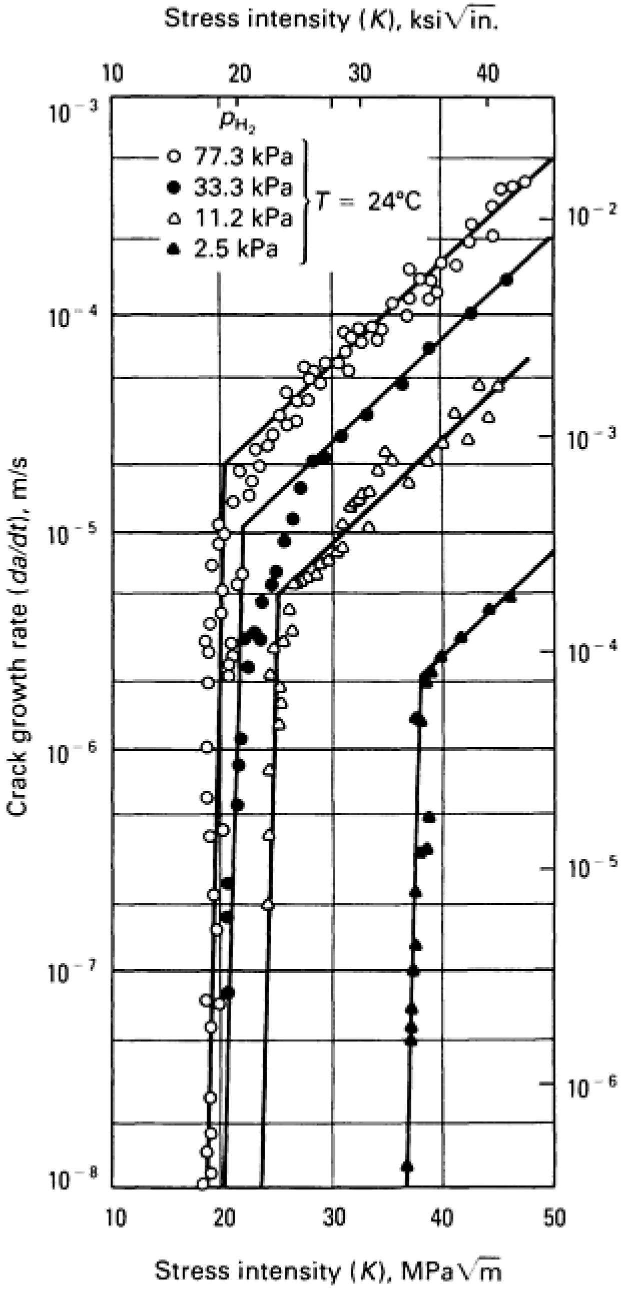

Fig. 39 The *K* dependence of *da/dt* at various hydrogen pressures at 24 °C (75 °F) for AISI 4340 steel. Source: Ref 89

Temperature also plays an important role in the hydrogen embrittlement of ferrous alloys. Embrittlement is most severe near room temperature (Ref 90) and becomes less severe or nonexistent at higher or lower temperatures (Fig. 40). At lower temperatures, the diffusivity of hydrogen is too sluggish to fill sufficient traps, but at high temperatures, hydrogen mobility is enhanced and trapping is diminished. As can be seen in Fig. 40, embrittlement is also strongly strain rate dependent. At high strain rates, fracture may proceed without the assistance of hydrogen because the mobility of hydrogen is not sufficient to maintain a hydrogen atmosphere around moving dislocations.

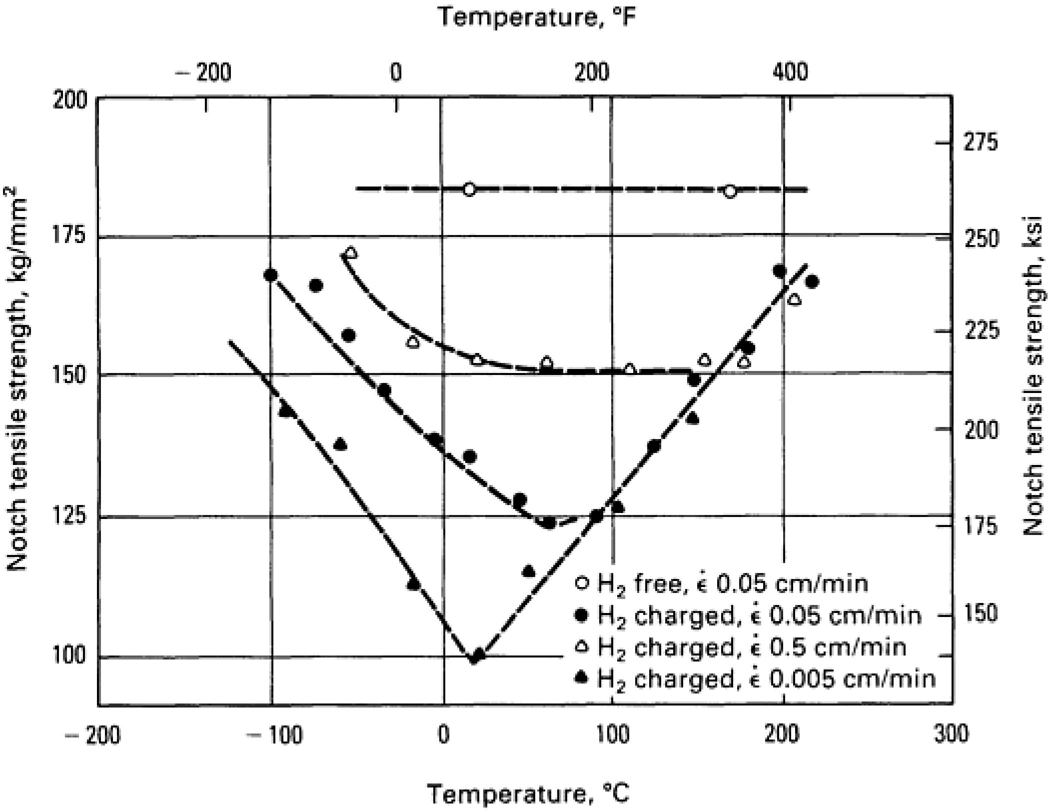

Fig. 40 Notch tensile strength of high-strength steel plotted against testing temperature for three strain rates (crosshead speeds). Source: Ref 90

Figure 41 shows threshold stress intensity as a function of yield strength of AISI 4340 steel in aqueous and gaseous hydrogen. It can be seen that the threshold stress intensity for crack growth generally decreases with increasing yield strength, regardless of environment, and that very high-strength steels are not usable in hydrogen environments. Threshold stress intensities and crack growth rates are a function of the specific hydrogen environments, with H_2S being one of the most severe environments (Fig. 42). At lower yield strengths, the mechanism for hydrogen-assisted failure apparently changes, and blistering becomes the more common feature of failure. The threshold stress intensities for high-strength steels subjected to hydrogen environments are significantly less than those thresholds measured under benign conditions. These lower thresholds lead to subcritical crack growth when compared to critical values expected from fracture mechanics. Therefore, it is common to designate these thresholds as K_{ISCC} or K_{IH}.

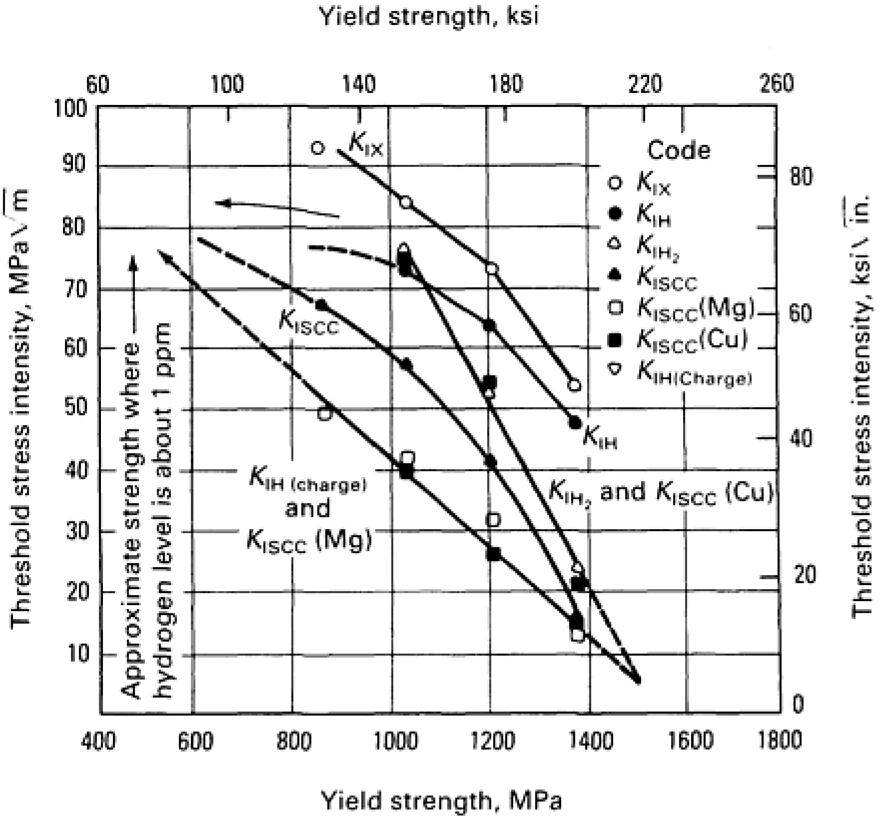

Fig. 41 Effect of yield strength on some threshold stress intensity parameters for crack growth in a commercial AISI 4340 plate. K_{IX} = threshold stress intensity as a function of the yield strength in air; K_{IH} is similar to K_{IX} but slowly loaded; K_{ISCC} (Mg) and K_{ISCC} (Cu) represent specimen coupled to magnesium and copper, respectively. Source: Ref 91

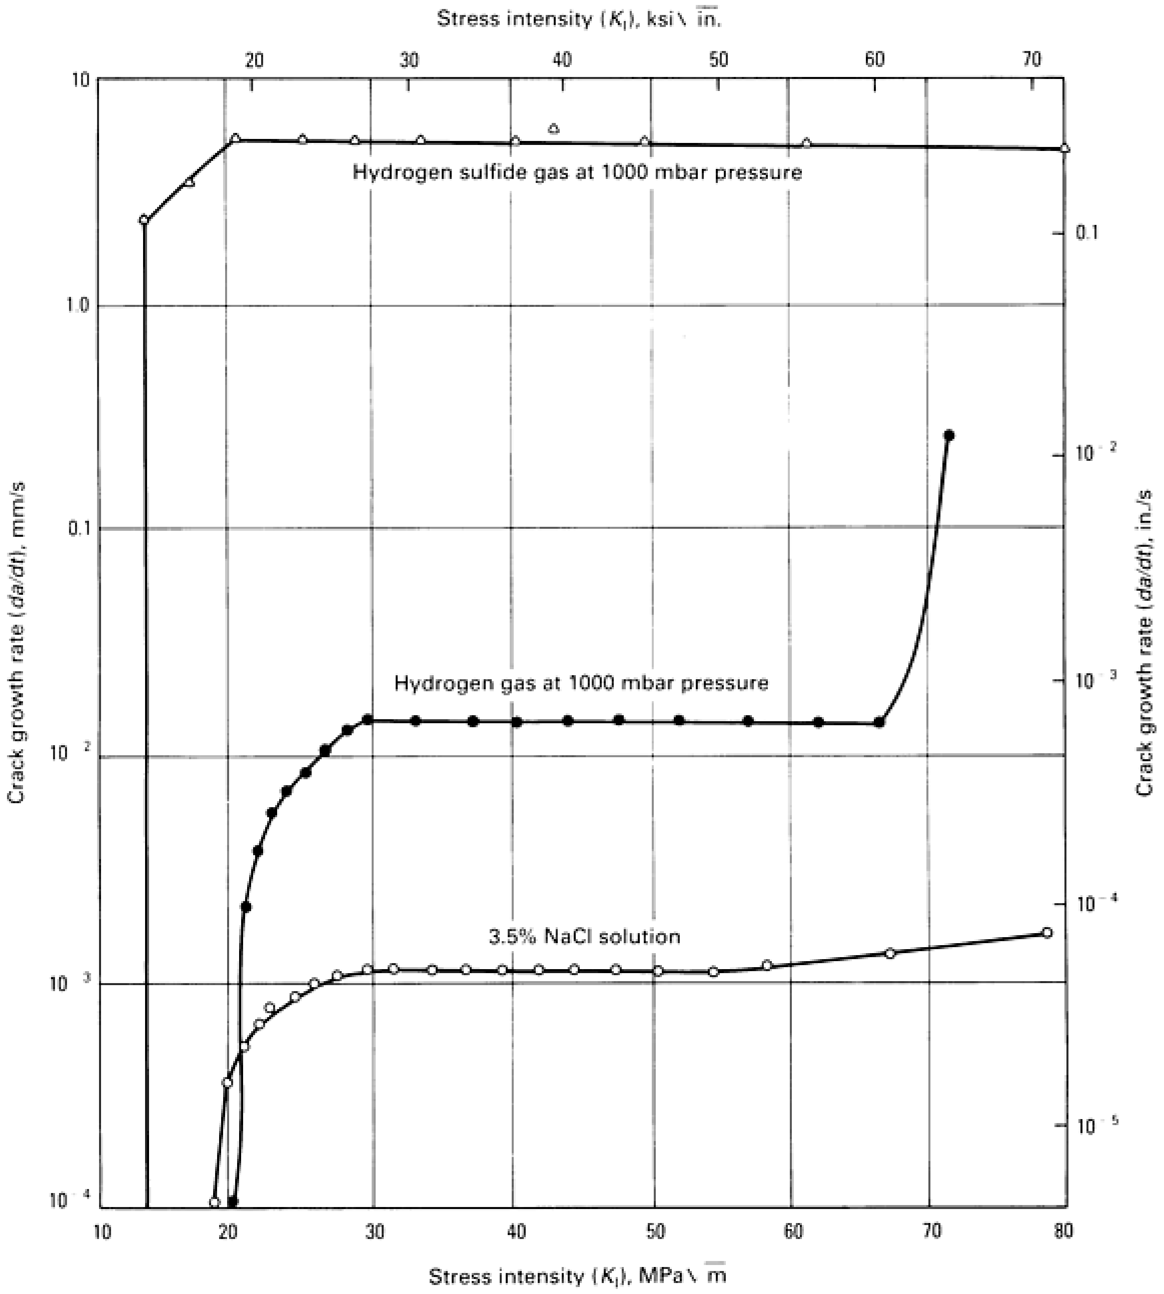

Fig. 42 Crack velocity as a function of stress intensity for a chromium-molybdenum-vanadium steel at 291 K (18 °C, or 64 °F). Source: Ref 92

In low-strength steels (700-MPa, or 100-ksi, yield or less), hydrogen damage occurs predominately by loss in tensile ductility or blistering. For loss in tensile ductility, hydrogen promotes the formation and/or growth of voids by enhancing the decohesion of the matrix at carbide particle and inclusion interfaces.

At higher hydrogen fugacities and often in the absence of stress, blistering or a form of cracking also associated with inclusions--referred to as stepwise, or blister cracking--can occur. Stepwise cracking has been observed frequently in low-strength steels subjected to H_2S-containing environments in the absence of stress (Fig. 43).

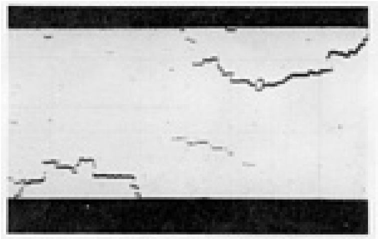

Fig. 43 Stepwise cracking of a low-strength pipeline steel exposed to H_2S. 6×

Fracture of low-strength steels in hydrogen environments may be characterized by ductile dimple-rupture, tearing, cleavage, quasi-cleavage, and, less frequently under certain conditions, intergranular cracking. The article "Modes of Fracture" in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook,* contains fractographs illustrating the effects of hydrogen on the fracture appearance of steels.

High-strength steels (>700-MPa, or 100-ksi, yield) are prone to fracture either in an intergranular fashion or by quasi-cleavage, depending on the stress intensity. These steels commonly display an incubation time before fracture initiates under sustained loading, usually in association with regions of high-stress triaxiality. Because triaxial stresses are created at notch roots or under plane strain, fracture initiates internally in the steel. Intergranular fracture is promoted by the presence of impurity elements at prior-austenite or ferrite grain boundaries. Elements such as phosphorus, sulfur, tin, antimony, and arsenic have been found to enhance the intergranular fracture of high-strength steels in hydrogen, and as expected, temper-embrittled steels are even more susceptible to hydrogen stress cracking than steels that are not embrittled.

Metallurgical structure can have a profound effect on the resistance of steels to hydrogen embrittlement. When compared at equivalent strength levels, a quenched-and-tempered fine-grain microstructure is more resistant to cracking than a normalized or bainitic steel. However, this is also dependent to large extent on the strength level at which this comparison is made. In general, the most resistant microstructure is a highly tempered martensitic structure with equiaxed ferrite grains and spheroidized carbides evenly distributed throughout the matrix. Because microstructure is dependent on heat treatment and composition, these factors are not easily separated and must be considered together. There is also a grain size effect that produces enhanced resistance to hydrogen with decreasing prior-austenite grain size (Fig. 44). However, if the grain size is significantly larger than the plastic zone size, the reverse may be true.

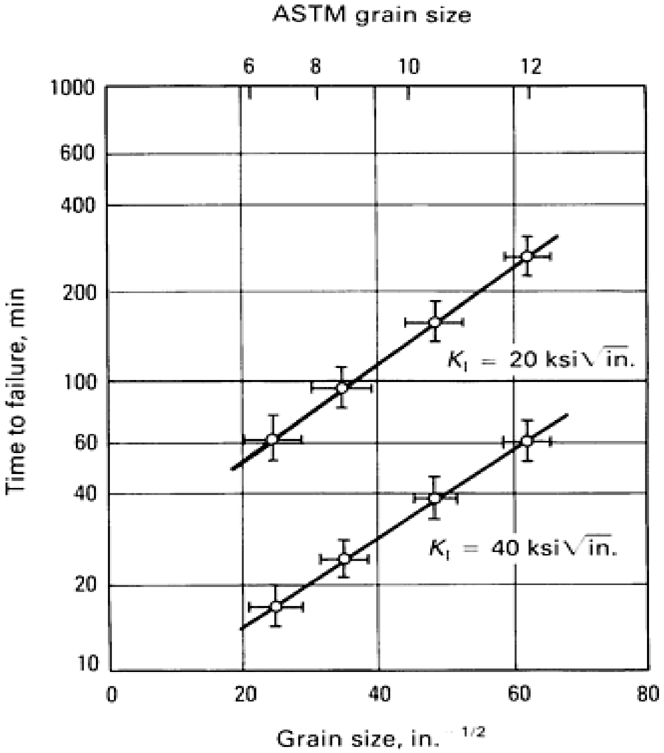

Fig. 44 Illustration of how a refinement in grain size improves resistance to hydrogen failure as measured by the time to failure of two strengths of AISI 4340 steels. Source: Ref 93

The role of alloying elements is quite complex and not easily distinguished from the effects of heat treatment, microstructure, and strength level. Depending on the microstructure and strength level, a specific alloying element may or may not contribute to the hydrogen embrittlement resistance of an alloy or may even increase susceptibility to cracking. The concentration of the alloying element is also a factor in the behavior of alloys in hydrogen. Molybdenum, for example, is beneficial in reducing susceptibility to sulfide stress cracking, a form of hydrogen stress cracking, in AISI 4130 steels up to approximately 0.75 wt%. However, beyond this concentration, a separate Mo_2C phase precipitates in the alloy after tempering at above 500 °C (930 °F), significantly reducing resistance to sulfide stress cracking.

In general, elements such as carbon, phosphorus, sulfur, manganese, and chromium impart greater susceptibility to hydrogen embrittlement in low-alloy steels. However, large increases in such elements as chromium, nickel, and molybdenum in order to produce stainless steels alter the crystal structure, microstructure, and subsequently the heat treatment requirements and therefore the hydrogen embrittlement behavior of this group of ferrous alloys.

The response of stainless steels to hydrogen-bearing environments is basically related to their strength level. Ferritic stainless steels have excellent resistance to hydrogen embrittlement because of their low strength and enhanced ductility. However, if the ferritic stainless steels are cold worked, they may become susceptible to cracking in hydrogen environments. Similarly, austenitic stainless steels are highly resistant to hydrogen cracking in the annealed or lightly cold-worked condition, but can become quite susceptible when heavily cold worked. This increased susceptibility to hydrogen cracking due to increasing yield strength from cold working is similar to the dependence of carbon and low-alloy steel on strength. Decreased resistance to hydrogen for highly cold-worked austenitic stainless steels is largely attributed to the deformation-induced formation of martensite. For those austenitic stainless steels having a very stable austenite phase and high yield strength (such as 21Cr-6Ni-9Mn) susceptibility is considered to be solely a function of yield strength similar to the body-centered cubic (bcc) low-alloy steel behavior.

Other factors that may affect the susceptibility of austenitic stainless steels to hydrogen damage are the possible formation of metastable hydride phase that would produce a hydride-based fracture path and the interaction of hydrogen with stacking faults to reduce stacking fault energy in the austenite, leading to planar slip and brittle fracture. The degree of participation of any of these factors has not been established.

Just as a similarity exists between austenitic stainless steels and low-alloy steels at the high-strength end of the spectrum, the lower-strength austenitics behave in the same manner as the low-alloy steels in hydrogen by a reduction in ductility. Figure 45 shows the loss in reduction in area for several austenitic stainless steels in high-pressure hydrogen. It is apparent that a wide variation in hydrogen damage exists between these various austenitic alloys. Type 304L is the most susceptible to loss in tensile ductility, and the stable austenitic alloys, such as 15Cr-25Ni, are almost unaffected. As observed in carbon and low-alloy steels, there is a temperature effect (∼0 °C, or 32 °F) involved with the ductility loss in austenitic stainless steels, although it is somewhat lower than the room-temperature dependence observed for low-alloy steels.

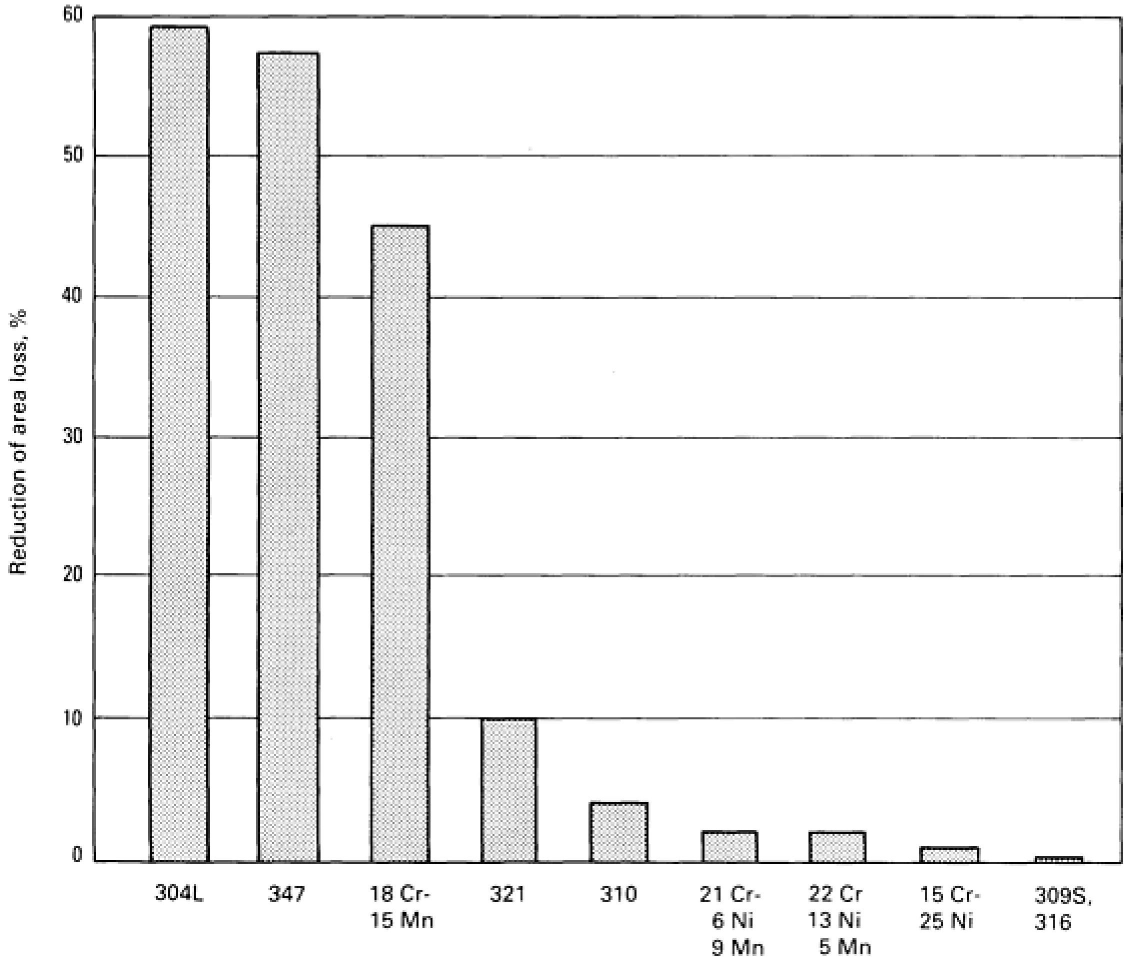

Fig. 45 Ductility loss for several austenitic stainless steels in high-pressure hydrogen. Source: Ref 94

It is apparent that there are many similarities in behavior between stainless steels and carbon and low-alloy steels in hydrogen. Similarly, the martensitic and precipitation-hardening stainless steels exhibit the same dependence on strength level and microstructure as observed in low-alloy steels. Martensitic and precipitation-hardening stainless steels are extremely susceptible to hydrogen embrittlement with increasing yield strength. Figure 46 compares several grades of precipitation-hardening stainless steel with type 410 martensitic stainless steel tested in an aqueous environment saturated with H_2S. The numbers adjacent to each data point represent the tempering or aging treatment. Generally, the same trend of decreasing time to failure with increasing yield strength is observed as for low-alloy steels. The poor performance of the type 410 martensitic stainless compared to precipitation-hardening stainless steels is typical of the behavior of most martensitic stainless steels, which also compare poorly with low-alloy steels at the same strength level.

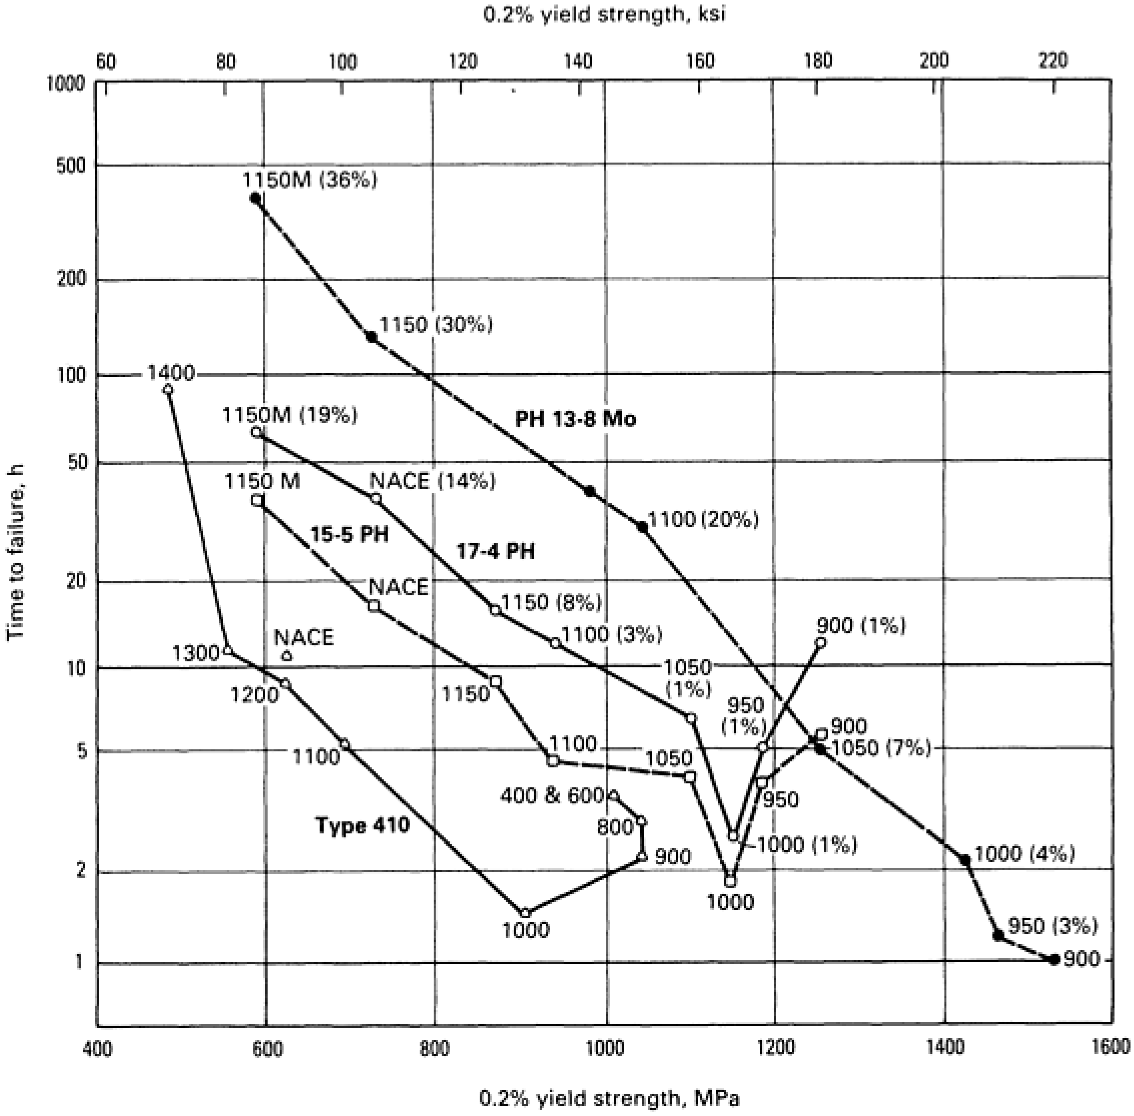

Fig. 46 Time to failure of various alloys as a function of yield strength when tested under 345 MPa (50 ksi) of applied stress in saturated H_2S. Numbers adjacent to data points represent tempering or aging treatment; parenthetical values indicate approximate amounts of austenite. Source: Ref 95

Ultrahigh-strength (>1400 MPa, or 200 ksi) martensitic stainless steels, low-alloy steels, and maraging steels are extremely susceptible to cracking in hydrogen environments, including aqueous solutions containing NaCl. Although chlorides are the primary cause of SCC in many alloy systems, it is generally accepted that the mechanism of cracking in ultrahigh-strength steels is related to hydrogen embrittlement.

Figure 47 compares the crack growth rate of AISI 4340 in several environments against grade 250 maraging steel. The maraging steel has much better resistance to crack propagation in 3.5% NaCl than 4340 and displays a high threshold stress intensity for crack propagation. For maraging steels, there is evidence that peak-aged condition or slight overaging may improve resistance to hydrogen embrittlement, but underaging is detrimental to resistance.

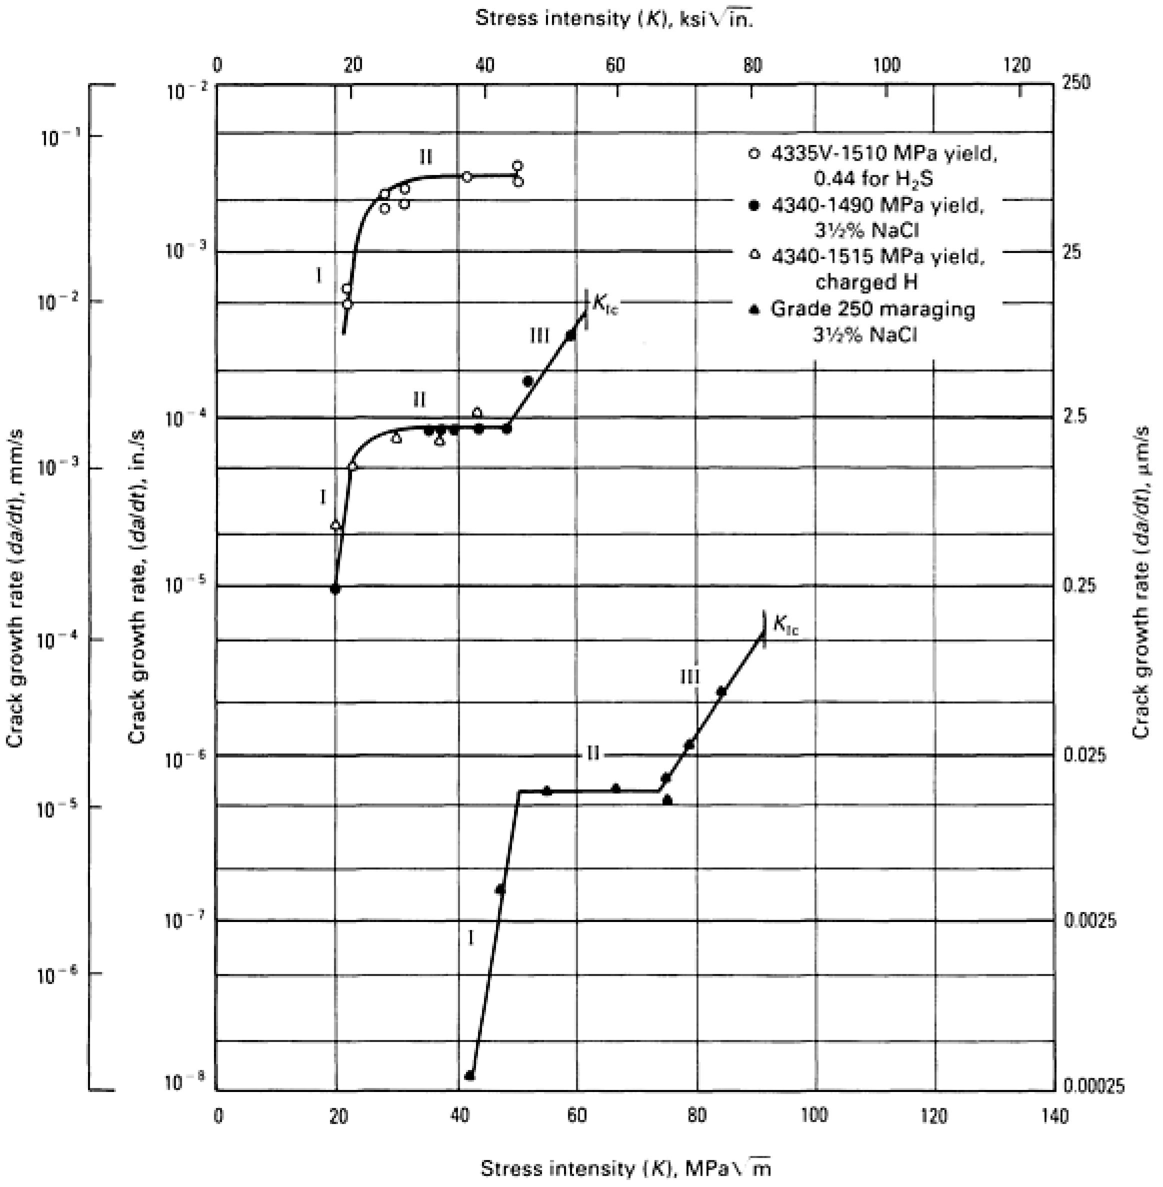

Fig. 47 Effect of material, environment, and stress intensity level on crack growth. Source: Ref 87

Hydrogen attack is strictly a high-temperature form of hydrogen damage that primarily affects ferritic steels. Hydrogen attack is dependent on time, temperature, and hydrogen pressure. After a certain incubation time, a diminution of properties occurs with the onset of decarburization and cracking (Fig. 48). Resistance of steels to hydrogen attack is related to the stability of the carbides, and as such, the addition of carbide-stabilizing elements such as vanadium, titanium, niobium, and molybdenum enhance the resistance to this form of hydrogen damage.

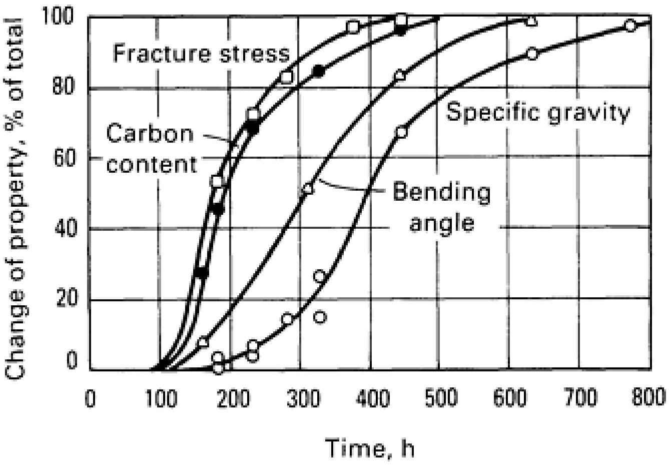

Fig. 48 Relative change of properties of an SAE 1020 steel as a function of time of exposure to hydrogen at 427 °C (800 °F) and 6.2 MPa (900 psi) partial pressure. Source: Ref 85

Chromium-molybdenum steels have been found to be the most resistant to hydrogen attack for the cost involved; therefore, a great deal of industrial experience has been gained with these alloys. Much of this experience has been compiled and plotted to provide a guideline for steel selection as a function of temperature and hydrogen partial pressure and is presented as a series of curves often referred to as a Nelson diagram (Ref 96). As more experience is gathered on the use of these steels in hydrogen, this series of curves is periodically updated by the American Petroleum Institute.

Nickel Alloys

Nickel and its alloys are susceptible to hydrogen damage in both aqueous and gaseous hydrogen environments. The same factors that affect hydrogen embrittlement susceptibility in ferrous alloys are also prevalent in nickel alloys, although to a lesser degree. In general, fcc metals, because of their greater ease of slip and reduced solute diffusivities as compared to bcc materials, are less susceptible to hydrogen damage. As with ferrous alloys, hydrogen in nickel and its alloys may introduce intergranular, transgranular, or quasi-cleavage cracking, and although the macroscopic features appear to be brittle, on a microscopic scale there is a high degree of local plasticity, suggesting that hydrogen enhances flow at the crack tip. Figure 49 shows the reduction in ductility associated with hydrogen charging a 72Ni-28Fe alloy as a function of strain rate. Almost identical behavior was observed for unalloyed nickel.

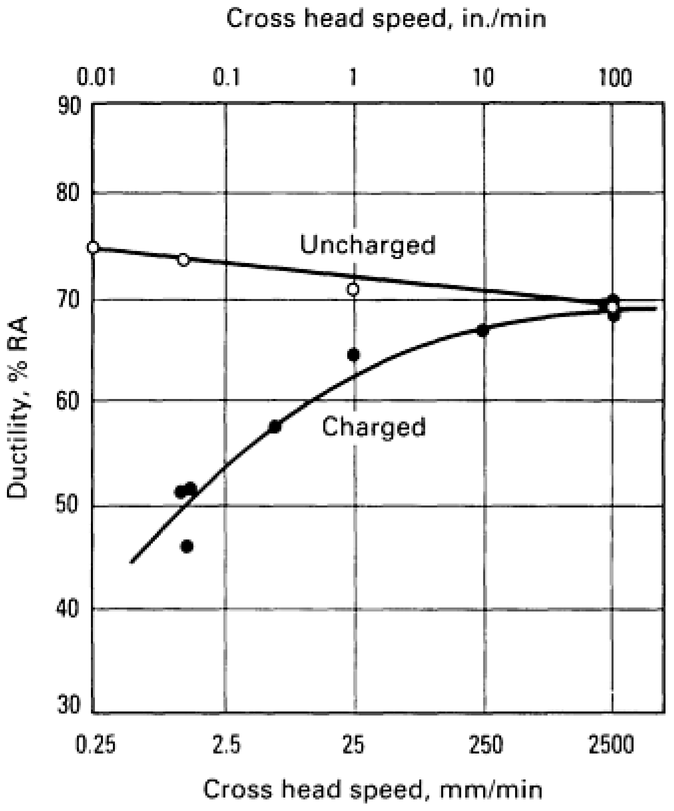

Fig. 49 Ductility at fracture as a function of strain rate in a hydrogen-charged and uncharged 72Ni-28Fe alloy. Source: Ref 81

Alloys based on the ternary Fe-Ni-Cr system (Incoloy) and Inconel alloys show reductions in ductility when charged with hydrogen, depending on the specific thermomechanical treatments performed on the alloy. Generally, these alloys are more resistant to hydrogen stress cracking in the cold-worked and unaged condition as compared to the cold-worked and aged condition. Age-hardenable alloys show the least resistance to hydrogen when aged to their peak or near-peak strength. Stabilization treatments, followed by aging, reduce the resistance of these alloys as compared to direct aging. Increased cold work also produces a loss in tensile ductility. Hydrogen stress cracking of these alloys may also occur, rather than a loss in tensile ductility, when they possess high yield strengths or are under high hydrogen fugacity. The nickel-copper alloys (Monels) have also been found to be susceptible to hydrogen embrittlement, with increasing strength obtained by cold working or aging.

Several nickel-base alloys are resistant to hydrogen-stress cracking when cold worked to yield strengths in excess of 1240 MPa (180 ksi). However, when these alloys (Hastelloy alloy C-276, Hastelloy alloy C-4, and Inconel alloy 625) are aged at low temperature, their resistance to hydrogen cracking is considerably diminished. This behavior is attributed to the segregation of phosphorus and sulfur to grain boundaries, which provide low-energy fracture paths (much the same as occurs in high-strength steels), or to an ordering reaction of the form $Ni_2(Cr, Mo)$. Figure 50 presents data that relate the reduction in area loss to ordering for the ordering alloy Ni_2Cr charged with hydrogen.

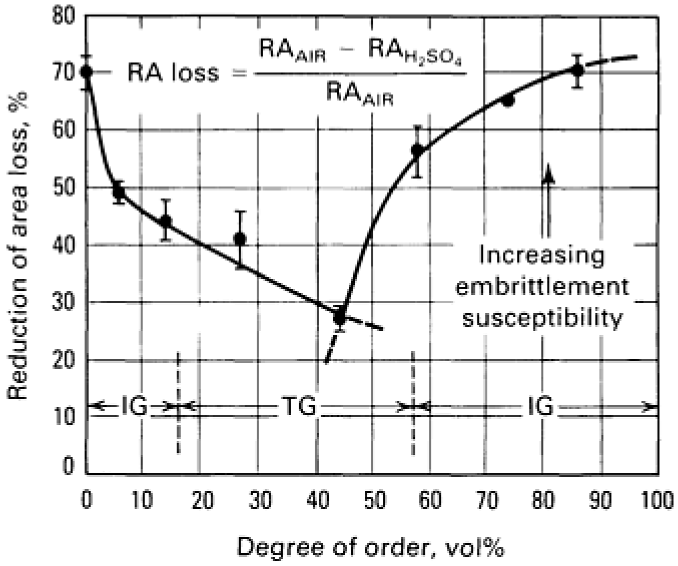

Fig. 50 Effect of the degree of order on the embrittlement susceptibility of Ni_2Cr. Regions of intergranular (IG) and ductile transgranular fracture (TG) are shown. Source: Ref 97

Aluminum Alloys

Only recently has it been determined that hydrogen embrittles aluminum. For many years, all environmental cracking of aluminum and its alloys was represented as SCC; however, testing in specific hydrogen environments has revealed the susceptibility of aluminum to hydrogen damage. Hydrogen damage in aluminum alloys may take the form of intergranular or transgranular cracking or blistering. Blistering is most often associated with the melting or heat treatment of aluminum where reaction with water vapor produces hydrogen. Blistering due to hydrogen is frequently associated with grain-boundary precipitates or the formation of small voids. Blister formation in aluminum is different from that in ferrous alloys in that it is more common to form a multitude of near-surface voids that coalesce to produce a large blister.

In a manner similar to the mechanism in iron-base alloys, hydrogen diffuses into the aluminum lattice and collects at internal defects. This occurs most frequently during annealing or solution treating in air furnaces prior to age hardening.

Dry hydrogen gas is not detrimental to aluminum alloys; however, with the addition of water vapor, subcritical crack growth increases dramatically (Fig. 51). The threshold stress intensity for cracking of aluminum also decreases significantly in the presence of humid hydrogen gas at ambient temperature (Fig. 52).

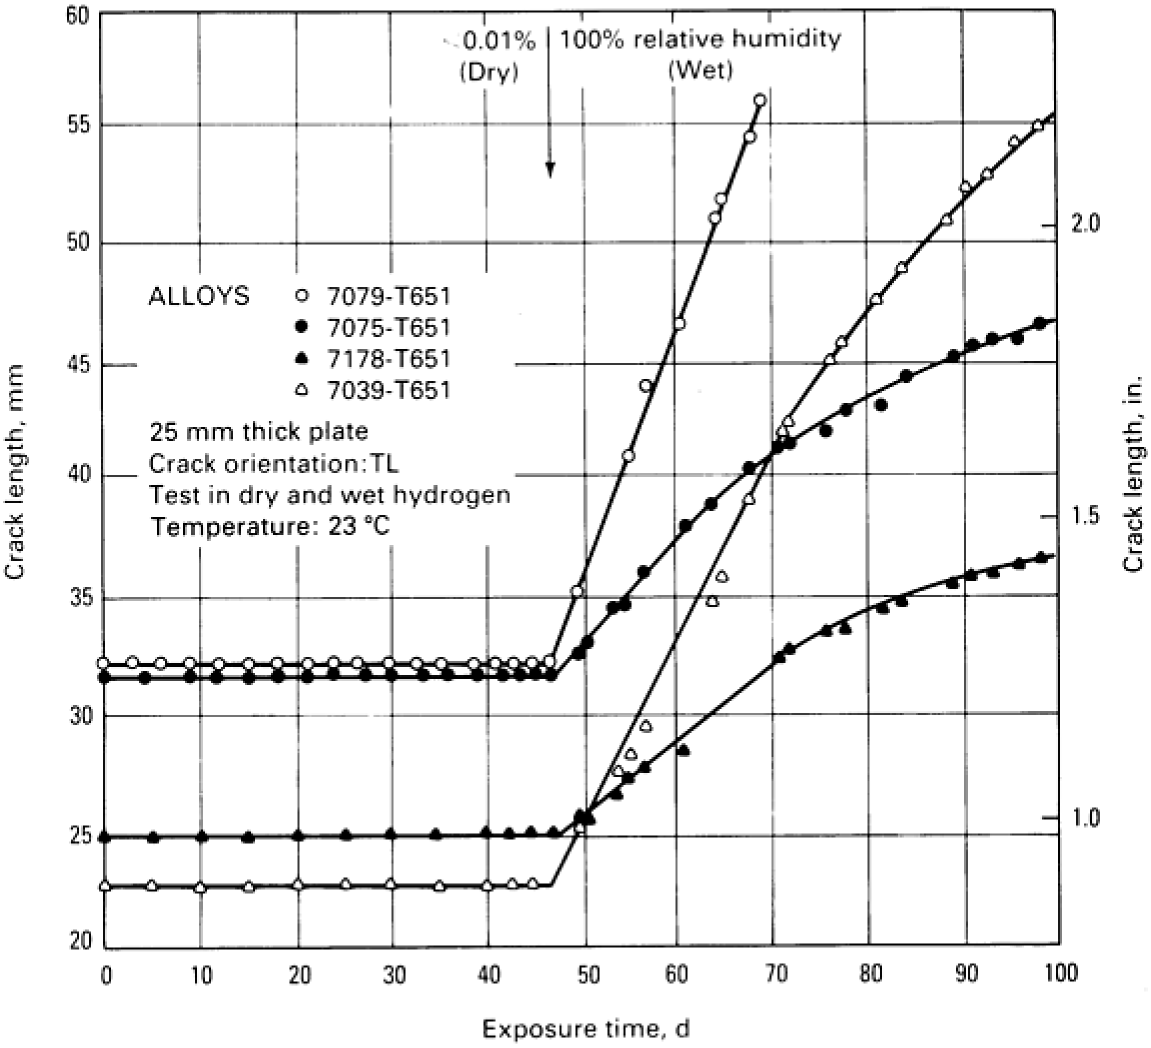

Fig. 51 Effect of humidity on subcritical crack growth of high-strength aluminum alloys in hydrogen gas. Source: Ref 98

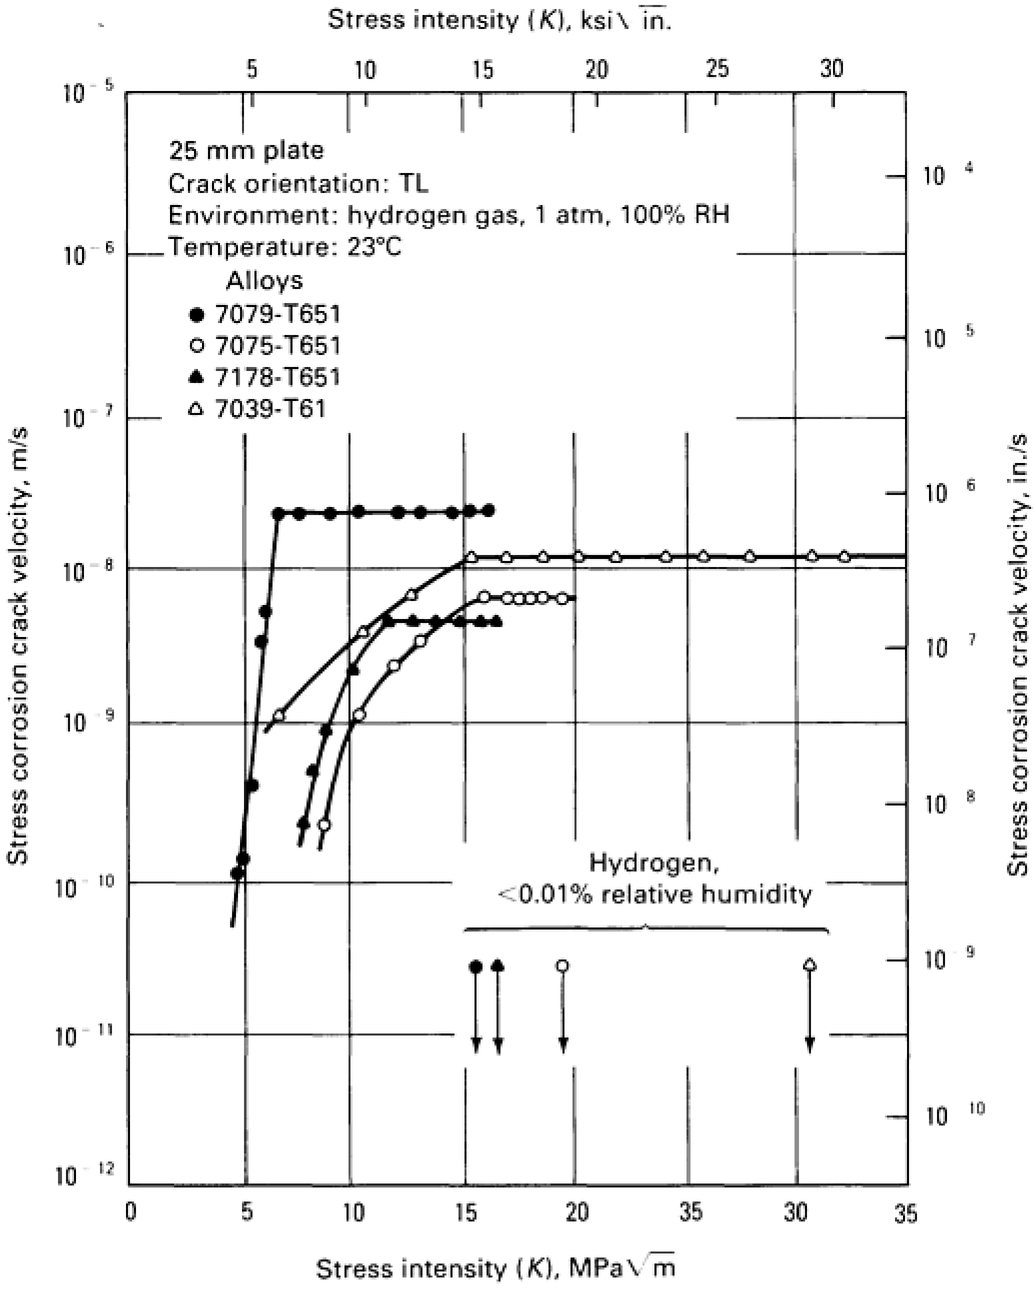

Fig. 52 Crack velocity of four high-strength aluminum alloys plotted as a function of crack-tip stress intensity in moist and dry hydrogen gas. Source: Ref 98

Crack growth in aluminum in hydrogen is also a function of hydrogen permeability, as in the iron- and nickel-base alloys. Hydrogen permeation and the crack growth rate are a function of potential, increasing with more negative potentials, as expected for hydrogen embrittlement behavior. Similarly, the ductility of aluminum alloys in hydrogen is temperature dependent, displaying a minimum in reduction in area below 0 °C; this is similar to other fcc alloys (Ref 98).

Most of the work on hydrogen embrittlement of aluminum alloys has been on the 7000 series (Al-Zn-Mg); therefore, the full extent of hydrogen damage in aluminum alloys has not been determined or the mechanisms established. Some evidence for a metastable aluminum hydride has been found that would explain the brittle intergranular fracture of aluminum-zinc-magnesium alloys in water vapor. However, the instability of the hydride is such that is has been difficult to evaluate. Another explanation for intergranular fracture of these alloys is preferential decohesion of grain boundaries containing segregated magnesium. Overaging of these alloys increases their resistance to hydrogen embrittlement in much the same way as for highly tempered martensitic steels.

Copper Alloys

A common form of hydrogen damage in copper has been known for years as steam embrittlement and is observed only when copper contains oxygen. Hydrogen entering the metal reacts with oxygen either is solid solution or at oxide inclusions to form water. At temperatures above the critical temperature for water, steam forms, and the pressure generated is sufficient to produce microcavity formation and cracking. The equation for reaction with cuprous oxide particles is:

$$Cu_2O + 2H = 2Cu + H_2O(g)$$

The circumstances under which this form of hydrogen damage occurs are typically related to the annealing of copper in a hydrogen atmosphere. At lower temperatures, steam is not generated and therefore does not create the problem. Although the use of oxygen-free copper essentially eliminates susceptibility to steam embrittlement, the heavy cold working of oxygen-free copper can result in grain-boundary void formation when hydrogen is introduced.

Compared to the ferrous and nickel alloys, relatively little work has been performed specific to the hydrogen embrittlement of copper-base alloys. There is some indication that age-hardenable alloys such as beryllium copper are susceptible to embrittlement under severe charging conditions, producing a loss in tensile ductility. A systematic study of these alloys remains to be performed.

Titanium Alloys

Titanium and its alloys suffer hydrogen damage primarily by hydride-phase formation. Pure α-titanium is relatively unaffected by small concentrations (<200 ppm) of hydrogen; however, above this content, the impact toughness is impaired. The purity of the α-titanium is important to its behavior in hydrogen. Commercially pure titanium is much more sensitive to hydrogen than pure titanium is. The amount of hydrogen necessary to induce ductile-to-brittle transition behavior in commercially pure titanium is one-half the amount needed in pure titanium.

Loss in impact toughness also occurs in α/β-titanium and β-titanium alloys and is sometimes referred to as impact embrittlement. This hydrogen damage at high strain rates is the result of hydrides that precipitate after the high-temperature exposure of titanium to hydrogen.

Another mode of failure for titanium alloys in hydrogen predominates under slow strain rate loading. Figure 53 shows the strain rate behavior for an α/β alloy. As the strain rate increases, the effect of hydrogen is lost. As in steels, the reduction in area and the elongation of titanium alloys are diminished in hydrogen.

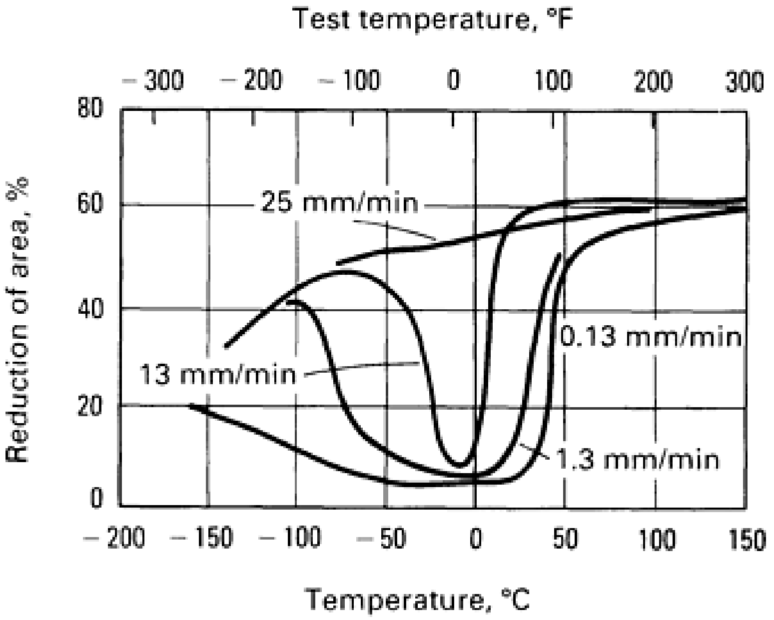

Fig. 53 Effects of hydrogen content (375 ppm), strain rate, and temperature on the tensile ductility of typical α/β titanium alloy unnotched tensile specimens. Source: Ref 99

Both types of failure for titanium alloys in hydrogen are attributed to hydride-phrase precipitation. The low strain rate embrittlement is related to hydride formation caused by strain-enhanced precipitation, but embrittlement under impact is caused by hydride-phase formation after fabrication or heat treatment. Unlike many hydride-forming systems, titanium forms a stable hydride, but the kinetics of precipitation are slow compared to the Group Vb metals. Therefore, embrittlement is more prone to occur at low strain rates at which precipitation can proceed at a rate that is sufficient to provide a brittle crack path.

Because hydrogen solubility increases with temperature for these alloys, hydride embrittlement typically decreases as the temperature increases. Additionally, at higher temperatures, the hydride many become more ductile, reducing brittle crack initiation. As expected, the threshold stress intensity for crack propagation is also a function of the hydrogen content decreasing with increasing hydrogen.

The role of microstructure in the hydrogen damage of titanium is quite complex and is not fully understood. However, it has been determined that under slow strain rates the α/β alloys fail by intergranular separation along boundaries but that completely α alloys fracture by transgranular cleavage. Embrittlement is not a severe in α/β alloys with a continuous equiaxed α matrix as for those alloys with a continuous acicular β matrix (Ref 100). However, this behavior is a function of hydrogen pressure and may be reversed at lower pressures (Ref 101).

Zirconium Alloys

Zirconium and its alloys suffer hydrogen damage by hydride precipitation, especially in the presence of notches or at low temperatures in smooth specimens. Failure occurs by cracking of the brittle, precipitated hydride phase during straining. These fractured hydrides may then accelerate fracture by ductile microvoid formation and coalescence, primarily enhancing the latter. Similarly to titanium, zirconium alloys precipitate stable hydrides. Depending on the hydrogen content of the alloy, one of two stable or one metastable hydride may precipitate. The two stable zirconium hydrides are δ-hydride (fcc) and ε-hydride (face-centered tetragonal, fct). The metastable γ-hydride also has an fct structure (Ref 102).

As in other alloy systems, the tensile ductility generally diminishes with increasing hydrogen content (Fig. 54). Similarly, the hydrogen embrittlement of these alloys is dependent on stress state, becoming more pronounced as the stress state moves from uniaxial to biaxial to triaxial tension. For example, the local stress state ahead of a sharp notch can produce a region of biaxial or triaxial stress, thus increasing the susceptibility to hydrogen embrittlement.

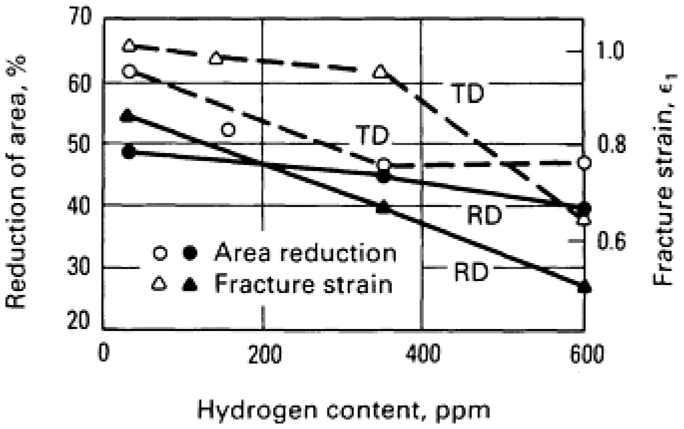

Fig. 54 Influence of hydrogen on the reduction of area at fracture and the true strain at fracture for Zircaloy-2. TD transverse direction; RD, rolling direction. Source: Ref 103

The embrittlement by zirconium hydride formation is a strong function of temperature, because increasing the temperature will reduce the volume fraction of hydride due to the increased solid solubility of hydrogen with temperature. Ductile-to-brittle transition behavior has been observed in hydrided zirconium alloys, and the transition temperature has been found to be a function of hydrogen content, increasing with hydrogen concentration (Fig. 55).

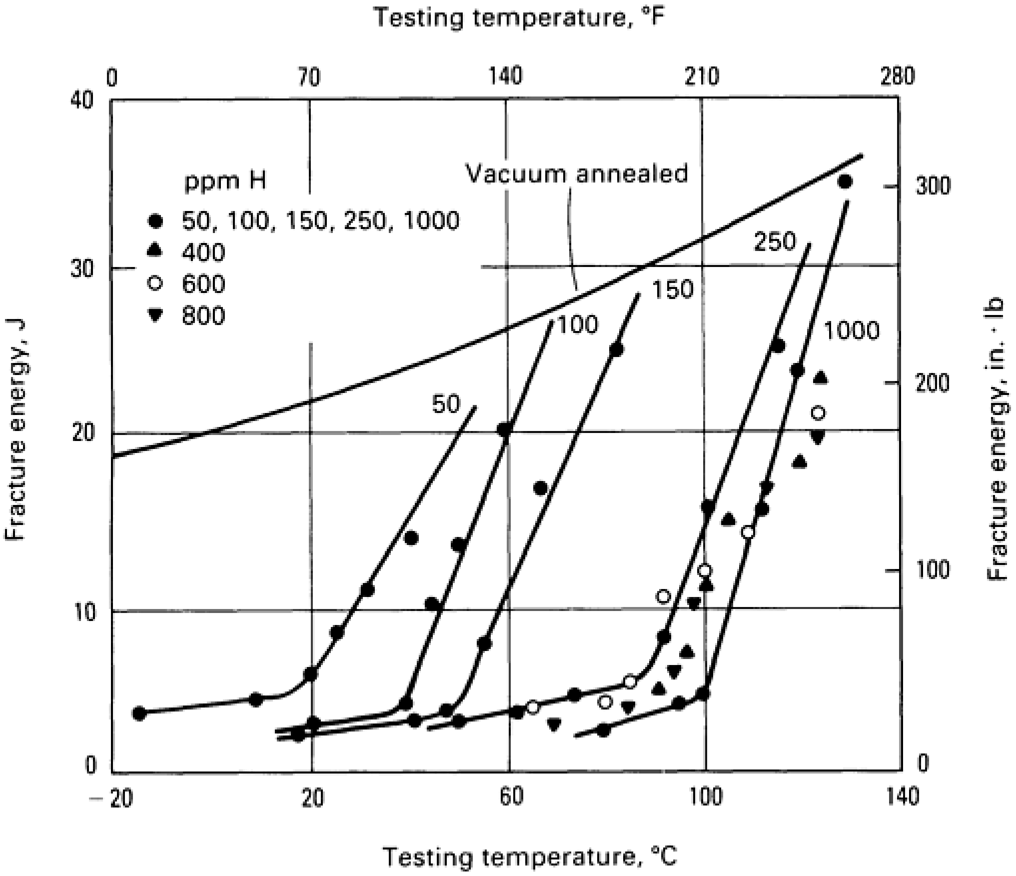

Fig. 55 Ductile-to-brittle transitions in hydrided zirconium. Source: Ref 104

Hydride distribution and morphology are other important factors in the extent of hydrogen damage in zirconium alloys. Because the brittle hydride phase provides an easy crack path for fracture, the distribution and morphology of this phase in relation to the sense of the applied tensile stress determine the degree of embrittlement. The shape and distribution of the hydrides are dependent on heat treatment prior to precipitation and cooling rate during precipitation. Rapid cooling produces a more uniform dispersion of hydrides, while slow cooling enhances the grain-boundary precipitation of the hydride platelets. Toughness is not as dramatically affected in the former case as in the latter.

Vanadium, Niobium, Tantalum, and Their Alloys

These metals and alloys are all embrittled by hydrogen--primarily by hydride-phase formation; however, unlike titanium and zirconium alloys, these systems do not form a stable hydride. The introduction of hydrogen into unalloyed vanadium, niobium, and tantalum increases the yield strength of these metals and creates ductile-to-brittle transition behavior (Fig. 56).

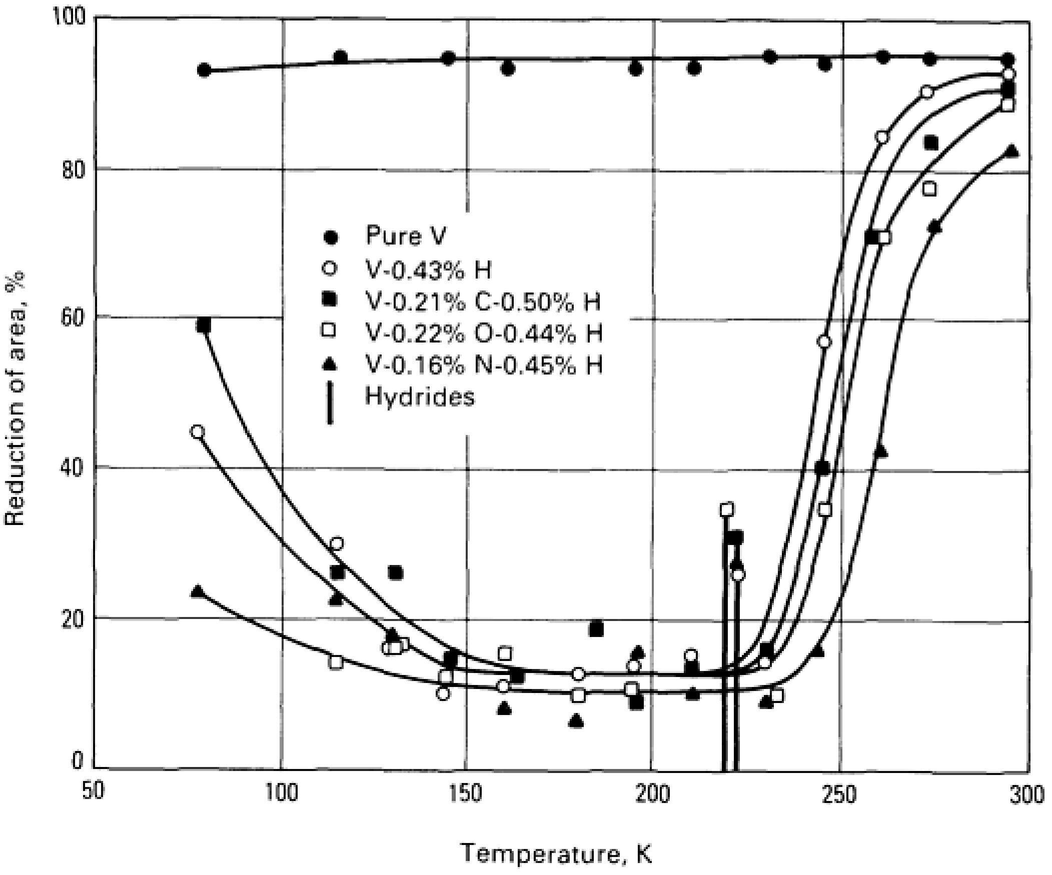

Fig. 56 Effect of hydrogen and combined carbon, nitrogen, or oxygen and hydrogen on the temperature dependence of ductility in vanadium. Source: Ref 105

Many of these alloy systems display ductile-to-brittle transition behavior in the presence of hydrogen in much the same manner as that described for zirconium and titanium. However, these alloys have been found to exhibit grain-boundary cracking when low levels of hydrogen are present in solid solution below the terminal solid-solubility limit. In fact, all of the hydride-forming systems exhibit hydrogen damage from solute hydrogen at low concentrations of hydrogen at which hydrides are not expected to precipitate. Although fracture transition is correlated with hydride formation in vanadium, other systems, such a niobium, zirconium, titanium, and tantalum, display more classical hydrogen embrittlement without a corresponding hydride-phase precipitation (Ref 102, 105).

Once the hydrogen content exceeds terminal solid solubility, damage may proceed by hydride precipitate formation. Below this solubility limit, the relative resistance to cracking or loss in tensile ductility is largely a function of the hydrogen concentration and alloying elements (Fig. 57). However, the terminal solid solubility for a particular metal-hydrogen system that forms hydrides is an extremely strong function of stress so that reference to stress-free equilibrium phase diagrams for predicting hydride phase behavior may be inaccurate (Ref 107).

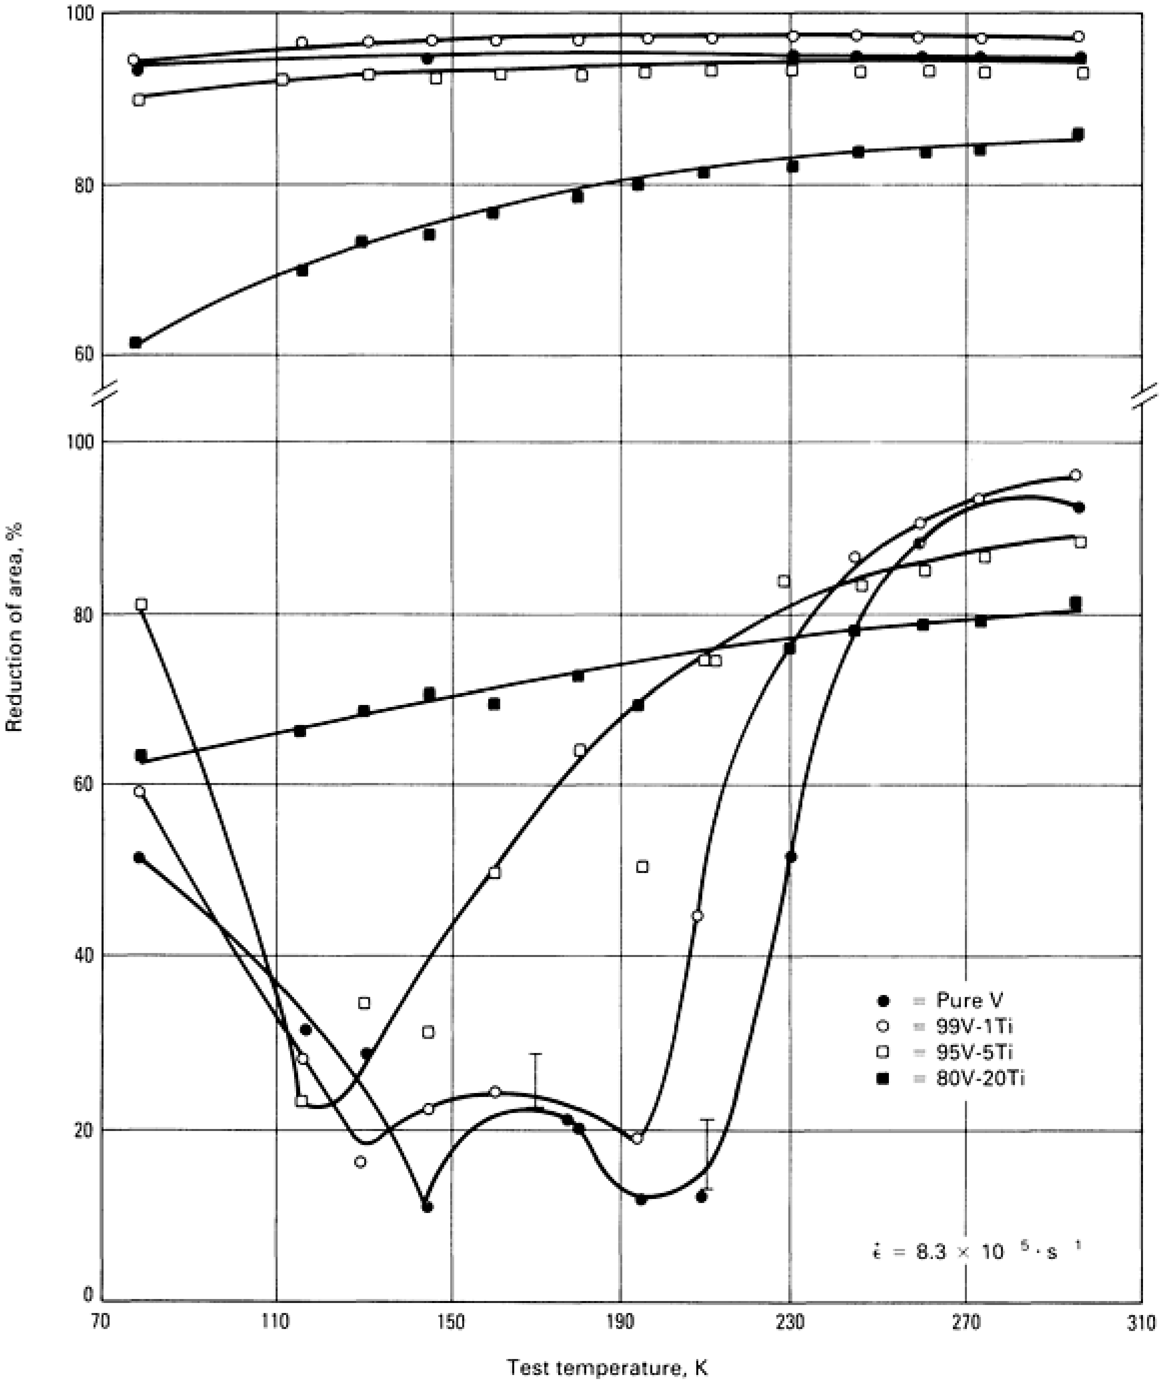

Fig. 57 Temperature dependence of reduction of area for selected hydrogen-charged (bottom) and uncharged (top) vanadium-titanium alloys. Source: Ref 106

There are many other metals and alloys that form hydrides (for example, thorium, uranium, and beryllium), but far less is known about these systems. Therefore, a great deal of investigation into the metal/hydrogen interactions in many alloy systems remains to be done, especially considering the trend in new materials for advanced technologies.

Liquid-Metal Embrittlement

M.H. Kamdar, Benet Weapons Laboratory, U.S. Army Armament Research, Development, and Engineering Center

Liquid-metal embrittlement is the catastrophic brittle failure of a normally ductile metal when coated with a thin film of a liquid metal and subsequently stressed in tension. The fracture mode changes from a ductile to a brittle intergranular or brittle transgranular (cleavage) mode; however, there is no change in the yield and flow behavior of the solid metal. As shown in Fig. 58, embrittlement manifests itself as a reduction in fracture stress, strain, or both. Fracture can occur well below the yield stress of the solid. The stress needed to propagate a sharp crack or a flaw in liquid is significantly lower than that necessary to initiate a crack in the liquid-metal environment. In most cases, the initiation or the propagation of cracks appears to occur instantaneously, with the fracture propagating through the entire test specimen. The velocity of crack or fracture propagation has been estimated to be 10 to 100 cm/s (4 to 40 in./s).

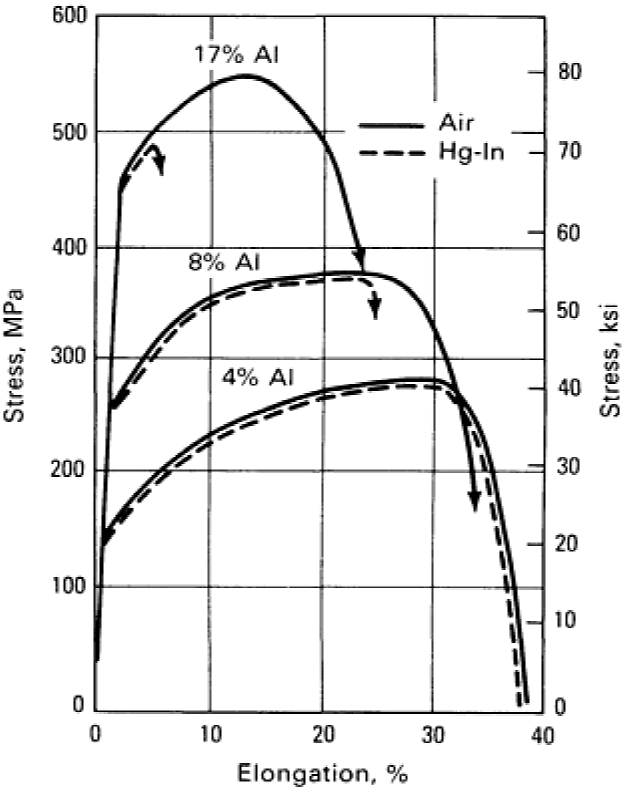

Fig. 58 Effects of environment on the yield stress and strain-hardening rate on various iron-aluminum alloys tested in air and mercury-indium solutions

Examination of LME fracture surfaces shows complete coverage by the liquid metal. Liquid metal is in intimate contact with the solid and is usually difficult to remove. The fracture mode becomes apparent when special techniques are used to remove the liquid. It should be emphasized that gross amounts of liquid are not necessary; even micrograms of liquid lead can cause LME in 75-mm (3-in.) thick steel tubes (Fig. 59). The fracture is usually brittle intergranular, with little indication of crack branching or striation to indicate slow crack propagation.

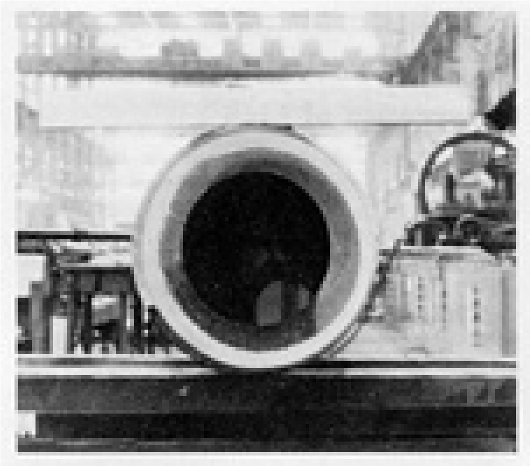

Fig. 59 Liquid lead induced brittle fracture of a 75-mm (3-in.) section of a 4340 steel pressure vessel tube

The presence of liquid at the moving crack tip appears necessary for fast fracture. However, in high-strength brittle metals, a crack initiated in the liquid may propagate in a brittle manner in the absence of liquid. In low-strength metals, a transition may occur from brittle-to-ductile failure under similar circumstances, Although far less frequent than brittle fracture, embrittlement can also occur by a ductile dimpled rupture mode in certain steels, copper alloys, and aluminum alloys. The embrittlement then manifests itself as the degradation of the mechanical properties in the solid metal. Fracture is not limited to polycrystalline metals and the presence of grain boundaries. Single crystals of zinc and cadmium are also embrittled by liquid metal and result in fracture by a brittle cleavage mode (Fig. 60). These are but a few of the manifestations of LME.

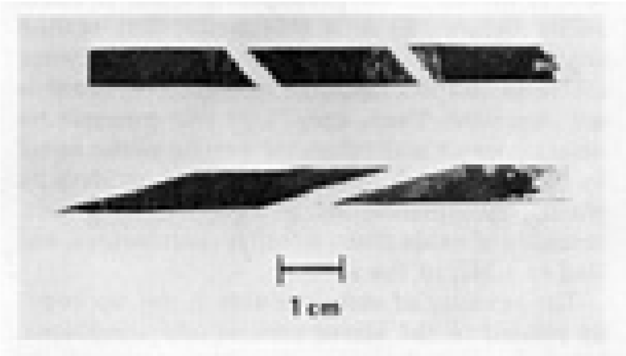

Fig. 60 Cleavage fracture of cadmium monocrystals at 25 °C (75 °F) following a coating with Hg-60In (at.%) solution

Embrittlement is not a corrosion, dissolution, or diffusion-controlled intergranular penetration process, but is considered to be a special case of brittle fracture that occurs in the absence of an inert environment and at low temperatures. Time- and temperature-dependent processes are not considered to be responsible for the occurrence of LME. Also, in most cases of LME, little or no penetration of liquid metal into the solid metal is observed. The embrittlement of the solid metal coated with liquid metal or immersed in the liquid does not depend on the time of exposure to the liquid metal before testing (Fig. 61) or on whether the liquid is pure or presaturated with the solid. Usually, one of the prerequisites is that the solid has little or no solubility in the liquid and forms no intermetallic compound to constitute an embrittlement couple. However, exceptions to this empirical rule have been noted.

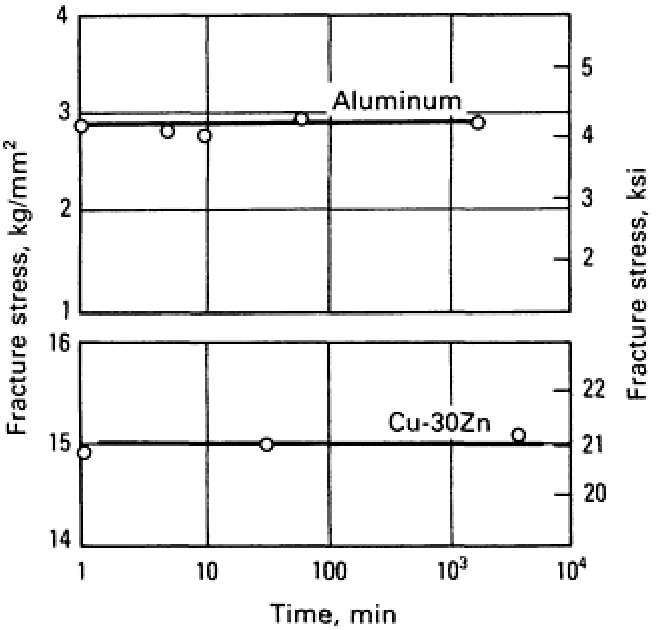

Fig. 61 Fracture stress of polycrystalline aluminum and Cu-30Zn brass as a function of exposure to liquid mercury before testing in this environment

An increase in test temperature decreases embrittlement, which leads to a brittle-to-ductile transition. Severe embrittlement occurs near the freezing temperature of the liquid. In fact, in iron-lead, iron-indium (Fig. 62), and many other metallic couples, embrittlement occurs below the melting temperature of the liquid. This new phenomenon is called solid metal induced embrittlement (SMIE) of metals and is described in the following section of this article.

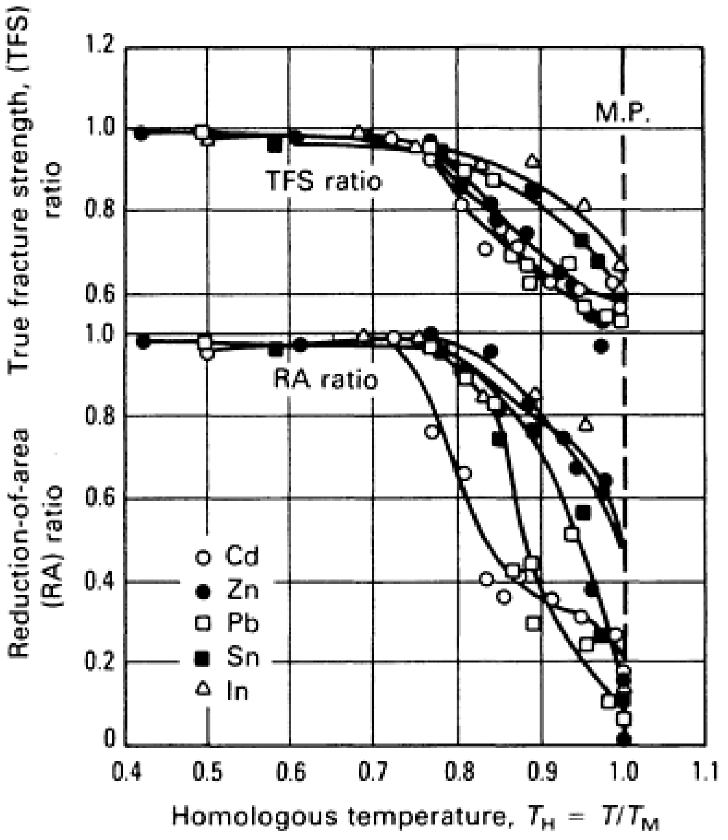

Fig. 62 Embrittlement of 4140 steel by various liquid metals below their melting point. Comparison of normalized true fracture strength (TFS) ratio and the reduction-of-area (RA) ratio as a function of homologous temperature T_H where T and T_M are the test and the melting temperature of the liquid metal, respectively, M.P., melting point

The occurrence of LME is not a laboratory curiosity. Such failures have been observed in metals and alloys in the following industrial applications and processes:

- Small amounts of alloying elements, such as lead and tellurium, added to steel to improve machinability may lead to embrittlement (Fig. 63). Internally leaded steels have cracked at lead inclusions. For example, leaded steel gears have cracked during induction-hardening heat treatments, and warm punching of leaded steel shafts has resulted in unexpected fracture during the forming operation
- Cadmium-plated titanium and steels are embrittled during high-temperature service by molten cadmium
- Indium, used as a high-vacuum seal in steel chambers, has caused cracking during bakeout operations
- Zircaloy tubes used in nuclear reactors have been cracked by both solid and liquid cadmium
- Although infrequent, LME also occurs in petrochemical plants and in the steel industry during heat treatment, hot rolling, brazing, soldering, and welding operations
- Embrittlement of steel occurs by electroplated or dipped cadmium, zinc, or tin--all of which provide corrosion resistance
- In liquid metal cooled reactors, liquid lithium can cause both corrosion and LME in metals and alloys

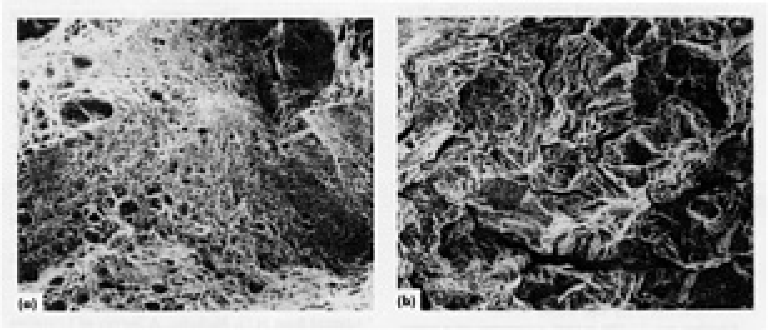

Fig. 63 Influence of lead on the fracture morphology of a 4340 steel. (a) Ductile failure after testing in argon at 370 °C (700 °F). (b) The same steel tested in liquid lead at 370 °C (700 °F) showing brittle intergranular fracture

The distinctive features of embrittlement and of the resultant fracture surfaces are a significant loss in mechanical properties and usually a brittle fracture mode, although ductile fracture morphologies have been reported. The fracture surfaces are easily distinguished from those due to SCC, which are similar to fracture due to hydrogen or temper embrittlement. The embrittlement is severe, and the propagation of fracture is very fast in the case of LME as compared to that in SCC. Thus, the predominant occurrence of brittle fracture surfaces, fast or catastrophic fracture, significant loss in ductility and strength, and the presence of liquid at the tip of the propagating crack are some of the characteristics that may be used to distinguish LME from other environmentally induced failures. Detailed information on the mechanisms of LME and the susceptibility of specific metals and alloys to liquid metal induced failures can be found in the Selected References provided at the end of this article.

Mechanisms of Embrittlement

Several mechanisms have been proposed to explain LME, including stress-assisted dissolution of the solid at the crack tip and reduction in the surface energy of the solid by the liquid metal. It has been suggested that embrittlement is associated with liquid-metal adsorption induced localized reduction in the strength of the atomic bonds at the crack tip or at the surface of the solid metal at sites of stress concentrations.

With this possibility in mind, consider the crack shown in Fig. 64. Crack propagation will occur by the breaking of A-A_0 bonds at the crack tip and, subsequently, the breaking of similar bonds at the propagating crack tip by the chemisorbed liquid-metal atom B (a vapor phase from a solid in a solid-solid metal embrittlement couple or an elemental gas, such as hydrogen, may also provide the embrittling atom B). Next, assume that liquid-metal atom B at the crack tip reduces the cohesive strength of A-A_0 bonds. The chemisorption process presumably occurs spontaneously or only after the A-A_0 bonds have been strained to some critical value. In any event, electronic rearrangement occurs because of adsorption, which weakens the bonds at the crack tip. When the applied stress is increased so that it exceeds the reduced breaking strength of A-A_0 bonds, then the crack propagates. The liquid-metal atom becomes stably chemisorbed on the freshly created surfaces. The surface diffusion of the liquid-metal atoms over the chemisorbed liquid-metal atoms feeds the advancing crack tip, thus propagating the crack at reduced stress and causing complete failure of the specimen.

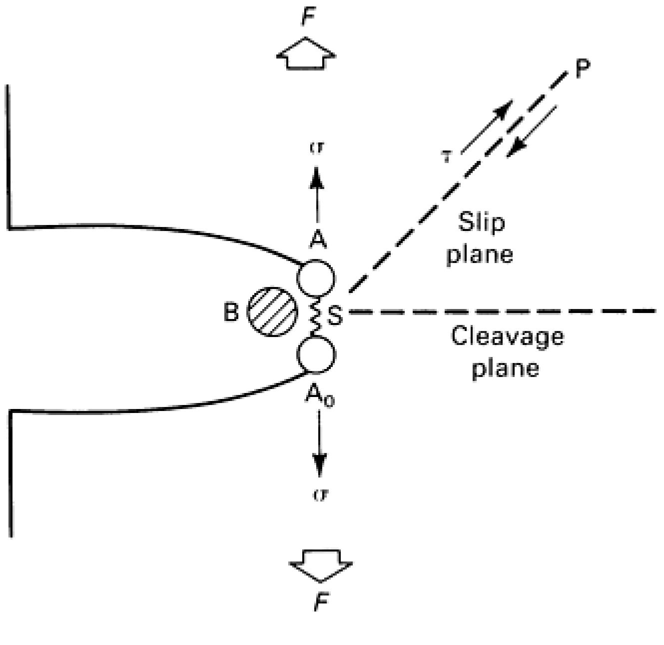

Fig. 64 Schematic illustrating displacement of atoms at the crack tip. The bond A-A_0 constitutes the crack tip, and B is the liquid-metal atom.

In the above mechanism, it is assumed that reduction in the tensile cohesion is predominantly responsible for the occurrence of embrittlement, although both tensile as well as shear cohesion are reduced. Embrittlement can also occur by the adsorption-induced reductions in the shear strength of the atomic bonds at the crack tip. The reduced shear strength facilitates nucleation of dislocations or slip at low stresses at or near the crack tip. This localized increase in plasticity produces a plastic zone with sufficiently large strains such that a void is nucleated ahead of the crack tip at precipitates, inclusions, or at subboundaries in a single crystal. The void will grow, and crack growth will occur. The fracture occurs by the ductile rupture mode, with the appearance of dimples on the fracture surfaces. The localized increased plasticity results in an overall reduction in the strain at failure as compared to that in the absence of liquid metal, thus causing embrittlement. For embrittlement due to reduced shear cohesion, lower strain at failure or subcritical crack growth by linkage of voids is the measure of LME.

A schematic representation of the above process is given in Fig. 65, and supporting fractographic evidence is given for high-strength steel (Fig. 66a) and beryllium-copper alloys (Fig. 66b) broken in liquid-metal environments. Conversely, Fig. 66(c) to (e) and Fig. 67 provide strong support for the reduced tensile cohesion mechanism.

(d) Scanning electron micrograph of the failed machine screw shown in (c). (e) Fracture surface of a Monel specimen that failed in liquid mercury. The fracture is predominantly intergranular with some transgranular contribution.

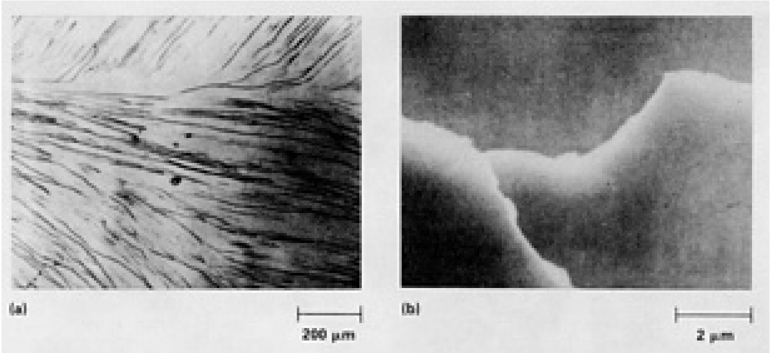

Fig. 67 Optical micrograph (a) and scanning electron micrograph (b) showing cleavage fracture surface produced by cracking zinc single crystal in liquid mercury

Most often, LME induces a brittle intergranular or cleavage fracture mode at reduced tensile stresses and thus supports the tensile decohesion mode. However, the dimpled ductile failure mechanism of LME should be considered an embrittling

process in a failure analysis in which the reduction in the mechanical parameters at fracture is the measure of embrittlement. AlthoughLME can occur by either a brittle or a ductile fracture mode, both degrade the mechanical properties of the solid metal.

Role of Liquid in Crack Propagation

In the mechanism of embrittlement described above, it was implied that once a crack is nucleated subsequent crack propagation occurs mechanically with liquid absent at the crack tip or occurs by the continuous presence of the liquid-metal atoms at the propagating crack tip caused by the surface diffusion of liquid-metal atoms over chemisorbed liquid-metal atoms. The role of liquid in embrittlement should be investigated by measuring the crack growth rate as a function of temperature and stress intensity. The velocity of crack propagation, or crack growth rate, in SCC has been extensively investigated. However, such investigations in liquid metal have been reported only recently for brass (Fig. 68) and aluminum in liquid mercury. The velocity of crack growth in brass in liquid mercury was at least two orders of magnitude higher than that in an inert environment. The crack propagation activation energy for brass in liquid mercury is only 3 to 5 kcal/mol (Fig. 69). This corresponds to diffusion of liquid mercury over mercury adsorbed on brass. The very high velocities of crack propagation and very low activation energies are considered to be distinguishing features from similar investigations in SCC environments in the same metals. Such characteristics can be used to differentiate liquid metal induced crack propagation from stress-corrosion or hydrogen damage.

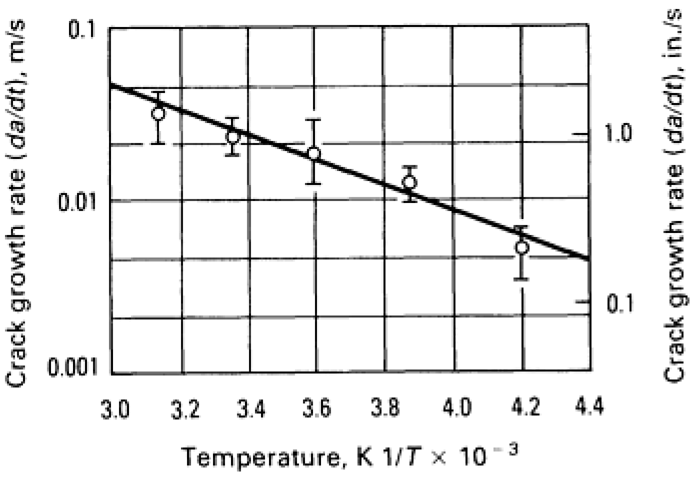

Fig. 69 Crack growth rate versus reciprocal of temperature for brass in liquid mercury. The activation energy, *Q*, is 4 cal/mol.

Occurrence of LME

Susceptibility to LME is unique to specific metals. For example, liquid gallium embrittles aluminum but not magnesium, and liquid mercury embrittles zinc but not cadmium. The equilibrium phase diagrams of most embrittlement couples show that they form simple binary systems with little or no solid solubility. Also, they form immiscible liquids in the liquid state, and they usually do not form intermetallic compounds. This is an empirical observation, and exceptions have been reported, although it is valid for many embrittlement couples.

The most critical and mandatory condition for LME is that the liquid should be in intimate contact with the surface of the solid to initiate embrittlement and should subsequently be present at the tip of the propagating crack to cause brittle failure. Even a thin oxide film several angstroms thick may prevent interaction between the solid and the liquid so that embrittlement is not observed. Thus, conditions that promote intimate contact and enhanced wetting of the liquid by the solid, such as freshly created surfaces by plastic deformation in a liquid environment, breaking of oxide films, or other such factors, will lead to LME of the solid.

The severity of embrittlement is not necessarily related to the above criteria and conditions, but it is related to the chemical nature of the embrittling species. For example, zinc is more severely embrittled by liquid gallium than by mercury. In addition, the severity of embrittlement is related to the properties of the solid and depends on such factors as strength, alloying elements, grain size, and strain rate. The severity or occurrence or nonoccurrence of embrittlement depends on the type of test and whether the solid contains stress concentrators, such as preexisting cracks or flaws, or is smooth and free of stress raisers. By increasing the possibilities of maintaining high stress concentrations, the susceptibility of the solid to LME is also increased. For example, smooth specimens of low-alloy low-strength steel are not embrittled by liquid lead, but the same steel containing a fatigue precrack is severely embrittled by liquid lead.

Certain other prerequisites must be fulfilled before fracture can initiate in a solid. For a ductile nonprecracked metal, these are an applied tensile stress, plastic deformation, and the presence of a stable obstacle to slip serving as a stress concentrator. This obstacle can be preexisting (for example, a grain boundary) or can be created during deformation (for example, a twin or kink band).

In addition, there should be an adequate supply of liquid metal to adsorb at the obstacle and subsequently at the propagating crack tip (only a few atomic monolayers of liquid-metal atoms are necessary for LME.) Plastic deformation or yielding may mean localized deformation in few grains rather than general yielding of the solid metal. If a specimen contains a preexisting crack, then adsorption of the liquid at the crack tip and some tensile stress are necessary to propagate a crack. If the solid is notch brittle, LME will occur at reduced stress. However, a crack, once initiated, may propagate in a brittle manner in the absence of the liquid at the tip. Thus, it may not be necessary for the liquid to be

present at the propagating crack tip. The occurrence of LME in an embrittlement couple requires good wetting of the surface of the solid by the liquid, the presence of sufficient stress concentration to initiate or propagate a crack in liquid, and possible concurrence with the empirical observations mentioned above.

Effects of Metallurgical, Mechanical, and Physical Factors

It has been shown that the prerequisites for liquid metal induced brittle fracture are the same as those for brittle fracture in an inert environment at low temperatures, that is, the need for plastic flow. A barrier for crack nucleation, sufficient tensile stress, and adsorption of liquid metal are necessary to initiate and/or propagate a crack. From the investigations reported for many embrittlement couples, including classic zinc-mercury couples, it has been concluded that adsorption-induced embrittlement can be regarded as a special case of brittle fracture that normally occurs in brittle materials at low temperatures in an inert environment (ductile fracture can also result by the adsorption-induced reductions in the shear strength of the atomic bonds at the crack tip). Thus, the effects of yield stress, grain size, strain rate, temperature, and so on, in a liquid-metal environment follow trends similar to those noted for metals tested in an inert environment.

Effects of Grain Size. The grain size dependence of fracture stress has been investigated for zinc-mercury, cadmium-gallium, brass and copper alloys in mercury, and low-carbon steel in lithium. In these and other instances, the fracture stress varied linearly with the reciprocal of the square root of grain size and followed the well-known Cottrell-Petch relationship of grain size dependence on fracture stress. For the zinc-mercury couple shown in Fig. 70, fracture is nucleation controlled in region I, whereas in region II it is propagation controlled.

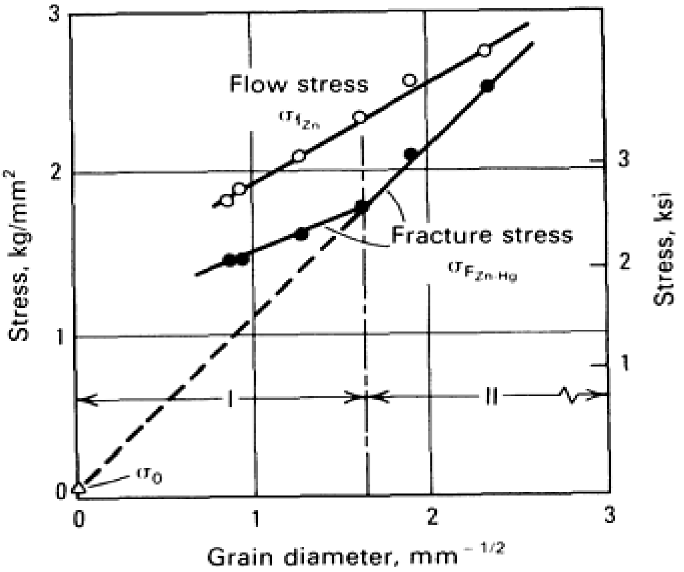

Fig. 70 Effect of grain size on LME. Variation of the flow stress of amalgamated zinc polycrystalline specimens, σf_{Zn}, and fracture stress of amalgamated zinc specimens, $\sigma^F{}_{Zn-Hg}$, as a function of grain size at 298 K

Nucleation-controlled embrittlement means that once a crack is initiated it propagates to failure in the presence or absence of the liquid metal at the crack tip. In propagation-controlled failure, microcracks are formed at some low stress in a liquid-metal environment, but the microcracks propagate to failure only when a higher stress is reached. Thus, in propagation-controlled failure, unpropagated microcracks may be found beside the main fracture, and complete fracture of the specimen occurs only in the presence of liquid metal. The reverse is observed when fracture is initiation controlled.

Effects of Temperature and Strain Rate. Liquid-metal embrittlement occurs at the melting point of liquid metal (there are quite a few instances in which embrittlement occurs below the melting point of liquid by SMIE). In most cases, the susceptibility to embrittlement may remain essentially unchanged with temperature. At a sufficiently high test temperature, a brittle-to-ductile transition occurs when embrittlement ceases and ductility is restored to the solid. Such transitions do not occur at a sharply defined temperature and are not predictable on a theoretical basis or in terms of

diffusion, dissolution, or other such embrittlement processes. It is generally accepted that a significant increase in ductility with temperature counteracts the inherent propensity for fracture in the embrittling liquid-metal environment.

In smooth steel specimens tested in liquid lead, brittle-to-ductile transition occurs at approximately 510 °C (950 °F), some 335 °C (600 °F) above the melting point of lead. In similar steel fracture mechanics type test specimens containing sharp notches tested in liquid lead, the transition occurs at approximately 650 °C (1200 °F), some 140 °C (250 °F) higher than that for smooth specimens. Transition temperature in this case depends on the presence or absence of a stress raiser in the specimen and on the type of test method used. Such brittle-to-ductile transitions have been reported for zinc-mercury, aluminum-mercury, brass-mercury, titanium-cadmium, steel-lead, and steel-lead-antimony solution embrittlement couples.

Transition temperature also varies with strain rate and grain size in a manner observed for metals tested in an inert environment. Thus, an increase in strain rate and a decrease in grain size increase the transition temperature. The effects of grain size on transition temperature have been reported for aluminum in Hg-3Sn solutions and brass-mercury embrittlement couples. The effects of strain rate on transition temperature have been reported for cadmium-gallium, zinc-mercury, aluminum-mercury, zinc-indium, brass-mercury, and titanium-cadmium embrittlement couples. Changes in the strain rate by orders of magnitude are usually required to change the transition temperature by 50 to 100 °C (90 to 180 °F). For example, in the titanium-cadmium couple, a change of approximately 60 °C (110 °F) occurs with a change of one to two orders of magnitude in the strain rate and corresponds to a comparable increase in yield stress with the strain rate. The effects of strain rate appear to be related to the increase in the yield stress. This corresponds to an increase in the embrittlement susceptibility and a decrease in the brittle-to-ductile transition temperature.

Effects of Stress. Static fatigue or delayed-failure tests are conducted to study the effects of time-dependent processes, such as diffusion penetration of the grain boundary, as the cause of embrittlement. Also, such tests are performed because they simulate service conditions of constant stress in an embrittling environment as a function of time and assist in the failure analysis. Delayed failure has been reported for notchinsensitive aluminum-copper and beryllium-copper alloys in liquid mercury. Penetration of mercury did not occur, and embrittlement was independent of time to failure; but failure time increased with an increased stress level of the tests. In notch-sensitive zinc tested in mercury, the time to failure was very sensitive to the stress level, with complete failure occurring instantly at a stress slightly higher than a threshold stress. Penetration of mercury was not observed.

These tests indicate that time-dependent diffusion penetration or dissolution processes are not the cause of LME. In isolated instances, grain-boundary penetration by the liquid has been the cause of embrittlement. For example, unstressed aluminum or commercial aluminum alloys disintegrate into individual grains when contacted with liquid gallium. Liquid antimony embrittles steel, and embrittlement increases with temperature; thus, diffusional processes cause antimony to embrittle steel. Liquid copper and liquid lithium embrittle steel in a similar manner (Fig. 71). However, in these cases, both diffusional and classic LME have been observed. Such behavior can be differentiated by the temperature dependence, by the susceptibility to embrittlement, or by embrittlement occurring in solid-metal environments.

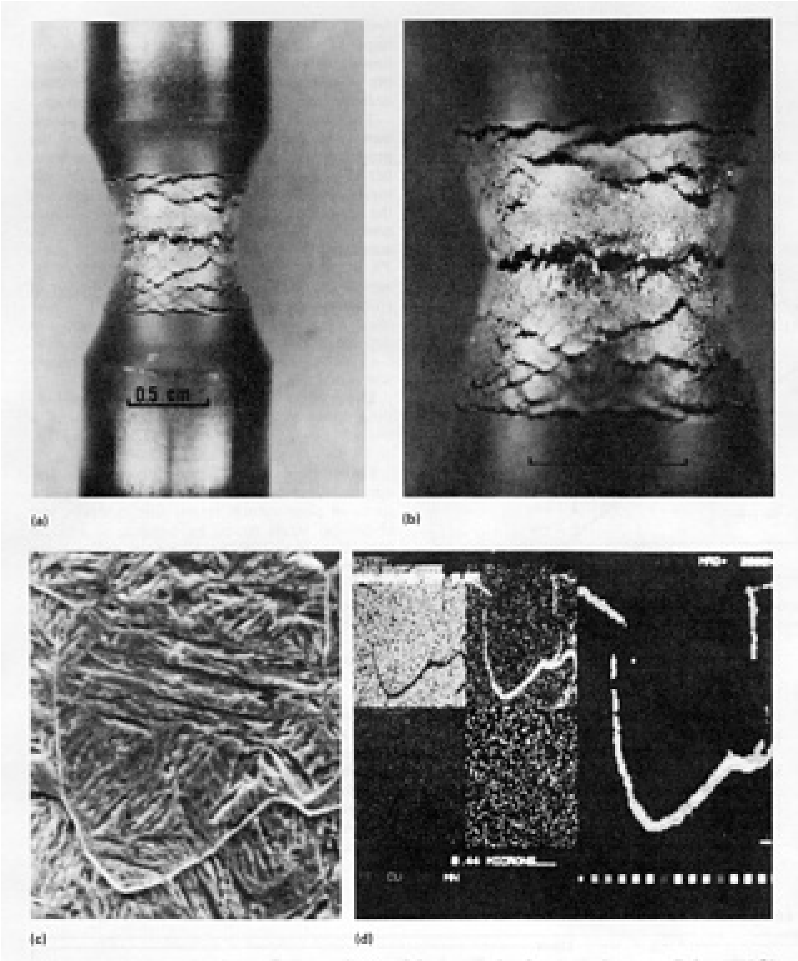

Fig. 71 Copper-induced LME of 4340 steel. (a) and (b) Copper-plated specimen that was pulled at 1100 °C (2010 °F) in a Gleeble hot tensile machine showing liquid copper embrittlement of steel. (c) Scanning electron micrograph of the pulled specimen. 1600×. (d) Computer-processed x-ray map showing the presence of copper in prior-austenite grain boundaries.

Inert Carriers and LME. In some cases, investigation of the embrittlement behavior of a potential solid-liquid metal couple is not possible. The reason is that the solid metal at temperatures just above the melting temperature of the liquid metal is either too ductile to initiate and propagate a brittle crack or the solid is excessively soluble in the liquid metal. It is possible, however, that a solid metal can be embrittled by a liquid metal of high melting point by dissolving it in an inert-carrier liquid metal of a lower melting point. Thus, the embrittling species is effectively in a liquid state at some temperature far below its melting point. In addition, it provides a means of investigating the variation in the degree of embrittlement induced in a solid metal as a function of the concentration and as a function of the chemical nature of the several active liquid-metal species dissolved separately in a common inert-carrier liquid metal.

For example, mercury does not embrittle cadmium, but indium may embrittle cadmium (melting point: 325 °C, or 617 °F). However, cadmium is quite ductile at 156 °C (313 °F), the melting temperature of indium. Mercury dissolves up to 70% ln at room temperature. The indium in the mercury-indium solution at room temperature embrittles cadmium (Fig. 72). In fact, cadmium single crystals, which are ductile even at liquid helium temperature, can be embrittled by indium and cleaved in indium-mercury solutions (Fig. 60). Another example of embrittlement by inert carriers is that of Zircaloy nuclear fuel claddings used in liquid metal cooled nuclear reactors. In liquid cesium, Zircaloy claddings fail in a ductile manner; in cesium saturated with cadmium, Zircaloy is subject to brittle fracture.

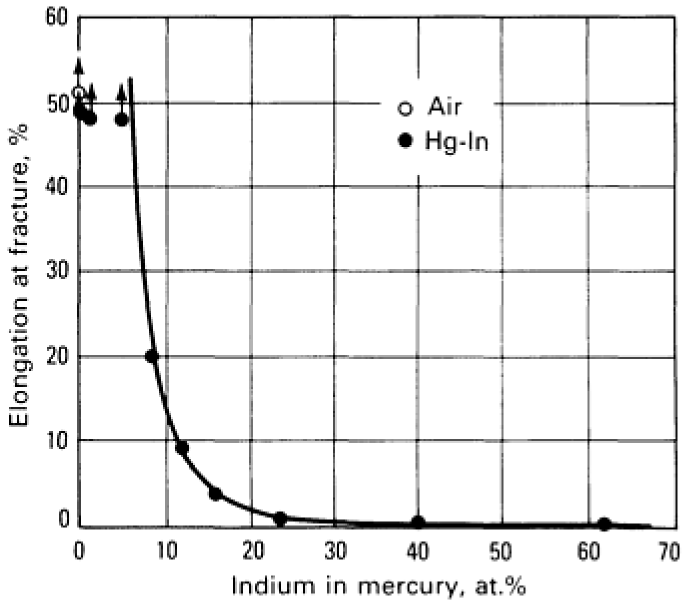

Fig. 72 Variation in ductility of polycrystalline cadmium as a function of indium content of mercury-indium surface coatings. Specimens were tested at 25 °C (75 °F) in air and in mercury-indium solution.

The concept of inert carrier LME is useful in failure analysis where LME has occured in a liquid solution--for example, solder rather than a pure liquid metal. The susceptibility of various species in the solder in causing LME can be investigated by incorporating each species in an inert liquid. This may suggest a means of preventing embrittlement by replacing the most potent embrittler with a nonembrittling species.

Fatigue in Liquid-Metal Environments

Most studies of LME have been concerned with the effects of tensile loading on fracture. Investigations of fatigue behavior are important because this test condition is more severe than other test conditions, including the tensile testing of metals. Thus, a solid tested in fatigue may become embrittled, but the same solid tested in tension may not exhibit embrittlement. This may be because at the high stress level corresponding to yield stress, which is a prerequisite for the occurrence of embrittlement in tough metals, the solid may be sufficiently ductile to prevent initiation of a crack in the liquid.

For example, smooth specimens of high-purity chromium-molybdenum low-alloy steel (yield stress: ~690 MPa, or 100 ksi) are not embrittled by liquid lead, but the same steel specimens containing a fatigue precrack are severely embrittled by liquid lead. The fatigue life in liquid lead is reduced to 25% of that in an inert argon environment. Crack propagation in a liquid-metal environment under fatigue and tensile loading can be significantly different. The stress intensity at failure of 7.7 MPa $\sqrt{m}$(7 ksi $\sqrt{in.}$) for a 4340 steel specimen containing a fatigue precrack tested in cyclic fatigue in liquid lead was five times lower than that for the same specimen tested in tension in static fatigue and was twenty times lower than that in an inert argon environment. Furthermore, the 7.7-MPa $\sqrt{m}$(7-ksi $\sqrt{in.}$) stress intensity was the same whether the specimen had a machined notch (0.13-mm, or 0.005-in., root radius) or had a fatigue precrack at the root of the notch; that is, embrittlement was independent of root radius. These results indicate that embrittlement is very severe and even blunt cracks can propagate to failure. Similar results have also been reported for the same steel tested in liquid mercury.

These results clearly indicate that fatigue testing of a notched or a fatigue precracked specimen provides the most severe test condition and therefore causes maximum susceptibility to embrittlement in a given liquid-metal environment. To determine whether a solid is susceptible to LME in a particular liquid, it is advisable to test the solid metal with a stress raiser or a notch in a tension-tension fatigue test.

Decrease or Elimination of LME Susceptibility

The reduction in the cohesion mechanism of embrittlement indicates that the electronic interactions, resulting in possible covalent bonding due to electron redistribution between the solid- and the liquid-metal atoms, reduces cohesion and thus induces embrittlement. Such interactions at the electronic level are the inherent properties of the interacting atoms and are therefore difficult or impossible to change in order to reduce the susceptibility to LME.

One possibility is to introduce impurity atoms in the grain boundary that have more affinity for sharing electrons with the liquid-metal atoms than for sharing electrons with the solid-metal atoms. For example, additions of phosphorus to Monel segregate to the grain boundaries and reduce the embrittlement of Monel by liquid mercury. Additions of lanthanides to internally leaded steels reduce lead embrittlement of steel. However, in general, the best alternative is to electroplate or clad the solid surface with a metal as a barrier between the embrittling solid-liquid metal couple, making sure that the barrier metal is not embrittled by the liquid metal.

Another possibility is that a ceramic or a covalent material coating on the solid surface will inhibit embrittlement. Apparently, only materials with metallic bonding are susceptible to LME. The severity of embrittlement could be reduced by decreasing the yield stress of the solid below the stress required to initiate a crack or by cladding with a high-purity metal of the alloy that is embrittled but that has a very low yield stress. Thus, Zircaloy, which is clad with a high-purity zirconium, becomes immune to embrittlement by cadmium. The obvious possibility is to replace embrittling liquid metal or solutions by nonembrittling metals or solutions.

Embrittlement of Nonferrous Metals and Alloys*

Zinc is embrittled by mercury, indium, gallium, and Pb-20Sn solder. Mercury decreases the fracture stress of pure zinc by 50% and dilute zinc alloys (0.2 at.% Cu or Ag) by five times that in an inert environment. The fracture propagation energy for a crack in zinc single crystals in mercury is 60% and in gallium is 40% of that in air. Zinc is embrittled more severely by gallium than by indium or mercury.

Aluminum. Mercury embrittles both pure and alloyed aluminum. The tensile stress is decreased by some 20%. Fatigue life of 7075 aluminum alloy is reduced in mercury, and brittle-to-ductile transition occurs at 200 °C (390 °F). Additions of gallium and cadmium to mercury increase the embrittlement of aluminum. Delayed failure by LME occurs in mercury. Dewetting of aluminum by mercury has been found to inhibit embrittlement. The possible cause of dewetting is the dissolution of aluminum by mercury and oxidation of fine aluminum particles by air and formation of aluminum oxide white flowers at the aluminum/mercury interface.

Aluminum alloys are embrittled by tin-zinc and lead-tin alloys. The embrittlement susceptibility is related to heat treatment and the strength level of the alloy. Gallium in contact with aluminum severely disintegrates unstressed aluminum alloys into individual grains. Therefore, grain-boundary penetration of gallium is sometimes used to separate grains and to study topographical features and orientations of grains in aluminum. There is some uncertainty about whether zinc embrittles aluminum. However, indium severely embrittles aluminum. Alkali metals, sodium, and lithium are known to embrittle aluminum. Aluminum alloys containing either lead, cadmium, or bismuth inclusions embrittle aluminum when impact tested near the melting point of these inclusions. The severity of embrittlement increases from lead to cadmium to bismuth.

Copper. Mercury embrittles copper, and the severity of embrittlement increases when copper is alloyed with aluminum and zinc. Antimony, cadmium, lead, and thallium are also reported to embrittle copper. The apparent absence of embrittlement of copper, if observed, should be attributed to the test conditions and metallurgical factors discussed in this article. Mercury embrittlement of brass is a classic example of LME. Embrittlement occurs in both tension and fatigue and varies with grain size and strain rate. Mercury embrittlement of brass and copper alloys has been extensively investigated. Lead and tin inclusions in brass cause severe embrittlement when tested near the melting point of these inclusions. Lithium reduces the rupture stress and elongation at failure of solid copper. Sodium is reported to embrittle copper; however, cesium does not. The embrittling effects of bismuth for copper and their alloys are well documented.

Gallium embrittles copper at temperatures ranging from 25 to 240 °C (75 to 465 °F). Gallium also embrittles single crystals of copper. Indium embrittles copper at 156 to 250 °C (313 to 480 °F).

Other Nonferrous Materials. Tantalum and titanium alloys are embrittled by mercury and by Hg-3Zn solution. Refractory metals and alloys, specifically W-25Re, molybdenum, and Ta-10W, are susceptible to LME when in contact

with molten Pu-1Ga. Cadmium and lead are not embrittled by mercury. However, indium dissolved in mercury embrittles both polycrystalline and single crystal cadium (Fig. 60). The embrittlement of titanium and its alloys by both liquid and solid cadmium is well recognized by the aircraft industry. Cadmium-plated fasteners of both titanium and steel are known to fail prematurely below the melting point of cadmium. Cadmium-plated steel bolts have good stress-corrosion resistance, but cadmium is known to crack steel. Therefore, such bolts are not recommended for use. Zinc is reported to embrittle magnesium and titanium alloys. Silver, gold, and their alloys are embrittled by both mercury and gallium. Nickel is severely embrittled by cadmium dissolved in cesium. The fracture mode is brittle intergranular with bright grain-boundary fracture.

Failure of Zircaloy tubes used as cladding material for nuclear fuel rods has been suspected to result from nuclear-interaction reaction products, such as iodine and cadmium carried by liquid cesium, which is used as a coolant in the reactor. Systematic investigation in the laboratory has shown that cadmium, both in the solid and the liquid state or as a carrier species dissolved in liquid cesium, causes severe liquid and solid metal induced embrittlement of zirconium and Zircaloy-2. Embrittlement of Zircaloy by calcium, strontium, zinc, cadmium, and iodine has also been reported.

Embrittlement of Ferrous Metals and Alloys

Embrittlement by Aluminum. Tensile and stress rupture tests have been conducted on steels in molten aluminum at 690 °C (1275 °F). For short-term tensile tests, a reduced breaking stress and reduction of area were found as compared to the values in air. In the stress rupture tests, the time to failure was dependent upon the applied stress.

Embrittlement by Antimony. AISI 4340 steel tested in fatigue in liquid Pb-35Sb at 540 °C (1000 °F) and in antimony at 675 °C (1250 °F) was very severely embrittled. The embrittlement in lead-antimony occurred 165 to 220 °C (300 to 400 °F) higher than that observed for high-purity lead. Small additions of antimony (~5 wt%) to lead had no effect on embrittlement when tested in fatigue, although 0.002 to 0.2% Sb additions have caused a significant increase in the embrittlement of smooth AISI 4140 steel specimens tested in tension. Embrittlement by antimony increases with temperature and is thought to occur by the grain-boundary diffusion of antimony in steel.

Embrittlement by Bismuth. Upon testing in liquid bismuth at 300 °C (570 °F), no embrittlement was noted in bend tests on a quenched-and-tempered steel. The stress rupture data obtained on the low-carbon steel showed that the time to failure and reduction of area increased with decreasing load, but no intercrystalline attack was noted.

Embrittlement by Cadmium. In several studies of the embrittlement of low-alloy AISI 4340 steel, embrittlement occurred at 260 to 322 °C (500 to 612 °F) but not at 204 °C (399 °F) for high-strength steel. Cracks were observed in samples loaded to 90% of their yield stress at 204 °C (399 °F). The threshold stress required for cracking decreases with an increase in temperature. Cracking at 204 °C (399 °F) was strongly dependent on the strength level of the steel, and embrittlement was not observed for strength levels less than 1241 MPa (180 ksi). Delayed failure occurs in cadmium-plated high-strength steels (AISI 4340, 4140, 4130, and an 18% Ni maraging steel). Failures were observed at 232 °C (450 °F), which is about 90 °C (160 °F) below the melting point of cadmium. Static failure limits of 10% and 60% of the room-temperature notch strength have been reported for electroplated and vacuum-deposited cadmium, respectively, at 300 °C (570 °F). A discontinuous crack propagation mode was observed, consisting of a series of crack propagation steps separated by periods of no apparent growth. This slow crack growth region was characterized by cracks along the prior-austenite grain boundaries. Once the cracks reached a critical size, a catastrophic failure occurred that was characterized by a transgranular ductile fracture.

Embrittlement of high-strength steels occurs when they are stress rupture tested in liquid and solid cadmium. Cadmium produces a progressive decrease in the reduction of area at fracture of AISI 4140 steel over the temperature range of 170 to 321 °C (338 to 610 °F). Cadmium was identified as a more potent solid-metal embrittler than lead, tin, zinc, or indium.

Embrittlement by Copper. The embrittlement of low-carbon steel by copper plate occurred at 900 °C (1650 °F) during a slow-bend test. The embrittling effects of the copper plate exceeded those encountered with brazing alloys. Similar observations have been made for plain carbon steels, silicon steels, and chromium steels at 1000 to 1200 °C (1800 to 2190 °F).

The surface cracking produced during the hot working of some steels at 1100 to 1300 °C (2010 to 2370 °F) also has several characteristics of LME. It is promoted by surface enrichment of copper and other elements during oxidation and subsequent penetration along the prior-austenite grain boundaries. Elements such as nickel, molybdenum, tin, and arsenic that affect the melting point of copper or its solubility in austenite also influence embrittlement. A ductility trough has also been noted, with no cracking produced at temperatures above 1200 °C (2190 °F). Steel plated with copper and pulse heated to the melting point of copper in milliseconds was embrittled by both liquid and solid copper. Hot tensile testing in a Gleeble testing machine at high strain rates produced severe cracking in AISI 4340 steel by both the liquid and solid copper.

Embrittlement by Gallium. The alloy Fe-3Si is severely embrittled by gallium, as are the solid solutions of iron and AISI 4340 steel.

Embrittlement by Indium. Indium embrittles pure iron and carbon steels. Embrittlement depends on both the strength level and the microstructure. Pure iron was embrittled only at temperatures above 310 °C (590 °F), appreciably above the melting point of indium. However, other steels, such as AISI 4140 (ultimate tensile strength of 1379 MPa, or 200 ksi), were embrittled by both solid and liquid indium. Surface cracks were detected at temperatures below the melting temperature of indium. This was interpreted as a local manifestation of the underlying embrittlement mechanism, and it was assumed that the cracks must reach a critical size before the gross mechanical properties are affected.

Embrittlement by Lead. The influence of lead on the embrittlement of steel has been extensively investigated and has been found to be sensitive to both composition and metallurgical effects. The studies fall into two major classifications:

- LME due to contact with an external source of liquid lead
- Internal LME in which the lead is present internally as inclusions or a minor second phase, as in leaded steels

Both external and internal lead-induced embrittlement exhibit similar characteristics, but for the purpose of simplicity, each will be treated individually.

LME Due to External Lead. AISI 4145 and 4140 steels exposed to pure lead exhibit classical LME, as shown by substantial decreases in both the reduction of area and the elongation at fracture. The fracture stress and the reduction of area decreased at temperatures considerably below the melting point of lead and varied continuously through the melting point, suggesting that the same embrittlement mechanism is operative for both solid- and liquid-metal environments.

Additions of zinc, antimony, tin, bismuth, and copper increase the embrittling potency of lead. Additions of up to 9% Sn, 2% Sb, or 0.5% Zn to lead increased the embrittlement of AISI 4145 steel. In some cases, the embrittlement and failure occurred before the UTS was reached. The extent of embrittlement increases with increasing impurity content. No correlation was observed between the degree of embrittlement and wettability. The lead-tin alloys readily wetted steels, but the more embrittling lead-antimony alloys did not.

LME Due to Internal Lead. Leaded steels are economically attractive because lead increases the machining speed and the lifetime of the cutting tools. The first systematic investigation of embrittlement of leaded steels was reported in 1968 (Mostovoy and Breyer). Embrittlement characteristics similar to those promoted by external lead were observed. The degradation in the ductility began at approximately 120 °C (215 °F) below the melting point of lead, with the embrittlement trough present from 230 to 454 °C (446 to 849 °F). This was followed by a reversion to ductile behavior at about 480 °C (895 °F).

The severity of the embrittlement and the brittle-to-ductile transition temperature T_R have been shown to be dependent upon the strength level of the steel, with the degree of embrittlement and T_R increasing with strength level. In these studies, intergranular fracture was produced, which was propagation controlled at low temperatures and nucleation controlled at high temperatures. The degree of embrittlement was critically dependent on the lead composition, and the influence of trace impurities completely masked any variations due to different carbon and alloy compositions of the

steel. Lead embrittlement of a steel compressor disk was induced by bulk lead contents of 0.14 and 6.22 wt%. The lead is associated with the nonmetallic inclusions, and upon yielding, microcracks form at the weak inclusion/matrix interface, releasing a source of embrittling agent to the crack tip that aids subsequent propagation. An electron microprobe analysis of the nonmetallic inclusions identified the presence of zinc, antimony, tin, bismuth, and arsenic. With the exception of arsenic, all these trace impurities have been shown to have a significant effect on the external LME of steel.

The two most promising methods of suppressing LME are the control of sulfide composition and morphology and the cold working of the steel. The addition of rare-earth elements to the steel melt modifies the sulfide morphology and composition and can eliminate LME.

Embrittlement by Lithium. Exposure of AISI 4340 steel to lithium at 200 °C (390 °F) resulted in static fatigue, with the time to failure depending on the applied stress. A decreasing fracture stress and elongation to fracture were noted with increasing UTS of variously treated steels, and catastrophic failure occurred for those steels with tensile strengths exceeding 1034 MPa (150 ksi). The tensile ductility of low-carbon steel at 200 °C (390 °F) was drastically reduced in lithium, with intergranular failure after 2 to 3% elongation, but there was no effect on the yield stress or the initial work-hardening behavior. The fracture stress was shown to be a linear function of $d^{-\frac{1}{2}}$, where *d* is the average grain diameter, in accordance with the Petch relationship.

Embrittlement by Mercury. It has been shown that mercury embrittlement is crack nucleation controlled and can be induced in low-carbon steel samples by the introduction of local stress raisers. The fracture toughness of a notched 1Cr-0.2 Mo steel was significantly decreased upon testing in mercury. The effective surface energy required to propagate the crack was 12 to 16 times greater in air than in mercury. The fatigue life of 4340 steel in mercury is reduced by three orders of magnitude as compared to that in air.

The addition of solutes (cobalt, silicon, aluminum, and nickel) to iron, which reduced the propensity for cross-slip by decreasing the number of active slip systems and changed the slip mechanism from wavy to planar glide, increased the susceptibility to embrittlement. Iron alloys containing 2% Si, 4% Al, or 8% Ni and iron containing 20% V or iron containing 49% Co and 2% V have been shown to be embrittled by mercury in unnotched tensile tests. The degree of embrittlement behavior was extended to lower alloy contents by using notched samples. No difference in the embrittlement potency of mercury or a saturated solution of indium in mercury was noted.

Effect of Selenium. Selenium had no embrittling effect on the mechanical properties of a quenched-and-tempered steel (UTS: ~1460 MPa, or 212 ksi) bend tested at 250 °C (480 °F).

Embrittlement by Silver. Silver had no significant effect on the mechanical properties of a range of plain carbon steels, silicon steels, and chromium steels tested by bending at 1000 to 1200 °C (1830 to 2190 °F). However, a silver-base filler metal containing 45% Ag, 25% Cd, and 15% Sn has been reported to embrittle A-286 heat-resistant steel in static-load tests above and below 580 °C (1076 °F), the melting point of the alloy.

Effect of Sodium. Unnotched tensile properties of low-carbon steel remained the same when tested in air and in sodium at 150 and 250 °C (300 and 480 °F). Similarly, Armco iron, low-carbon steel, and type 316 steel were not embrittled by sodium at 150 to 1600 °C (300 to 2910 °F).

Embrittlement by Solders and Bearing Metals. A wide range of steels are susceptible to embrittlement and intercrystalline penetration by molten solders and bearing metals at temperatures under 450 °C (840 °F). Tensile tests have revealed embrittlement as a reduction in ductility. The embrittlement increased with grain size and strength level of the steel, except for temper-embrittled steels.

The tensile strength and ductility of carbon steel containing 0.13% C were decreased upon exposure to the molten solders and bearing alloys. The embrittlement was concomitant with a change to a brittle intergranular fracture mode and penetration along prior-austenite grain boundaries. Ductile failure was observed with samples tested in air or in the liquid metal at temperatures exceeding 450 °C (840 °F). No intercrystalline penetration of solder was noted in carbon steels containing 0.77% and 0.14% C at 950 °C (1740 °F).

It has been reported that solder embrittles steel more than Woods metal (a bismuth-base fusible alloy containing lead and tin), particularly if it contains 4% Zn. The bearing metals produced embrittlement similar to the solder containing 4% Zn alloy.

Embrittlement by Tellurium. Tellurium-associated embrittlement has been reported for carbon and alloy steels. Hot shortness occurs in AISI 12L14 + Te steel, with the most pronounced loss in ductility between 810 and 1150 °C (1490 and 2100 °F), embrittlement being most severe at 980 °C (1795 °F). The embrittlement has been shown to occur by the formation of a lead-telluride film at the grain boundary, which melts at 923 °C (1693 °F). The mechanical test data and the examination of fracture surfaces by Auger electron spectroscopy (AES) and scanning electron microscopy (SEM) indicated LME of steel by the lead-telluride compound.

Effect of Thallium. Thallium had no embrittling effects on the mechanical properties of a quenched-and-tempered steel (UTS: $\sim$1460 MPa, or 212 ksi) tested in bending at 325 °C (615 °F).

Embrittlement by Tin. The embrittling effect of tin has been observed in a range austenitic and nickel-chromium steels, the degree of embrittlement increasing with their strength level. Embrittlement depends on the presence of a tensile stress and is associated with intercrystalline penetration.

The embrittlement by solid tin occurs at approximately 120 °C (215 °F) below its melting point. The fracture surfaces exhibited an initial brittle zone perpendicular to the tensile axis that followed the prior-austenite grain boundaries. Layers of intermetallic compound present at the steel/tin interface did not impede the embrittlement process. Embrittlement has been observed in delayed-failure tests down to 218 °C (424 °F) (14 °C, or 25 °F, below the melting point of tin); however, in tensile tests, embrittlement by solid tin was effective at temperatures as low as 132 °C (270 °F), which is 100 °C (180 °F) below melting point.

AISI 3340 steel doped with 500 ppm of phosphorus, arsenic, and tin has been tested in the presence of tin while in the segregated (temper embrittled) and the unsegregated states. Temper-embrittled steels were found to be more susceptible to embrittlement than steel heat treated to a nontempered state.

A lower fatigue limit and lifetime at stresses below the fatigue limit for low-carbon steel and for 18-8 stainless steel have been noted when tested in tin at 300 °C (570 °F). The exposure time to the tin before testing had no influence on the fatigue life of the steel.

Embrittlement of Austenitic Steels by Zinc. Two main types of interaction of zinc and austenitic stainless steel have been observed. Type I relates to the effects on unstressed material in which liquid-metal penetration/erosion is the major controlling factor, and Type II relates to stressed materials in which classic LME is observed.

Type I Embrittlement. Zinc slowly erodes unstressed 18-8 austenitic stainless steel at 419 to 570 °C (786 to 1058 °F) and penetrates the steel, with the formation of an intermetallic βnickel-zinc compound at 570 to 750 °C (1060 to 1380 °F). At higher temperatures, penetration along the grain boundaries occurs, with a subsequent diffusion of nickel into the zinc-rich zone. This results in a nickel-exposed zone adjacent to the grain boundaries, reducing the stability of the γphase and causing it to transform to an α-ferrite; the associated volume change of the $\gamma \rightarrow \alpha$transformation produces an internal stress that facilitates fracture along the grain boundaries. Similar behavior has been observed in an unstressed 316C stainless steel held 30 min at 750 °C (1380 °F), in which penetration occurred to a depth of 1 mm (0.4 in.), and in an unstressed type 321 steel held 2 h at 515 °C (960 °F), in which a penetration of 0.127 mm (0.005 in.) was observed.

Type II embrittlement occurs in stainless steel above 750 °C (1380 °F) and is characterized by an extremely fast rate of crack propagation that is several orders of magnitude greater than that of Type I, with cracks propagating perpendicular to the applied stress. In laboratory tests, an incubation period was observed before the propagation of Type II cracks, suggesting that they may be nucleated by Type I cracks formed during the initial contact with zinc.

At 800 °C (1470 °F), a stressed type 316C stainless steel failed catastrophically when coated with zinc. Cracking was produced at a stress of 57 MPa (8 ksi) at 830 °C (1525 °F) and 127 MPa (18 ksi) at 720 °C (1330 °F), but failure was not observed at a stress of 16 MPa (2 ksi) at 1050 °C (1920 °F).

Liquid-metal embrittlement may be produced by the welding of austenitic steels in the presence of zinc or zinc-base paints. Intercrystalline cracking has been observed in the heat-affected zone in areas heated from 800 to 1150 °C (1470 to 2100 °F), and electron microprove analysis has been used to identify the grain-boundary enrichment of nickel and zinc, together with the formation of a low-melting nickel-zinc compound. The embrittlement of sheet samples of austenitic steel coated with zinc dust dye and zinchromate primer occurs at stresses of the order of 20 MPa (3 ksi).

Embrittlement of Ferritic Steels by Zinc. Embrittlement of ferritic steels and Armco iron by molten zinc has been reported in the temperature range of 400 to 620 °C (750 to 1150 °F). Long exposures and intercrystalline attack were needed to cause a reduction in the elongation to fracture; an iron-zinc intermetallic layer was formed that inhibited embrittlement until the layer was ruptured. High-alloy ferritic steels exhibit embrittlement by zinc at temperatures above 750 °C (1380 °F).

Delayed failure occurs in steel in contact with solid zinc at 400 °C (750 °F), which is 19 °C (34 °F) below the melting point of zinc. The slow crack growth region is characterized by intergranular mode of cracking.

Exposing AISI 4140 steel to solid zinc results in a decrease in the reduction of area and in fracture stress at 265 °C (510 °F), with no significant changes in the other mechanical properties. The tensile fracture initially propagates intergranularly, with the final failure occurring by shear. Liquid zinc embrittles 4140 steel at 431 °C (808 °F), and it has been shown that zinc is present at the crack tip. Figure 73 shows a compilation of liquid-metal embrittling and nonembrittling couples based on the theoretical calculations of the solubility parameter and the reduction in the fracture-surface energy. The embrittlement curve is separated by brittle and ductile fracture. A concise summary of embrittlement couples is provided in Table 5. Both pure and alloyed solids are listed.

Table 5 Summary of embrittlement couples

P, element (nominally pure): A, alloy: C, commercial: L, laboratory

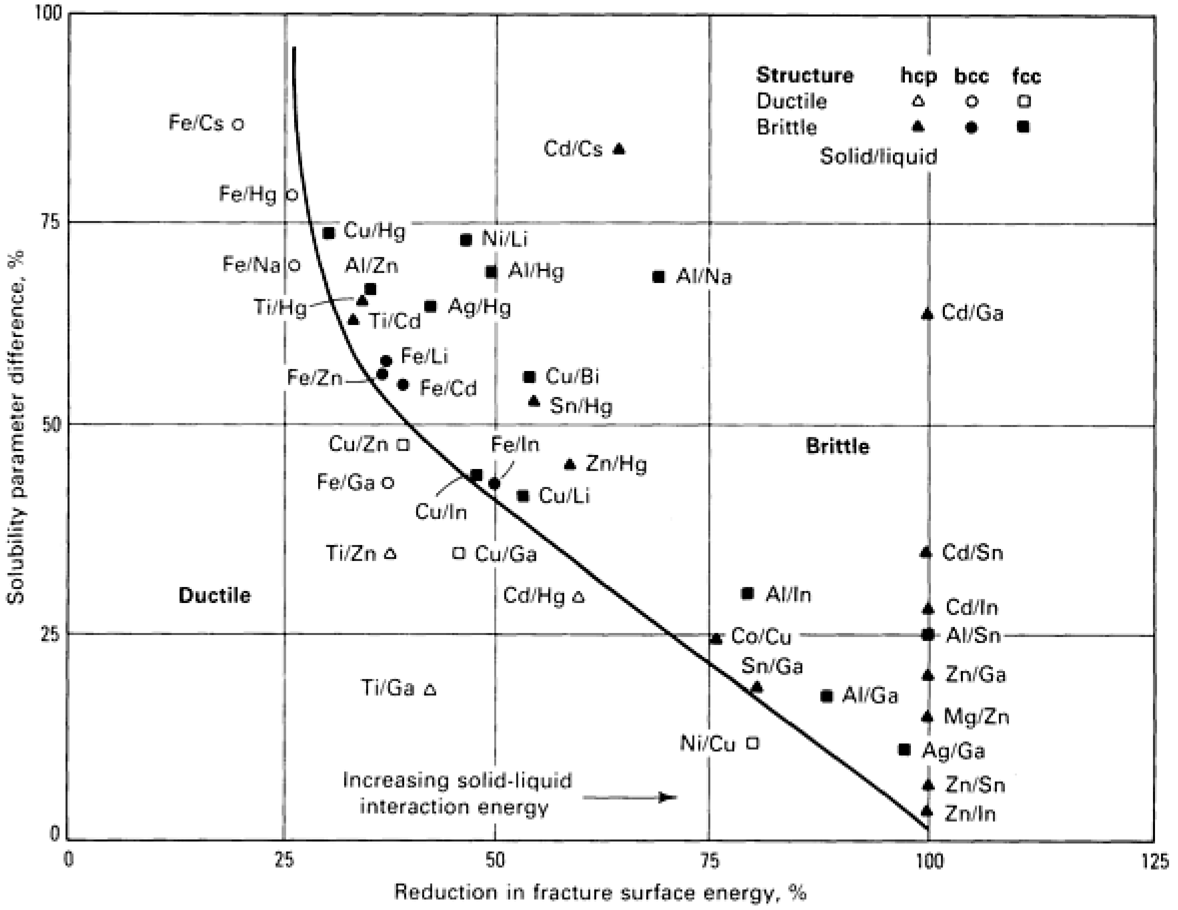

Fig. 73 Calculated reduction in the fracture surface energy relating to solubility parameter for many solid-liquid embrittlement couples. Note that the curve separates embrittlement couples from nonembrittled solid-liquid metal couples.

Solid Metal Induced Embrittlement

M.H. Kamdar, Benet Weapons Laboratory, U.S. Army Armament Research, Development, and Engineering Center

Embrittlement occurs below the melting temperature of the solid in certain LME couples. The severity of embrittlement increases with temperature, with a sharp and significant increase in severity at the melting point, T_m, of the embrittler (Fig. 74). Above T_m, embrittlement has all the characteristics of LME. The occurrence of embrittlement below the T_m of the embrittling species is known as solid metal induced embrittlement of metals.

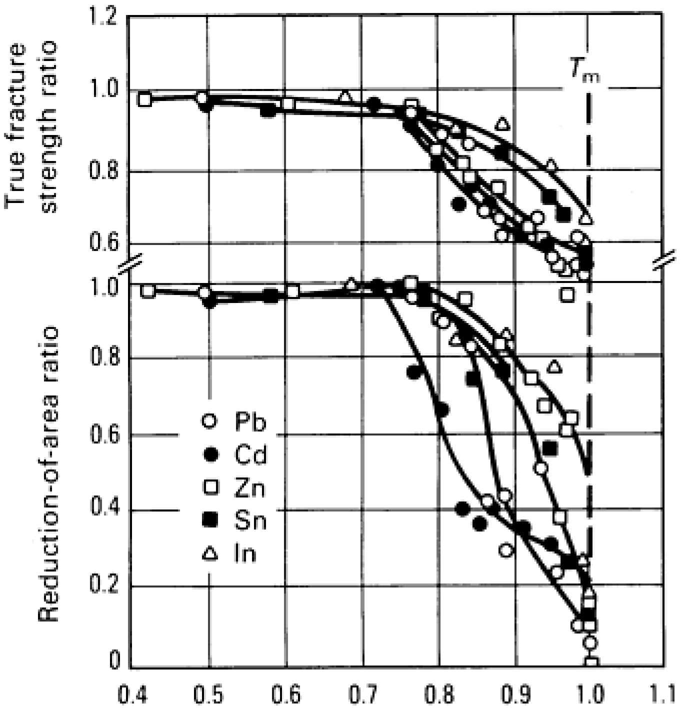

Fig. 74 Embrittlement of 4140 steel by various liquid metals below their melting point and their effects on normalized true fracture strength and reduction of area as a function of homologous temperature T_H. T and T_m are the test and melting temperatures of the liquid metal. Source: Ref 108

Although SMIE of metals has not been mentioned or recognized as an embrittlement phenomenon in industrial processes, many instances of loss in ductility, strength, and brittle fracture of metals and alloys have been reported for electroplated metals and coatings or inclusions of low-melting metals below their T_m (Ref 109). Delayed failure of cadmium-plated high-strength steel has been observed below the T_m of cadmium (Ref 110, 111). Accordingly, cadmium-plated steel bolts, despite their excellent resistance to corrosion, are not recommended for use above 230 °C (450 °F). Notched tensile specimens of various steels are embrittled by solid cadmium. Solid cadmium, silver, and gold embrittle titanium. Leaded steels are embrittled by solid lead, with considerable loss in ductility below the T_m of lead; this phenomenon accounts for numerouselevated-temperature failures of leaded steels, such as radial cracking of gear teeth during induction-hardening heat treatment, fracture of steel shafts during straightening at elevated temperature, and heat treatment failure of jet-engine compressor disks. Liquid and solid cadmium metal environments, as well as cadmium dissolved in inert nonembrittling coolant liquid, serve to embrittle the Zircaloy-2 nuclear fuel cladding tubes used in nuclear reactors (Ref 112). Inconel vacuum seals are cracked by solid indium. These reports of brittle failure clearly indicate the importance of SMIE in industrial processes.

Solid metal induced embrittlement was first recognized and investigated in the mid-1960s and early 1970s by studying the delayed failure of steels and titanium in a solid-cadmium environment (Ref 113, 114, 115). Results of these studies are shown in Fig. 75 and 76. A systematic investigation of SMIE of steel by a number of solid-metal embrittling species (Fig. 74) found that solid metal as an external environment can cause embrittlement and for steels represents a generalized phenomenon of embrittlement.

Solid metal induced embrittlement can also occur when the embrittling solid is an internal environment, that is, present in the solid as an inclusion (Ref 108). It has been clearly demonstrated that internally leaded steel is embrittled below the T_m of the lead inclusion of steel (Ref 108).

Brittle fracture in LME and SMIE is of significant scientific interest because the embrittling species are in the vicinity of or at the tip of the crack and are not transported by dislocations or by slip due to plastic deformation into the solid, as is hydrogen in the hydrogen embrittlement of steels. Also, embrittling species are less likely to be influenced by the effects of grain-boundary impurities, such as antimony, phosphorus, and tin, which cause significant effects on the severity of hydrogen and temper embrittlement of metals. Investigations of SMIE and LME, therefore, can be interpreted less ambiguously than similar effects in other environments, such as hydrogen and temper embrittlement of metals. Thus, solid-liquid environmental effects provide a unique opportunity to study embrittlement mechanisms in a simple and direct manner under controlled conditions.

It is conceivable that a common mechanism may underlie solid, liquid, and gas phase induced embrittlement. The interactions at the solid/environment interface and the transport of the embrittling species to the crack tip may characterize a specific embrittlement phenomenon. A study of SMIE and LME may provide insights into the mechanisms of hydrogen and temper embrittlement. It is apparent that the phenomenon of SMIE is of both industrial and scientific importance. A review of the investigations of the occurrence and mechanisms of SMIE follows.

Characteristics of SMIE

To date, SMIE has been observed only in those couples in which LME occurs, suggesting that LME is a prerequisite for the occurrence of SMIE. Solid metal induced embrittlement may occur in the absence of LME if a brittle crack cannot be initiated at the T_m of the embrittler. A recent compilation of SMIE couples is given in Tables 6 and 7, which show that all solid-metal embrittlers are also known to cause LME.

Table 6 Occurrence of SMIE in steels

Base metal	**Embrittler (melting point)**	**Onset of embrittlement**		**Test type**[b]	Specimen type[c]

Solid metal induced embrittlement and liquid-metal embrittlement are strikingly similar phenomena. The prerequisites for SMIE are the same as those for LME: intimate contact between the solid and the embrittler, the presence of tensile stress, crack nucleation at the soli/embrittler interface from a barrier (such as a grain boundary), and the presence of embrittling species at the propagating crack tip. Also, metallurgical factors that increase brittleness in metals, such as grain size, strain rate, increases in yield strength, solute strengthening, and the presence of notches or stress raisers, all appear to increase embrittlement. The susceptibility to SMIE is stress and temperature sensitive and does not occur below a specific threshold value. Embrittlement by delayed failure is also observed for both LME and SMIE (Table 8).

Some differences also exist. Multiple cracks are formed in SMIE; in LME, a single crack usually propagates to failure. The fracture in SMIE is propagation controlled. However, crack propagation rates are at least two to three orders of magnitude slower than in LME. Brittle intergranular fracture changes to ductile shear because of the inability of the embrittler to keep up with the propagating crack tip. Incubation periods have been reported, indicating that the crack nucleation process may not be the same as in LME (Ref 116, 117, 118). Nucleation and propagation are two separate stages of fracture in SMIE.

These differences may arise because of the rate of reaction or interactions at the metal/embrittler interface and because the transport properties of solid- and liquid-metal embrittlers are of significantly different magnitudes. It has been suggested that reductions in the cohesive strength of atomic bonds at the tip are responsible for both SMIE and LME (Ref 109, 116, 117, 119, 120). However, transport of the embrittler is the rate-controlling factor in SMIE. Another possibility is that stress-assisted penetration of the embrittler in the grain boundaries initiates cracking, but surface self-diffusion of the embrittling species similar to that proposed for LME controls crack propagation.

Investigations of SMIE

The first investigations of delayed failure were reported in cadmium-, zinc-, and indium-plated tensile specimens of 4340, 4130, 4140, and 18% Ni maraging steel in the temperature range of 200 to 300 °C (390 to 570 °F), as shown in Fig. 77 and 78. The results indicated that 4340 was the most susceptible and that 18% Ni maraging steel was the least susceptible alloy to cadmium embrittlement. The activation energy for steel-cadmium embrittlement was 39 kcal/mol (Fig. 79), which corresponded to diffusion of cadmium in the grain boundary. A thin plated layer of nickel or copper has been reported to act as a barrier to the embrittler and to prevent SMIE of steel (Ref 110). Solid indium is reported to embrittle steels (Ref 117, 118), and an incubation period exists for crack nucleation.

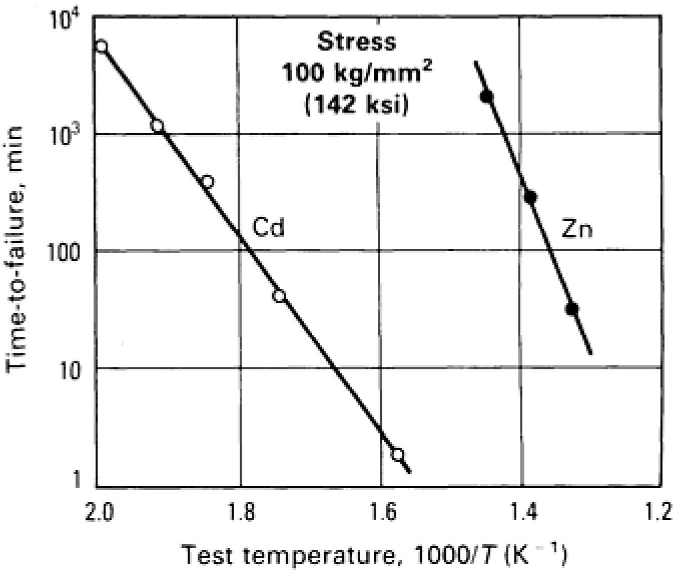

Fig. 79 Arrhenius plots of delayed failure in steel tested in cadmium and zinc. The activation energy Q is 39 kcal/mol for cadmium, 70 kcal/mol for zinc. Source: Ref 110

Embrittlement of different steels in lead was investigated as both an external and internal (leaded steel) environment; SMIE was conclusively demonstrated to be a reproducible effect (Ref 108, 109). It was also demonstrated that SMIE is an extension of LME (Ref 109, 117). Internally leaded high-strength steels are susceptible to severe embrittlement in the range of the T_m of lead, and this embrittlement is a manifestation of LME. However, it was found that the onset of embrittlement occurs some 95 °C (200 °F) below the T_m, of lead (330 °C, or 265 °F) and is continuous up to the T_m, with no discontinuity or anomalies in the variation of the embrittlement with temperature (Ref 109). At the T_m of lead, a sharp increase occurs in the severity of embrittlement, and ductile-to-brittle transition occurs in the temperature range of 370 to 450 °C (700 to 840 °F).

The same behavior was noted for pure lead as an external environment soldered onto 4140 steel and such embrittlement has also been observed for surface coatings of zinc, lead, cadmium, tin, and indium on steel (Ref 109). Embrittlement manifests itself as a reduction in tensile ductility over a range of temperatures extending from about three-quarters of the absolute T_m of the embrittler up to the T_m (Fig. 74). It has been shown the embrittlement is caused by the growth of stable subcritical intergranular cracks and that crack propagation is the controlling factor in embrittlement (Ref 109, 117). This indicated that transport of embrittlers to the crack tip was either by vapor phase or by surface or volume diffusion. In this study, the vapor pressure of the embrittling species at T_m varied widely and ranged from 20 to 6×10^{-36} Pa (1.5×10^{-1} to 4.5×10^{-38} torr) (Table 9). However, the crack propagation times for all embrittlers were similar. The estimated values of the diffusion coefficients ranged in the vicinity of 10^{-4} to 10^{-6} cm^2/s (6.5×10^{-4} to 6.5×10^{-6} in.^{2}/s). These values are comparable to surface or self-diffusion of embrittler over embrittler and suggest that diffusion, not vapor transport, is the rate-controlling process.

Table 9 Embrittler vapor pressures and calculated vapor-transport times at the embrittler-melting temperatures

Embrittler	Vapor pressure		Time, s
	Pa	torr	
Zn	20	1.5×10^{-1}	5×10^{-3}
Cd	10	7.5×10^{-2}	1×10^{-2}

(a) At room temperature.

Delayed Failure and Mechanism of SMIE

If a metal in contact with the embrittling species is loaded to a stress that is lower than that for fracture and is tested at various temperatures, then either the environment-induced fracture initiates and propagates instantaneously, as in a zinc-mercury LME couple, or delayed failure or static fatigue is observed. Examples of these two types of fracture processes are given in Table 8. Investigations of delayed failure provide an opportunity to separate crack nucleation from crack propagation and, specifically, to evaluate the transport-related role of the embrittling species. Solid metal induced

embrittlement is a propagation-controlled fracture process, and the time, temperature, and stress dependence of embrittlement presents an opportunity to study the kinetics of the cracking process.

The most critically investigated embrittlement system is 4140 steel embrittled by solid and liquid indium. Measurement of the decrease in electrical potential has been used to monitor crack initiation and propagation and to investigate the effects of temperature and stress level on delayed failure in 4140 steel by liquid and solid indium (Ref 116). The effects of temperature and stress level on the initiation time (incubation period for crack initiation) for both SMIE and LME are given in Fig. 80. The activation energy of the crack initiation process is approximately 37 kcal/mol and is essentially independent of the applied stress level. The activation energy represents the energy for stress-aided self-diffusion of both liquid and solid indium in the grain boundaries of the steel. Thus, crack initiation in both SMIE and LME occurs first by the adsorption of the embrittler at the site of crack initiation.

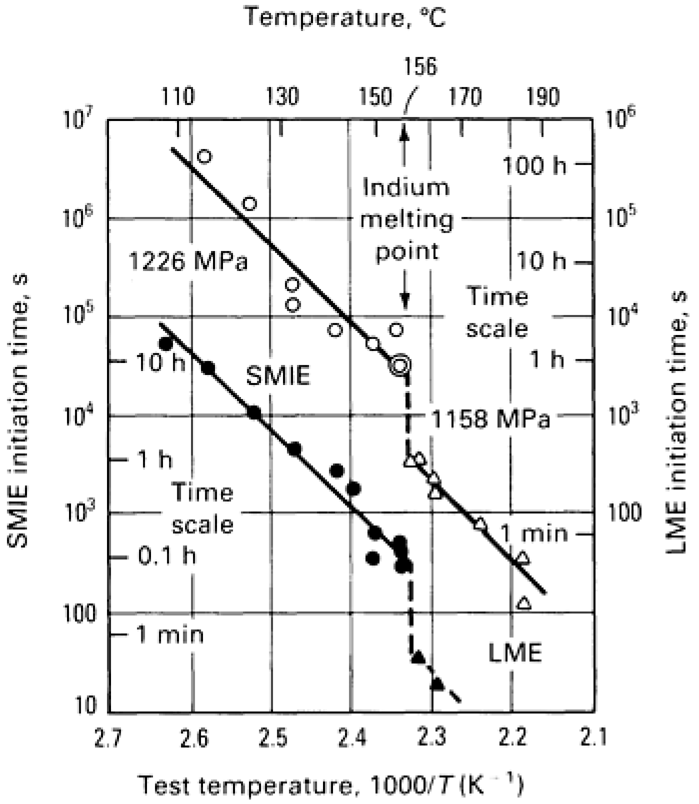

Fig. 80 Initiation time versus temperature in SMIE and LME of 4140 steel in indium at two stress levels. Source: Ref 117

However, because of the presence of an incubation period, the rate-controlling process is stress-aided diffusion penetration of the base-metal grain boundaries. Such penetration reduces the stress necessary to initiate a crack, causing embrittlement of the base metal. On this basis, it is difficult to explain embrittlement of single crystals, which do not contain grain boundaries. Thus, rather than stress-aided diffusion penetration along grain boundaries, the embrittling species may reduced cohesion of atoms at the grain boundaries in accord with the reduction-in-cohesion mechanism. This mechanism would also explain SMIE of single crystals. Crack propagation time as a function of temperature and stress level for both SMIE and LME of steel by indium is plotted in Fig. 81. The activation energy for crack propagation for this couple was 5.6 kcal/mol, which represents the energy for self-diffusion of indium over indium. Thus, propagation is controlled by the diffusion of indium over several multilayers of indium adsorbed on the crack surface or by the so-called waterfall mechanism of embrittlement. This mechanism is a variation of that proposed and discussed in detail as the reduction-in-cohesion mechanism for LME.

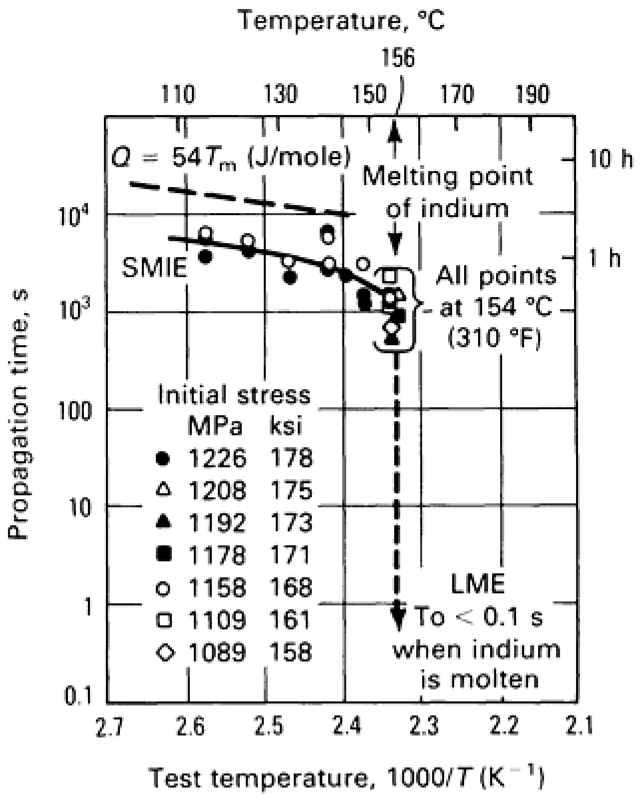

Fig. 81 Propagation time versus temperature for 4140 steel in indium at various temperatures and stress levels. Note the occurrence of SMIE and LME and little dependence on stress level of test. Source: Ref 117

Adsorption of the embrittler at the solid surface is followed by the rate-controlling step of stress-aided diffusion of the embrittler in the grin boundary of the base metal. The embrittler reduces cohesion of the grain-boundary base metal atoms, thus initiating a crack at a lower stress than that observed for the alloy in the absence of the embrittling species, resulting in embrittlement. Crack propagation occurs by multilayer self-diffusion of the embrittling species. These processes are valid for both LME and SMIE in the steel-indium embrittlement couple. It is clear that SMIE is similar to LME except that SMIE is a slower, embrittler transport-limited process. In this regard, the study of SMIE is important in eliminating the possibility in LME that a crack, once nucleated, may propagate in a brittle manner in the absence of the embrittling species at the tip of the crack. Solid metal induced embrittlement is a recent phenomenon, and further research is needed concerning the effects of metallurgical, mechanical, and chemical parameters on embrittlement. However, it is clear that SMIE must be recognized as yet another phenomenon of environmentally induced embrittlement.

Corrosion of Carbon Steels

Chairman: James H. Bryson, Inland Steel Company

Introduction

CARBON STEEL, the most widely used engineering material, accounts for over 64 million tons, or approximately 88%, of the annual steel production in the United States (Tables 1 and 2). Despite its relatively limited corrosion resistance, carbon steel is used in large tonnages in marine applications, nuclear power and fossil fuel power plants, transportation, chemical processing, petroleum production and refining, pipelines, mining, construction, and metal-processing equipment. The specific steps taken in these industries to mitigate the corrosion of carbon steel are discussed in detail in the Section "Specific Industries and Environments" in this Volume and will not be repeated here.

This article consists of five major sections:

- Carbon Steels
- Weathering Steels
- Protection of Steel From Corrosion
- Metallic Coated Steels
- Organic Coated Steels

Where applicable, reference will be made to a specific article in this Handbook in which more detailed information can be found. In addition, previous 9th Edition Volumes of *Metals Handbook* should be consulted for data related to carbon steels. Of particular note are Volume 1, *Properties and Selection: Irons and Steels;* Volume 4, *Heat Treating;* and Volume 9, *Metallography and Microstructures.*

Carbon Steels

A.G. Preban, Inland Steel Company

The cost of metallic corrosion to the total economy must be measured in hundreds of millions of dollars per year. Because carbon steels represent the largest single class of alloys in use, both in terms of tonnage and total cost, it is easy to understand that the corrosion of carbon steels is a problem of enormous practical importance. This, of course, is the reason for the existence of entire industries devoted to providing protective systems for irons and steels. Aspects of corrosion control will be discussed later in this article. In this section, only the intrinsic aspects of the corrosion system, primarily the environmental and compositional factors, will be addressed. This is not meant to imply that design is not important. Indeed, design changes are often the most efficient manner of dealing with a particular corrosion problem. This aspect of corrosion control is discussed in the article "Design Details to Minimize Corrosion" in this Volume.

Carbon, or mild, steels are by their nature of limited alloy content, usually less than 2% by weight for the total of all additions. Unfortunately, these levels of addition do not generally produce any remarkable changes in general corrosion behavior. One possible exception to this statement would be the weathering steels, in which small additions of copper, chromium, nickel, and/or phosphorus produce significant reductions in corrosion rate in certain environments. These steels will be discussed more fully in the following section of this article. At the levels present in low-alloy steels, the usual impurities have no significant effect on corrosion rate in the atmosphere, neutral waters, or soils. Only in the case of acid attack is an effect observed. In this latter case, the presence of phosphorus and sulfur markedly increase the rate of attack. Indeed, in acid systems, the pure irons appear to exhibit the best resistance to attack.

In solving a particular corrosion problem, a dramatic change in attack rate can often be attained by altering the corrosive environment. The deaeration of water and the addition of corrosion inhibitors are two examples that have broad application in the area of aqueous corrosion. These and other methods that may be useful in some cases are discussed in the Section "Corrosion Protection Methods" in this Volume.

Because corrosion is such a multifaceted phenomenon, it is generally useful to attempt to categorize the various types. This is usually done on an environmental basis. Therefore, in this section, atmospheric corrosion, aqueous corrosion, and

some other corrosion types of interest, such as corrosion in soils, concrete, and boilers and heating plants, will be addressed.

Atmospheric Corrosion

Atmospheres are often classified as being rural, industrial, or marine in nature. Such a classification is of course a gross oversimplification of the situation. It is easy to list locations along the seacoast that have heavy industrial pollution in the atmosphere. Such locations are both marine and industrial. Furthermore, two decidedly rural environments can differ widely in average yearly temperature and rainfall and can therefore have considerably different corrosive tendencies. Industrial expansion into formerly rural areas can easily change the aggressiveness of a particular location. Finally, long-term trends in the environment, such as changes in rainfall patterns, mean temperature, and perhaps acid rain, can make extrapolations from past behavior less reliable.

Other factors that limit the usefulness of atmospheric-exposure data are the general nonlinearity of weight loss due to corrosion with time and the fact that most atmospheric-corrosion data are presented as an average over the entire test panel surface. Most atmospheric exposure data for steels show a decrease in the rate of attack with time of exposure so that extrapolations of such data to times longer than those covered by the exposure data can lead to an overdesign in cross section. Finally, in many cases, the average weight loss per unit area is of less concern than the time to perforation. This factor is more related to localized attack, which can be masked by the averaging of data, as is done in weight loss determinations.

Given all the caveats mentioned above, the design engineer is well justified in using atmospheric-corrosion data as more indicative than quantitative. With all of this in mind, some of the corrosion data for various carbon steels in some representative environments will be discussed. More detailed information is available in Ref 1, 2, and 3.

The effect of various environments on the corrosion rate is indicated in Table 3. Table 3 is a compilation of weight loss measurements for cold-rolled carbon steels after 2 years of exposure. The most startling feature of Table 3 is the extreme range of corrosion rates existing. Galeta Point Beach, Panama, is more than 450 times as aggressive than the site at Norman Wells, N.W.T., Canada. This difference in corrosion rate is easily greater than any effect that can be produced by small changes in composition of the steel. Again, this underscores the fact that in dealing with the corrosion of carbon steels the alteration of design or environmental factors is usually more effective than changing the grade of steel.

Table 3 Comparative rankings of 45 locations based on steel loss of weight (grams) of 10- × 15-cm (4- × 6-in.) specimens of steel

Ranking to State College, PA	**Location**	2-year exposure, grams lost
1	Norman Wells, N.W.T., Canada	**0.73**
2	Phoenix, AZ	**2.23**
3	Saskatoon, Sask., Canada	**2.77**

45	**Galeta Point Beach, Panama, C.Z.**	**336.0**

Source: Ref 4

Further examination of Table 3 shows that the marine environments tend to be near the aggressive end of the list and that cold environments are generally less aggressive than warm sites. The average yearly temperature cannot, in general, be isolated from the moisture effect, because most of the more tropical exposure sites are also in regions with high humidity. One exception is arid Phoenix, AZ.

Corrosion Film Formation and Breakdown. The corrosion of carbon steel in the atmosphere and in many aqueous environments is best understood from a film formation and breakdown standpoint. It is an inescapable fact that iron in the presence of oxygen and/or water is thermodynamically unstable with respect to its oxides. Thus, the question is never

whether the steel will rust, but rather at what rate. In the absence of film formation and with a constant environment, one would expect the oxidation rate to be constant. Conversely, if the corrosion product film that forms isolates the steel from the corrosive environment, one would expect a zero corrosion rate after the initial film formation period. A tightly adherent film that permits only diffusion transfer of the reactants would be characterized by a corrosion rate that decreases with the square root of the exposure time.

Because the above idealizations are rarely encountered in the corrosion of carbon steels, it is obvious that other factors that tend to disrupt stable film formation must be operative. These factors can be external, such as erosion by wind or rain, or they may be internal to the film itself, such as stresses caused by the different specific volumes of metal and oxide. It is the complexity of these various breakdown processes that makes a quantitative prediction of corrosion so difficult, makes extrapolations of data from short-term behavior to longer times so difficult, and makes precise predictions of behavior at a particular test site based on observations at a different site virtually impossible.

The corrosion of iron in the atmosphere proceeds by the formation of hydrated oxides. The half-cell reactions can be expressed as:

$$\tfrac{1}{2}O_2 + H_2O + 2e \rightarrow 2(OH)^- \text{ (cathodic)}$$

$$Fe \rightarrow Fe^{2+} + 2e \text{ (anodic)}$$

Further reactions can then occur, such as:

$$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2$$

$$2Fe(OH)_2 + H_2O + \tfrac{1}{2}O_2 \rightarrow 2Fe(OH)_3$$

The hydrated oxides can lose water during dry periods and revert to the anhydrous ferrous and ferric oxides. In addition, a layer of magnetite (Fe_3O_4) or $FeO{\cdot}Fe_2O_3$ often forms between iron oxide (FeO) and hematite (Fe_2O_3). Actually, the various oxides and hydroxides of iron form a rather complicated system of compounds. The compound FeOOH has been found to exist in three different crystal forms plus an amorphous form. The occurrence of the various oxide species is dependent on pH, oxygen availability, various atmospheric pollutants, and the composition of the steel, as in weathering steels containing copper and phosphorus (Ref 5). The actual nature of the rust film is important because FeO and FeOOH seem to be more adherent than Fe_3O_4 and Fe_2O_3, and therefore more likely to slow the corrosive attack, but the higher oxides and oxy-hydroxides are more prone to spallation.

Atmospheric Factors in Atmospheric Corrosion

Because there is a substantial variation in the corrosion rates of carbon steels at different atmospheric-test locations, it is only logical to ask which factors contribute to these differences. Although the prediction of corrosivity is still not possible, it appears that humidity, temperature, and the levels of chloride, sulfate, and probably other atmospheric pollutants present each exert an influence on the corrosion rate of carbon steels.

Humidity and Atmospheric Pollutants. Because atmospheric corrosion is an electrolytic process, the presence of an electrolyte is required. This should not be taken to mean that the steel surface must be awash with water; a very thin absorbed film of water is all that is required. During an actual exposure, the metal spends some portion of the time awash with water because of rain or splashing and a portion of the time covered with a thin adsorbed water film. The portion of time spent covered with the thin water film depends quite strongly or relative humidity at the exposure site (Fig. 1). This fact has led many corrosion scientists to investigate the influence of the time of wetness on the corrosion rate (Ref 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17).

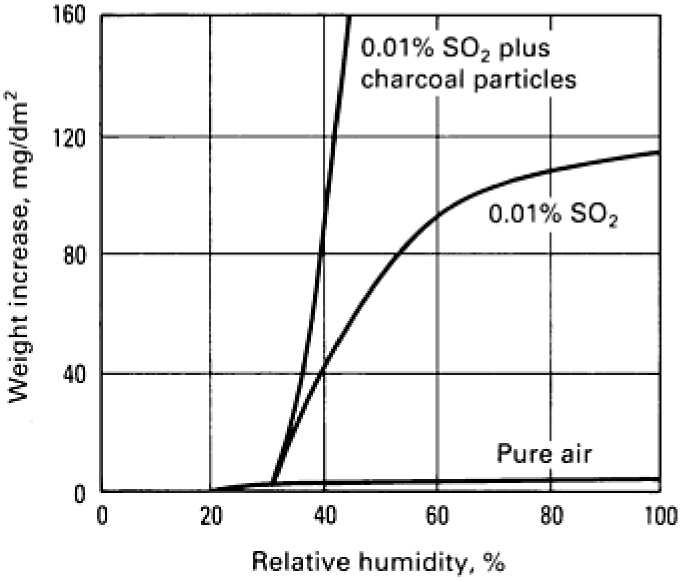

Fig. 1 Relationship between the corrosion rate of iron and the relative humidity in an environment containing 0.01% SO_2. Exposure period: 55 days. The corrosion rate of iron exposed for 55 days at 100% relative humidity is shown for comparison. Source: Ref 6

These studies have shown that time of wetness, although an important factor, cannot be considered in isolation when estimating corrosion rates. An excellent example of this fact is demonstrated in Fig. 2, in which the weight gain of iron is plotted as a function of relative humidity for an exposure of 55 days in an atmosphere containing 0.01% sulfur dioxide (SO_2). In the lower right-hand corner of Fig. 2 is the measured corrosion rate for iron exposed for the same time in an SO_2-free atmosphere at 99% relative humidity. The increase in corrosion rate produced by the addition of SO_2 to the atmosphere is substantial, as demonstrated in Fig. 3, which shows actual exposure data from four different exposure sites with varying levels of sulfur pollution in the atmosphere. The accelerating effect of sulfur is obvious.

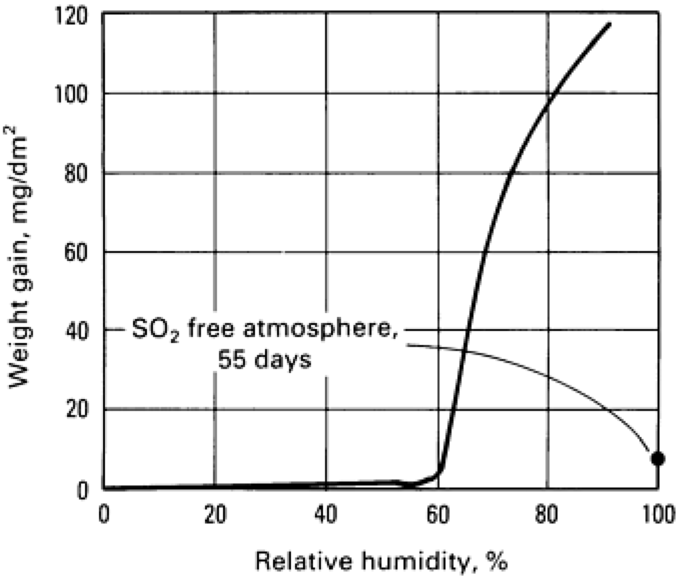

Fig. 2 Effect of relative humidity and atmospheric pollution on the rusting of iron. A critical humidity near 60% relative humidity is observed. Source: Ref 18

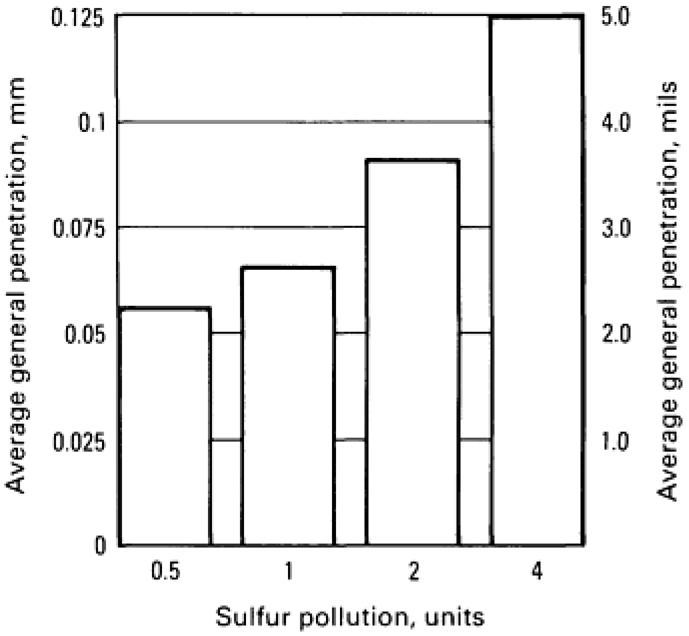

Fig. 3 Effect of atmospheric pollution on rusting. Exposure sites include Godalming, Teddington, U.K. (0.5 sulfur pollution unit); Hornchurch, Leicester, U.K. (1 sulfur pollution unit); Barking, Salford, U.K. (2 sulfur pollution units); and Manchester, Sheffield, U.K. (4 sulfur pollution units). The steel tested contained 0.28% Cu. Test duration: 1 year. Source: British Iron and Steel Research Association

Another feature of interest is the apparent existence of a critical humidity level below which the corrosion rate is small. As shown in Fig. 2, the critical humidity in an SO_2-containing atmosphere is approximately 60%. This behavior contrasts with that of steel in contact with particles of sea salt, as illustrated in Fig. 4. In Fig. 4, the corrosion rate shows a steady increase with increasing humidity. Although there is a scarcity of data, it seems reasonable that oxides of nitrogen in the atmosphere would also exhibit an accelerating effect on the corrosion of steel. Indeed, any gaseous atmospheric constituent capable of strong electrolytic activity should be suspected as being capable of increasing the corrosion rate of steel. Figure 5 shows the corrosion rate per day of wetness at six test sites and demonstrates the accelerating effect of temperature on corrosion rate. From Fig. 5(e) and 5(f), one can infer the accelerating effect of chloride ions on atmospheric corrosion.

Effects of Alloying Additions. Because carbon steels are by definition not very highly alloyed, it is not surprising that most grades do not exhibit large differences in atmospheric-corrosion rate. Nevertheless, alloying can make changes in the atmospheric-corrosion rate of carbon steel. The elements generally found to be most beneficial in this regard are copper, nickel, silicon, chromium, and phosphorus. Of these, the most striking example is that of copper; increases from 0.01 to 0.05% have been shown to decrease the corrosion rate by a factor of two to three (Ref 20, 21). Additions of the above elements in combination are generally more effective than when added singly, although the effects are not additive. The effects from one study are shown in Fig. 6, 7, 8, 9, and 10. The effectiveness of these elements in retarding corrosion also appears to depend on the corrosive environment, with the most benefit appearing in industrial atmospheres (Ref 23).

Kinetics of Atmospheric Corrosion

The rate of atmospheric corrosion of steels is not constant with time but usually decreases as the length of exposure increases. This fact indicates the difficulty in using most of the published atmospheric-corrosion data in any quantitative way. Much of the published data consists of weight loss due to corrosion averaged over the time of exposure, which is itself often variable. Such corrosion rate calculations are misleading, especially when the exposure time is short, because the ensuing rate of attack can be considerably lower. Several authors have shown that the amount of corrosion occurring as a function of time can be expressed as (Ref 24, 25, 26, 27, 28, 29, 30):

$$W = Kt^n \qquad \textbf{(Eq 1)}$$

where W is the weight loss of metal due to corrosion, t is the exposure time in years, and K and n are empirical constants. The goodness of fit seems to be excellent, but until more data from various atmospheric-exposure sites are analyzed, Eq 1 is of limited value. Because the values of K and n depend on both the alloy system and the exposure site, a great deal of work must be done before general use of Eq 1 can be made in real applications. The one possible exception would be when data for the exposure situation and alloy system are already known. In this case, Eq 1 can be very useful in estimating long-term corrosion behavior from as little as 2 years of data (Ref 24), although 3- to 4-year data give a better estimate.

Perhaps most important, Eq 1 points out that it is impossible to describe either the extent or rate of corrosion under atmospheric conditions with a single parameter, which is what much of the reported corrosion data persists in doing. When the results of a several-year exposure test are condensed to a single value, such as the average loss per year or the total loss for the exposure period, one cannot estimate the values of the kinetic parameters governing the system. Without the values of these parameters, extrapolation of results to longer exposure periods becomes quite unreliable. When good estimates for the kinetic parameters are available, extrapolations to 7- or 8-year performance from 1- and 2-year data have been found to agree within 5% of observed performance (Ref 24).

Atmospheric Corrosion

Atmospheres are often classified as being rural, industrial, or marine in nature. Such a classification is of course a gross oversimplification of the situation. It is easy to list locations along the seacoast that have heavy industrial pollution in the atmosphere. Such locations are both marine and industrial. Furthermore, two decidedly rural environments can differ widely in average yearly temperature and rainfall and can therefore have considerably different corrosive tendencies. Industrial expansion into formerly rural areas can easily change the aggressiveness of a particular location. Finally, long-term trends in the environment, such as changes in rainfall patterns, mean temperature, and perhaps acid rain, can make extrapolations from past behavior less reliable.

Other factors that limit the usefulness of atmospheric-exposure data are the general nonlinearity of weight loss due to corrosion with time and the fact that most atmospheric-corrosion data are presented as an average over the entire test panel surface. Most atmospheric exposure data for steels show a decrease in the rate of attack with time of exposure so that extrapolations of such data to times longer than those covered by the exposure data can lead to an overdesign in cross section. Finally, in many cases, the average weight loss per unit area is of less concern than the time to perforation. This factor is more related to localized attack, which can be masked by the averaging of data, as is done in weight loss determinations.

Given all the caveats mentioned above, the design engineer is well justified in using atmospheric-corrosion data as more indicative than quantitative. With all of this in mind, some of the corrosion data for various carbon steels in some representative environments will be discussed. More detailed information is available in Ref 1, 2, and 3.

The effect of various environments on the corrosion rate is indicated in Table 3. Table 3 is a compilation of weight loss measurements for cold-rolled carbon steels after 2 years of exposure. The most startling feature of Table 3 is the extreme range of corrosion rates existing. Galeta Point Beach, Panama, is more than 450 times as aggressive than the site at Norman Wells, N.W.T., Canada. This difference in corrosion rate is easily greater than any effect that can be produced by small changes in composition of the steel. Again, this underscores the fact that in dealing with the corrosion of carbon steels the alteration of design or environmental factors is usually more effective than changing the grade of steel.

Table 3 Comparative rankings of 45 locations based on steel loss of weight (grams) of 10- × 15-cm (4- × 6-in.) specimens of steel

Ranking to State College, PA	Location	2-year exposure, grams lost
1	Norman Wells, N.W.T., Canada	0.73
2	Phoenix, AZ	2.23
3	Saskatoon, Sask., Canada	2.77
4	Esquimalt, Vancouver Island, Canada	6.50
5	Detroit, MI	7.03
6	Fort Amidor Pier, Panama, C.Z.	7.10
7	Morenci, MI	9.53

8	Ottawa, Ont., Canada	9.60

45	Galeta Point Beach, Panama, C.Z.	336.0

Source: Ref 4

Further examination of Table 3 shows that the marine environments tend to be near the aggressive end of the list and that cold environments are generally less aggressive than warm sites. The average yearly temperature cannot, in general, be isolated from the moisture effect, because most of the more tropical exposure sites are also in regions with high humidity. One exception is arid Phoenix, AZ.

Corrosion Film Formation and Breakdown. The corrosion of carbon steel in the atmosphere and in many aqueous environments is best understood from a film formation and breakdown standpoint. It is an inescapable fact that iron in the presence of oxygen and/or water is thermodynamically unstable with respect to its oxides. Thus, the question is never

whether the steel will rust, but rather at what rate. In the absence of film formation and with a constant environment, one would expect the oxidation rate to be constant. Conversely, if the corrosion product film that forms isolates the steel from the corrosive environment, one would expect a zero corrosion rate after the initial film formation period. A tightly adherent film that permits only diffusion transfer of the reactants would be characterized by a corrosion rate that decreases with the square root of the exposure time.

Because the above idealizations are rarely encountered in the corrosion of carbon steels, it is obvious that other factors that tend to disrupt stable film formation must be operative. These factors can be external, such as erosion by wind or rain, or they may be internal to the film itself, such as stresses caused by the different specific volumes of metal and oxide. It is the complexity of these various breakdown processes that makes a quantitative prediction of corrosion so difficult, makes extrapolations of data from short-term behavior to longer times so difficult, and makes precise predictions of behavior at a particular test site based on observations at a different site virtually impossible.

The corrosion of iron in the atmosphere proceeds by the formation of hydrated oxides. The half-cell reactions can be expressed as:

$$\frac{1}{2}O_2 + H_2O + 2e \rightarrow 2(OH)^- \text{ (cathodic)}$$

$$Fe \rightarrow Fe^{2+} + 2e \text{ (anodic)}$$

Further reactions can then occur, such as:

$$Fe^{2+} + 2OH^- \rightarrow Fe(OH)_2$$

$$2Fe(OH)_2 + H_2O + \frac{1}{2}O_2 \rightarrow 2Fe(OH)_3$$

The hydrated oxides can lose water during dry periods and revert to the anhydrous ferrous and ferric oxides. In addition, a layer of magnetite (Fe_3O_4) or $FeO{\cdot}Fe_2O_3$ often forms between iron oxide (FeO) and hematite (Fe_2O_3). Actually, the various oxides and hydroxides of iron form a rather complicated system of compounds. The compound FeOOH has been found to exist in three different crystal forms plus an amorphous form. The occurrence of the various oxide species is dependent on pH, oxygen availability, various atmospheric pollutants, and the composition of the steel, as in weathering steels containing copper and phosphorus (Ref 5). The actual nature of the rust film is important because FeO and FeOOH seem to be more adherent than Fe_3O_4 and Fe_2O_3, and therefore more likely to slow the corrosive attack, but the higher oxides and oxy-hydroxides are more prone to spallation.

Atmospheric Factors in Atmospheric Corrosion

Because there is a substantial variation in the corrosion rates of carbon steels at different atmospheric-test locations, it is only logical to ask which factors contribute to these differences. Although the prediction of corrosivity is still not possible, it appears that humidity, temperature, and the levels of chloride, sulfate, and probably other atmospheric pollutants present each exert an influence on the corrosion rate of carbon steels.

Humidity and Atmospheric Pollutants. Because atmospheric corrosion is an electrolytic process, the presence of an electrolyte is required. This should not be taken to mean that the steel surface must be awash with water; a very thin absorbed film of water is all that is required. During an actual exposure, the metal spends some portion of the time awash with water because of rain or splashing and a portion of the time covered with a thin adsorbed water film. The portion of time spent covered with the thin water film depends quite strongly or relative humidity at the exposure site (Fig. 1). This fact has led many corrosion scientists to investigate the influence of the time of wetness on the corrosion rate (Ref 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17).

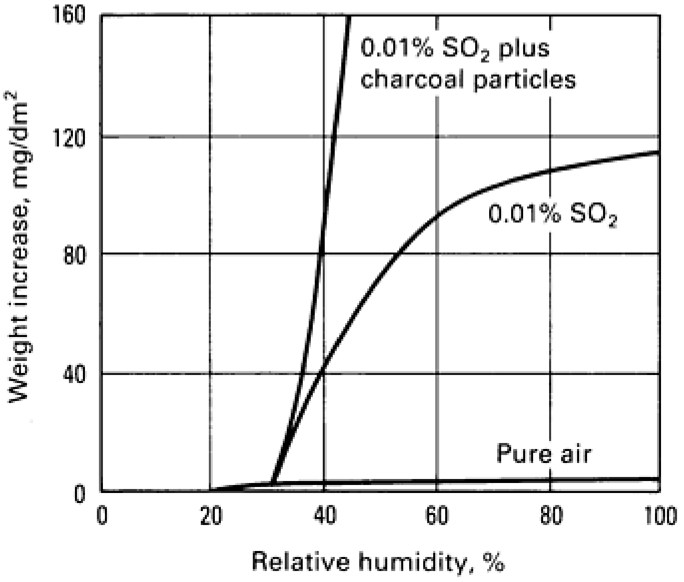

Fig. 1 Relationship between the corrosion rate of iron and the relative humidity in an environment containing 0.01% SO_2. Exposure period: 55 days. The corrosion rate of iron exposed for 55 days at 100% relative humidity is shown for comparison. Source: Ref 6

These studies have shown that time of wetness, although an important factor, cannot be considered in isolation when estimating corrosion rates. An excellent example of this fact is demonstrated in Fig. 2, in which the weight gain of iron is plotted as a function of relative humidity for an exposure of 55 days in an atmosphere containing 0.01% sulfur dioxide (SO_2). In the lower right-hand corner of Fig. 2 is the measured corrosion rate for iron exposed for the same time in an SO_2-free atmosphere at 99% relative humidity. The increase in corrosion rate produced by the addition of SO_2 to the atmosphere is substantial, as demonstrated in Fig. 3, which shows actual exposure data from four different exposure sites with varying levels of sulfur pollution in the atmosphere. The accelerating effect of sulfur is obvious.

Kinetics of Atmospheric Corrosion

The rate of atmospheric corrosion of steels is not constant with time but usually decreases as the length of exposure increases. This fact indicates the difficulty in using most of the published atmospheric-corrosion data in any quantitative way. Much of the published data consists of weight loss due to corrosion averaged over the time of exposure, which is itself often variable. Such corrosion rate calculations are misleading, especially when the exposure time is short, because the ensuing rate of attack can be considerably lower. Several authors have shown that the amount of corrosion occurring as a function of time can be expressed as (Ref 24, 25, 26, 27, 28, 29, 30):

$$W = Kt^n \quad \textbf{(Eq 1)}$$

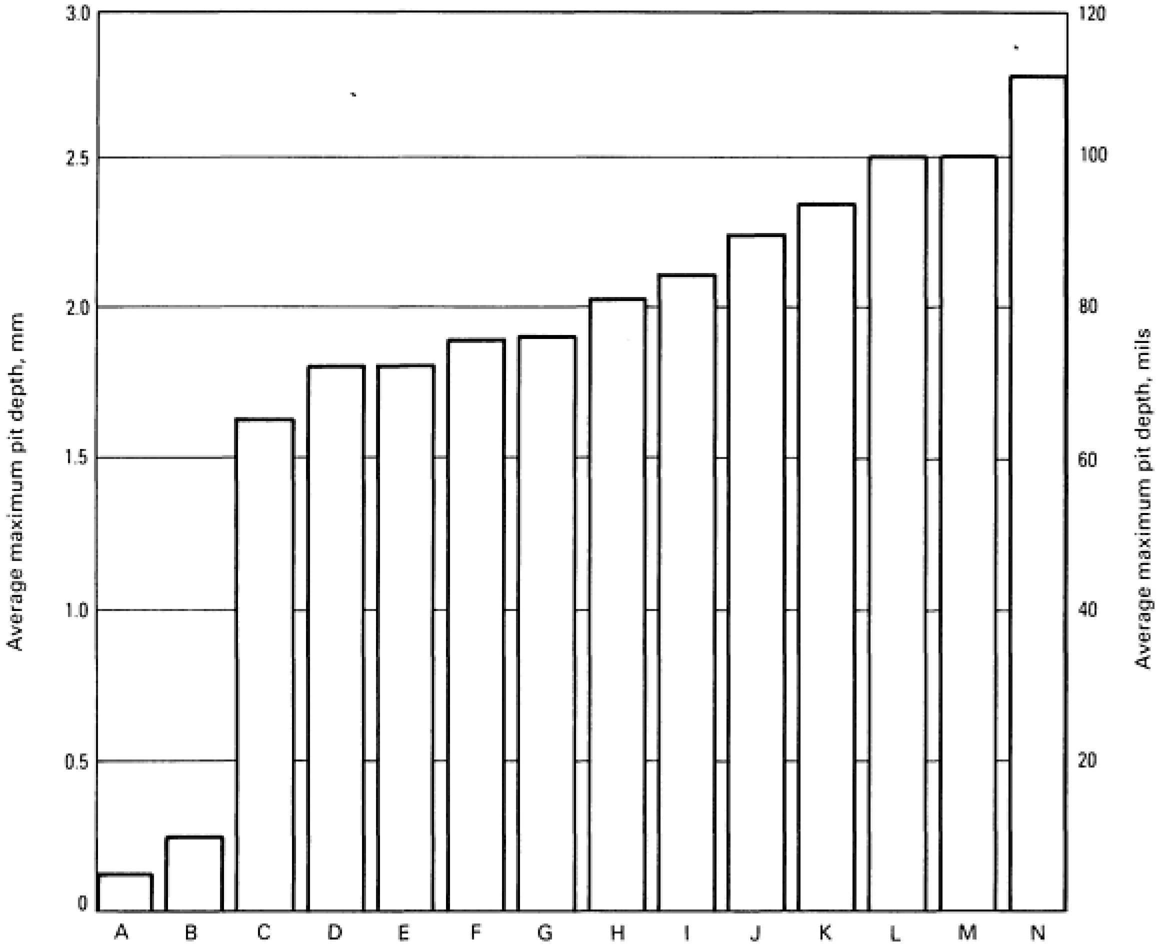
where *W* is the weight loss of metal due to corrosion, *t* is the exposure time in years, and *K* and *n* are empirical constants. The goodness of fit seems to be excellent, but until more data from various atmospheric-exposure sites are analyzed, Eq 1 is of limited value. Because the values of *K* and *n* depend on both the alloy system and the exposure site, a great deal of work must be done before general use of Eq 1 can be made in real applications. The one possible exception would be when data for the exposure situation and alloy system are already known. In this case, Eq 1 can be very useful in estimating long-term corrosion behavior from as little as 2 years of data (Ref 24), although 3- to 4-year data give a better estimate.

Perhaps most important, Eq 1 points out that it is impossible to describe either the extent or rate of corrosion under atmospheric conditions with a single parameter, which is what much of the reported corrosion data persists in doing. When the results of a several-year exposure test are condensed to a single value, such as the average loss per year or the total loss for the exposure period, one cannot estimate the values of the kinetic parameters governing the system. Without the values of these parameters, extrapolation of results to longer exposure periods becomes quite unreliable. When good estimates for the kinetic parameters are available, extrapolations to 7- or 8-year performance from 1- and 2-year data have been found to agree within 5% of observed performance (Ref 24).

Soil Corrosion

The response of carbon steel to soil corrosion depends primarily on the nature of the soil and certain other environmental factors, such as the availability of moisture and oxygen. These factors can lead to extreme variations in the rate of attack. For example, under the worst conditions, a buried vessel may perforate in less than 1 year, although archaeological digs in arid desert regions have uncovered iron tools dating back hundreds of years. Because of this intrinsic variability, any cumulative weight loss data or kinetic information is virtually worthless for design use. Some general rules can be formulated, however. Soils with high moisture content, high electrical conductivity, high acidity, and high dissolved salts will be most corrosive. At the other extremes of character, the soil will be virtually inert to carbon steel. The effect of aeration on soils is somewhat different from the effect of aeration on water because poorly aerated conditions in water can lead to accelerated attack by sulfate-reducing anaerobic bacteria.

The effect of low levels of alloying additions on the soil corrosion of carbon steels is modest at best, with most common additions showing no significant benefit. Some data (Fig. 13) seem to show a small benefit of 1% Cu + 2.5% Ni over plain carbon steel; however, it is debatable whether this improved performance could justify the added alloy cost. This decision must involve other factors, such as the cost of a failure and the cost of replacement.



Alloy	Nominal composition, wt %
A	18% Cr, 8% Ni
B	18% Cr
C	Special cast iron (2.5C-1.4Si-0.3Mn-0.08S-0.13P-0.5Cu)
D	High-alloy cast iron (3.0C-2.1Si-1.0Mn-2.6Cr-15Ni-6.6Cu)
E	Copper-nickel steel (2.5Ni-1.0Cu)
F	Special cast iron (2.9C-2.0Si-0.8Mn-0.06S-0.25P-0.6Cu)
G	Cast iron (3.6C-1.6Si-0.5Mn-0.07S-0.7P)
H	Cast iron (3.6C-1.6Si-0.5Mn-0.07S-0.8P)
I	Low-carbon steel + 5% Cr
J	Low-alloy cast iron (3.5C-2.5Si-0.7Mn-0.05S-0.4P-0.3Cu-0.15Ni)
K	Wrought iron (0.02C-0.1Si-0.3Mn-0.02S-0.16P)
L	Low-carbon steel (0.15C-0.49Mn-0.03S-0.013P)
M	Wrought iron (0.02C-0.13Si-0.4Mn-0.02S-0.11P)
N	Copper-molybdenum iron (0.52Cu-0.15Mo)

Fig. 13 Averages of maximum pit depths on ferrous pipes removed from Merced clay adobe after an exposure of 5 years. Source: Ref 39

Interestingly, it has been demonstrated that both the weight loss and maximum pit depth in soil corrosion can be represented by an equation of the form (Ref 40):

$$Z = at^m \qquad \textbf{(Eq 2)}$$

where Z is either the weight loss of maximum pit depth, t is time of exposure, and a and m are constants that depend on the specific soil corrosion situation. Equation 2 is of the same form as Eq 1 . The similarities between Eq 1 and Eq 2 may be due to the general applicability of a power law relationship, but because both types of corrosion are fundamentally

electrolytic, there may be some underlying connection. A more detailed discussion of underground corrosion is available in Ref 40. Tests for evaluating corrosion in soils are discussed in the article "Simulated Service Testing" (see the Section "Corrosion Testing in Soils") in this Volume.

Corrosion in Concrete

The corrosion process in concrete is such that it tends to create conditions that increase the rate of attack. This phenomenon is related to the fact that the various corrosion products of iron and steel have a larger specific volume than the steel itself. The increase in volume of the corrosion products causes stresses that can lead to cracks in the concrete. These cracks allow easier access for the attacking medium and therefore more rapid attack. When the cracks are open to the exterior, corrosion products can be washed out and often lead to cosmetically objectionable stains. Of greater concern is the case of prestressed concrete. In this material, the corrosion process can lead to loss of structural strength and eventual failure. Of the cases studied, the failures of prestressed structures are not associated with stress corrosion, but are merely due to the loss of load-bearing area of steel (Ref 41).

The presence of chloride ions appears to be the principal cause of steel corrosion in concrete (Ref 42). Various attempts at reducing or eliminating the corrosion problem have focused on protective coatings for the steel members (galvanized, paints, and so on), decreasing the concrete permeability, increasing the depth of concrete cover, or eliminating the chloride ion through the use of sealants, and so on. Although many of these approaches have shown some degree of success, the application of cathodic protection has been the most successful in arresting corrosion (Ref 43).

There does not appear to be any significant body of data relating the severity of corrosion to the composition of the steel reinforcing member. It is likely that alloying could reduce the overall rate attack, but whether the reduction would be significant in light of the added cost is problematic. Additional information on the corrosion and corrosion protection of steels in concrete can be found in Ref 44, 45, 46, 47, 48, and in the articles "Corrosion in Structures" and "Cathodic Protection" in this Volume.

Boiler Service

Corrosion in boilers is a special case of aqueous corrosion that involves elevated temperatures. The availability of oxygen appears to be the rate-determining step insofar as general attack is concerned. In closed-loop systems, the initial oxygen supply of the water is rapidly consumed in the early stages of film formation so that corrosion rates are usually not a problem. In nonclosed-loop systems, deaeration is usually adequate for eliminating general corrosion problems.

Of more concern in boiler systems is the occurrence of pitting. In pitting corrosion, both dissolved oxygen and carbon dioxide (CO_2) promote attack. Deaeration is useful is stopping the oxygen attack, but CO_2 pitting is more effectively handled by maintaining an alkaline pH in the water. Surface deposits of corrosion products, mill scale, or even oil films have occasionally been implicated in the pitting attack of boilers. The treatment of boiler water is described in Ref 49.

Steel boilers are also susceptible to a form of stress-corrosion cracking (SCC) termed caustic cracking. This can occur even when the bulk concentration of caustic is below the danger level because of a variety of processes that can lead to localized accumulations of caustic well in excess of average concentrations. Because alkalinity is desired to avoid pitting attack, it is obvious that methods for preserving the benefit of pit suppression without incurring caustic cracking are necessary. Fortunately, such procedures have been devised; they are described in Ref 49. As a guide, Fig. 14 is presented for boiler water treatment with trisodium phosphate as a function of pH level necessary for crack suppression. Additional information on high-temperature aqueous corrosion can be found in the article "Corrosion in Fossil Fuel Power Plants" in this Volume.

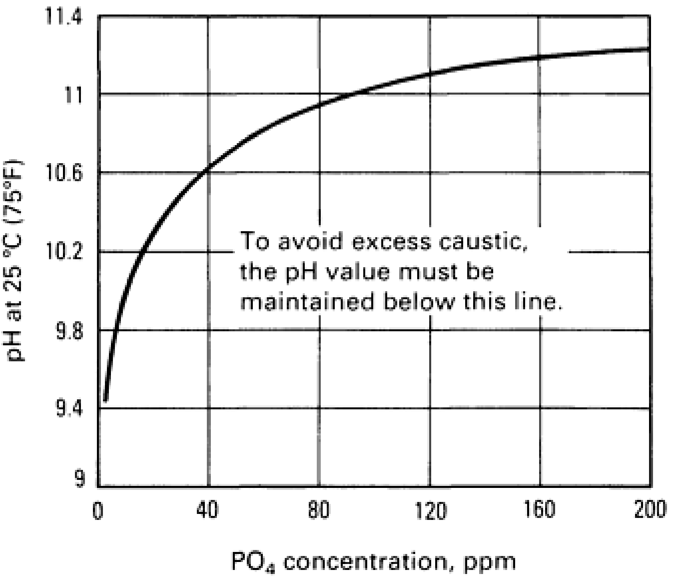


Fig. 14 Relationship of pH values to trisodium phosphate concentration in boiler water

Liquid-Metal Corrosion

Liquid metals can attack plain carbon steels in several ways. First, if iron is soluble in the liquid metal, dissolution will occur until the liquid metal is saturated. At this point, dissolution will cease in an isothermal system. Unfortunately, real systems almost always have temperature gradients. The presence of these gradients leads not only to dissolution in the high-temperature portions of the systems but also to a precipitation or plating out in the colder areas. This precipitation decreases the solute content below the level that was present at the higher temperature, thus enabling additional dissolution to occur at the high temperature. The end result of this material transfer process is either the complete dissolution of the container on the high-temperature side of the system or, in the case in which the liquid metal is contained in channels or pipes, a blockage on the cold side from the continued precipitation.

A second mode of attack involves the formation of intermetallic alloys of the steel with the liquid metal. If the particular intermetallic is poorly adherent or if it can be spalled off by mechanical or thermal stresses (this exposes fresh surface to form more alloy), perforation can eventually result. On the other hand, if the intermetallic alloy that forms is tightly adherent and resistant to cracking, it can act as a barrier to diffusion and can slow the rate of attack.

Another form of attack that can occur and is more pernicious is intergranular penetration and/or dissolution by liquid metal. The unfortunate aspect of this mode of attack is that it can result in a loss of strength without any large weight loss or change in appearance. In this respect, it resembles the more familiar aqueous intergranular corrosion. More detailed information on dissolution by liquid metals can be found in the articles "Fundamentals of High-Temperature Corrosion in Liquid Metals" and "General Corrosion" (see the section "Corrosion in Liquid Metals") in this Volume.

Finally, there is the phenomenon of liquid-metal embrittlement, which requires the presence of both stress and a liquid metal. The cracks that occur during the embrittlement process may be intergranular or transgranular. The process seems to be similar in many ways to SCC. Steels have been reported to undergo embrittlement by lithium, indium, cadmium, zinc, tellurium, and various lead-tin solders. Additional information can be found in the article "Environmentally Induced Cracking" (see the Section "Liquid Metal Embrittlement") in this Volume.

Resistance of Plain Carbon Steels to Liquid-Metal Corrosion

Sodium and Sodium-Potassium Alloys. Plain carbon and low-alloy steels are generally suitable for long-term use in these media at temperatures to 450 °C (840 °F). Beyond these temperatures, stainless steels are required.

Lithium is somewhat more aggressive to plain carbon steels that sodium or sodium-potassium. As a result, low-alloy steels should not be considered for long-term use above 300 °C (570 °F). At higher temperatures, the ferritic stainless steels show better results at higher temperatures.

Cadmium. Low-alloy steels exhibit good serviceability to 700 °C (1290 °F).

Zinc. Most engineering metals and alloys show poor resistance to molten zinc, and carbon steels are no exception.

Antimony. Low-carbon steels have poor resistance to attack by antimony.

Mercury. Although plain carbon steels are virtually unattacked by mercury under nonflowing or isothermal conditions, the presence of either a temperature gradient or liquid flow can lead to drastic attack. The corrosion mechanism seems to be one of dissolution, with the rate of attack increasing rapidly with temperature above 500 °C (930 °F). Alloy additions of chromium, titanium, silicon, and molybdenum, alone or in combination, show resistance to 600 °C (1110 °F). Where applicable, the attack of ferrous alloys by mercury can be reduced to negligible amounts by the addition of 10 ppm Ti to the mercury; this raises the useful range of operating temperatures to 650 °C (1200 °F). Additions of metal with a higher affinity for oxygen than titanium, such as sodium or magnesium, may be required to prevent oxidation of the titanium and loss of the inhibitive action.

Aluminum. Plain carbon steels are not satisfactory for long-term containment of molten aluminum.

Gallium is one of the most aggressive of all liquid metals and cannot be contained by carbon or low-alloy steels at elevated temperatures.

Indium. Carbon and low-alloy steels have poor resistance to molten indium.

Lead, Bismuth, Tin, and Their Alloys. Low-alloy steels have good resistance to lead up to 600 °C (1110 °F), to bismuth up to 700 °C (1290 °F), and to tin only up to 150 °C (300 °F). The various alloys of lead, bismuth, and tin are more aggressive.

Weathering Steels

S.K. Coburn, Corrosion Consultants, Inc.; Yong-Wu Kim, Inland Steel Company

The weathering steels had their origin in the early studies of D.M. Buck. After a decade of effort, Buck established the efficacy of copper as a means of enhancing the atmospheric-corrosion resistance of unpainted carbon steel in a variety of environments (Ref 50, 51, 52). While this work was going on, a large study was initiated in 1916 by the American Society for Testing and Materials (ASTM) to evaluate the atmospheric performance of a variety of ferrous materials.

By 1929, United States Steel Corporation had initiated studies to enhance the performance of copper-bearing steel further through the addition of a number of alloying elements. By 1933, the first commercially available high-strength low-alloy steel was introduced into the railroad industry for coal hopper car use in the unpainted condition. These high-strength low-alloy steels were capable of resisting the leachates from sulfur-bearing coals better than the existing carbon and copper-bearing steel cars. Since that time, the original architectural grade has been covered by ASTM A 242 (Ref 53). When the heavier structural grades of high-strength low-alloy steels became available, they were covered by ASTM A 588 (Ref 54).

Through the exposure of small test panels in various atmospheres, the performance of the steel composition as well as the aggressiveness of the particular location were both calibrated. Other characteristics of the high-strength low-alloy steels were studied, such as the ability to develop the protective oxide film under sheltered conditions in the atmosphere, in the soil, and immersed in freshwater and seawater. Studies were conducted on the staining characteristics and the ability to perform in contact with other materials. Finally, studies were performed to determine the manner in which protective coatings would function.

Copper-Bearing Steel

To appreciate the nature of the current composition of the weathering steels, it is useful to recall some of Buck's findings. In the early days, scrap steel was not in common use. Thus, Buck accidentally noticed that one test sheet outperformed the others. Upon examination, the copper level of this sheet was found to exceed the 0.01 to 0.02% common to the remainder of the test sheets. This finding resulted in Buck's initiating a series of studies to identify the minimum amount of copper (found to be 0.20%) necessary to effect an improvement in performance and to determine the relationship of the copper content to the sulfur content of the steel. From 1929 to 1933, much effort was expended toward developing compositions with superior atmospheric-corrosion resistance to the accepted 0.20% Cu-containing steels.

High-Strength Low-Alloy Steels

In 1962, the results of a comprehensive 15.5-year study were published in which some 270 different steels were exposed in three atmospheres beginning in the late 1940s (Ref 22). The sites were at Kearny, NJ (industrial); South Bend, PA (semirural); and Kure Beach, NC (250 m, or 800 ft, from the ocean). Table 5 lists the performance of 18 representative compositions in which the different levels of copper are combined with one of the four alloying elements (nickel, chromium, silicon, and phosphorus) to show their respective influences on corrosion in the industrial and marine sites. In addition, this group contains seven compositions in which one of the alloying elements is omitted, the purpose being to demonstrate how the remaining elements are capable of contributing to a satisfactory performance in the various atmospheres. Figures 6, 7, 8, 9, and 10 in the previous section, "Carbon Steels," in this article also show the effects of the above-mentioned alloying elements on steel corrosion.

Table 5 Average reduction in thickness of steel specimens after 15.5-year exposure in different atmospheres

Source: Ref 22

The significance of copper levels is shown in compositions 1, 2 and 3 in Table 5. Compositions 4 and 5 show how nickel can compensate for a low copper level. In contrast, compositions 6 and 7 show that chromium requires copper except in the marine environment. In compositions 8 and 9, silicon shows useful properties in the absence of copper. Phosphorus also contributes to this effect (compositions 10 and 11). Compositions 12 through 18 show the results of combining all of the alloying elements or omitting one of the elements. Additional research revealed that lower concentrations of the alloying elements were still effective. The current compositions of two of the major suppliers are shown in Table 6. Other proprietary compositions can be found in Ref 55.

Table 6 Representative compositions of A588 high-strength low-alloy steel

Corrosion Behavior Under Different Exposure Conditions

The standard method for developing typical corrosion rates for comparative purposes is to expose 100- × 150-mm (4- × 6-in.) panels on test racks at an inclination of 30° from the horizontal facing south. An exposure rack with a sulfur dioxide candle in a louvered box is shown in Fig. 15. More detailed information on atmospheric-corrosion testing can be found in the article "Simulated Service Testing" in this Volume.

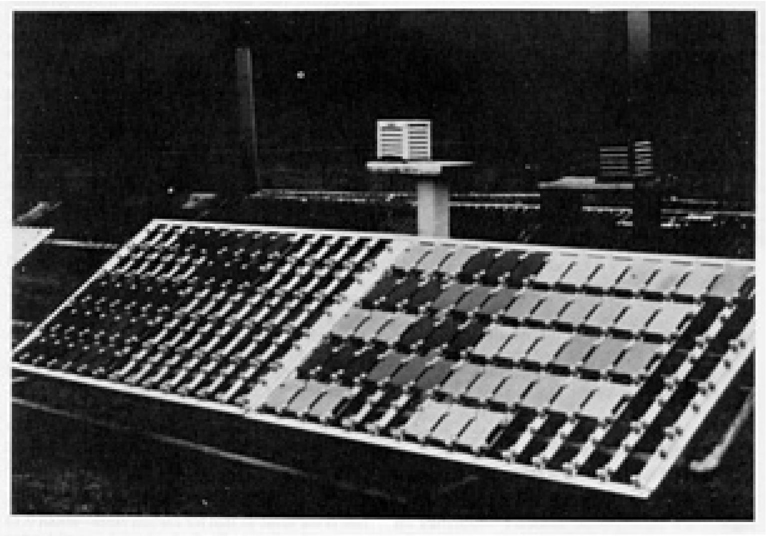

Fig. 15 Typical exposure rack with sulfur dioxide candle in louvered box

The panel performance is judged by the loss in weight sustained after varying exposure periods. The relationship between the loss in weight sustained by the skyward surface and the groundwater surface by exposing test panels in semirural South Bend, PA, and industrial Kearny, NJ, for 4 years was first reported in Ref 56. In this test, carbon steel, copper-bearing steel, and USS COR-TEN steel panels were exposed. In both environments, the contribution to the total weight loss of the test panels was essentially the same. The skyward surface that was washed by the rain and warmed by the wind and sun contributed 37% to the weight loss, while the groundward surface that was never washed by the rain nor dried as much by the sun contributed 63% to the weight loss. This is significant because the sheltered surface has a coarse granular oxide film due to the loosely attached initial oxide film that tends to retain dampness and to promote additional corrosion.

Another study was conducted to compare the loss in weight between a vertical panel and an inclined panel in three different environments using copper-bearing steel and copper-free steel (Ref 57). It is apparent from the data discussed in Table 7 that a vertical surface that is only occasionally washed by rain is likely to corrode approximately 20 to 25% more than an inclined surface.

Table 7 Relative corrosivity of panels in vertical and inclined positions in different environments

Location and environment	Position	Reduction in thickness after 2 years					
		Copper-free		**Ratio**	**Copper-bearing**		**Ratio**
		μm	**mils**		**μm**	**mils**

Because some weathering steels are licensed in many countries in Europe and the Far East, comparisons sometimes are made in which it is stated that poor results may occur because of some reduced performance level or excessive time interval before the protective oxide coating has matured in these different countries. What is often overlooked is that most European countries are located in latitudes that range from the equivalent Canadian border to the Arctic Circle. The sun is lower and the hours of sunlight are fewer than in the continental United States; thus, the time of wetness is longer (Table 8).

Table 8 Latitudes of North American and European countries

Latitude	U.S.	Canadian[(a)]	Italy	France	Germany	England	Scandinavia

To	45°	55°	45°	50°	53°	57°	70°

(a) Most densely populated area

Characteristics of the Protective Oxide Film

It is likely that rusting occurs more during the night when atmospheric moisture condenses on metal surfaces when the dew point is reached. On average, in the Midwest and middle Atlantic states up through Canada, a 5.5- to 8.3- °C (10- to

15- °F) drop in temperature when the daytime relative humidity is around 75% is sufficient to result in condensation at night. The moisture absorbs the gaseous contaminants of the local atmosphere and nucleates around a dust particle and thus brings an acidic droplet to the metal surface. The thin acidic moisture film is capable of solubilizing the steel and initiating the rusting or oxidizing process. By morning, the sun and the moving air dry the gelatinous ferric hydroxide compounds that form, and the oxide begins to consolidate itself on the surface. This alternate wetting and drying cycle produces the protective oxide film on weathering steel compositions, but it produces the more porous nonprotective oxide film on carbon steel. Repeated cycles of this type ultimately result in complete coverage of the surface and a slowing of the corrosion rate. This behavior can best be expressed by time/corrosion curves, as shown in Fig. 16.

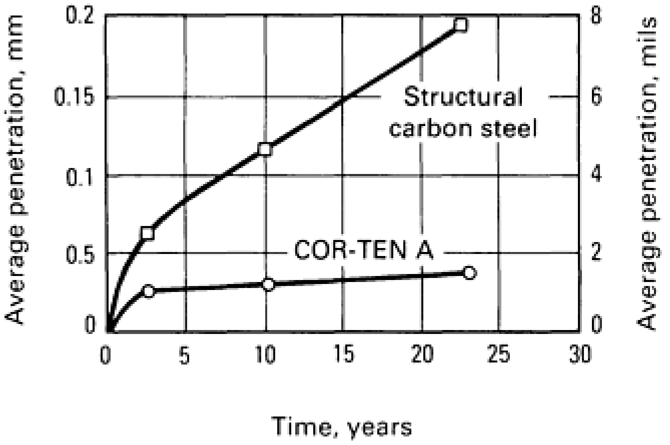

Fig. 16 Time/corrosion curves showing relative performance in a semi-industrial environment

It should be noted that the formation of a protective rust film can result in a deceleration, although not necessarily a cessation, of corrosion. However, as the alloying increases, the quality of protection increases, as evident with the weathering steel composition. There are a number of ways of demonstrating this improving condition. A practical test is that demonstrated with rusted test panels that are evaluated for their wicking tendency after various exposure periods. Table 9 contains the results of a wicking test in which the edge of a test panel contacts the surface of a dish containing water. The height of wicking is an indication of the compactness of the protective oxide film.

Table 9 Height of wicking of exposed steel panels

Exposure period, years	**USS COR-TEN steel**		Carbon steel	
	mm	**in.**	**mm**	in.
0.5	25.4	1.0	48.0	**1.89**
1.0	19.0	0.75	41.5	**1.63**
2.0	1.6	0.063	31.7	**1.25**
4.0	**1.6**	**0.063**	**14.2**	**0.56**

It is easy to understand the sealing action that occurs as the oxide film ages by virtue of the behavior of a drop of water applied to the surface of a rusted test panel. The water droplet on a weathering steel panel retains its spherical form

because of the sealed surface (Fig. 17). In contrast, the porous rust film on the carbon steel panel permits the droplet to wet out and penetrate the rust film.

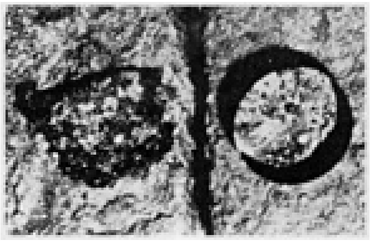

Fig. 17 Water droplet wetted out and penetrated carbon steel rust (left) but failed to penetrate sealed rust of weathering steel (right)

As indicated earlier, the key to the development of the protective oxide film is the alternate wetting and drying cycle typified by the normal night and day exposure. Under conditions of long-term immersion in freshwater or seawater, the corrosion rate is the same as that for carbon steel--about 0.13 mm/yr (5 mils/yr). Similarly, burial in soil having varying moisture levels will result in behavior similar to that of carbon steel. The lack of a drying cycle inhibits the formation of the characteristic oxide film. The implication then is to avoid features in any structure, such as pockets, that can retain water for lengthy periods and to paint any portion of a structure, such as a column, that will be in the soil subject to rain and snow drainage.

To illustrate the results of constant dampness, a sheet of copper-bearing steel was exposed on a 30° test rack (Ref 26). The bottom of the sheet was turned up to serve as a trough to retain rainwater. The top of the sheet was turned down on the back of the rack to serve as a vertical wall facing north. The failure time in months in terms of severe rusting is shown in Table 10. It is clearly evident from the service life of the bottom and the sides of the trough that long-term dampness has a deleterious effect on the steel. It is also significant that the lack of the drying effect of the sun and the lack of the washing effect of the rain have combined to limit the service life of the vertical portion facing the north. The ideal exposure conditions are those in which the surface is washed frequently to remove contaminants and the sun is present to dry the surface.

Table 10 Failure time for copper-bearing steel sheet

Sheet face	Months to severe rust	Performance ratio
Bottom of trough	25	1
Sides of trough	25	1
Vertical portion facing north	130	5.2
Inclined skyward surface facing south	170	6.8

Case Histories and Design Considerations

Thus, from the data presented in this section, the working rules for creating optimum conditions for the formation of the protective oxide film have evolved. The following case histories illustrate both the violations of these rules and suggestions on how to avoid certain maintenance problems.

Example 1: Assessing the Influence of Location.

The Gulf Coast, where onshore breezes are the rule, experiences considerable penetration of salt air because there are no forested areas or concentration of tall buildings to provide a snow fence effect to deflect the incoming breezes upward. Thus, structures are prone to impact by salt-laden air, permitting a buildup of a salt residue that can inhibit formation of the characteristic oxide film.

To assess a location properly, one should expose a small test rack for 18 to 24 months with panels of weathering steel and copper-bearing steel or carbon steel with less than 0.02% Cu. Two or three removals for weight loss determination will indicate whether a protective oxide is forming on the weathering steel. If proximity to the ocean is a question, then exposure of a chloride candle, either at ground level or preferably at an elevation comparable to the height of the structure, should be made, and the monthly chloride determinations should be performed for at least 12 months in order to assess the influence of the seasons.

Example 2: Storage and Stacking of Weathering Steels.

Electrical utilities store their tower angles at a central or regional location and along a power-line site. In either case, angles should be stored facedown rather than nesting faceup. This eliminates the possibility of retaining water in between nested members. They should be stored on small steel angles with one end of the bundles elevated to facilitate drainage. When angles or channels are nested so that they can retain water, a loose voluminous rust scale develops, as seen in Fig. 18. Fortunately, such a scale can be readily removed by hammering, brushing, or with a power-driven wire wheel.

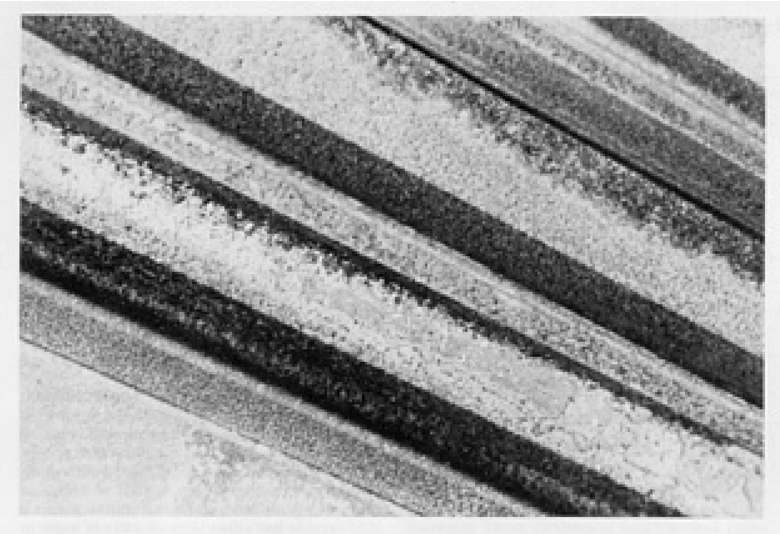

Fig. 18 View of loosely attached rust scale that formed among nested angles in a utility storage yard

Large girders, H-beams, and channels are often nested for economical stacking. These should also be stacked with one end elevated and resting on steel angles. All configurations should facilitate drainage and minimize retention of rainwater. Draping with a cover cloth is preferred when space restrictions require that nesting be done.

Before heavy girders and columns are erected, they should be inspected by hammering to ensure that a laminated sheet of rust has not formed during the storage period. If this inspection is not performed, the rusted slab will begin to delaminate once in place, and this will raise questions as to whether the steel is truly of the weathering composition.

Example 3: Galvanic Corrosion Problems.

Care must be exercised in preventing the mixing of carbon steel with a weathering steel stock. When a missing member is encountered, the erection crews may substitute a carbon steel member. This may go unnoticed for several years and then result in excessive deterioration, such as that shown in Fig. 19.

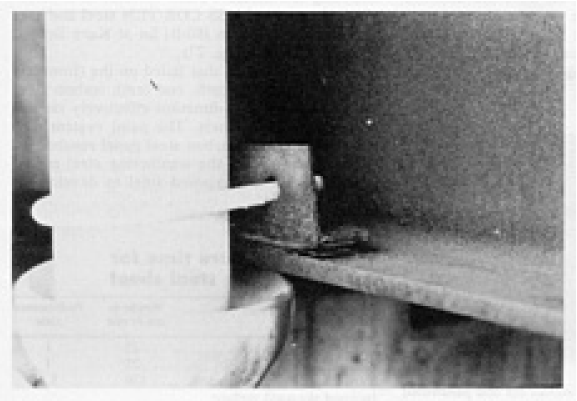

Fig. 19 Results of mixing carbon steel angle in a weathering steel structure

One of the more vivid examples of galvanically coupled metals is the use of the hanger pin detail shown in Fig. 20 to facilitate girder movement during expansion and contraction. In this case, a bronze washer is part of the assembly. When such a device is used in the snow-belt states, it can create a strong galvanic cell with the steel when deicing salt solution drains from the deck through the expansion joint and through the crevice created by the connection. The outcome can be corrosion of the steel, with the resulting rust formation freezing and therefore immobilizing the joint. The resulting corrosion is evident in Fig. 21.

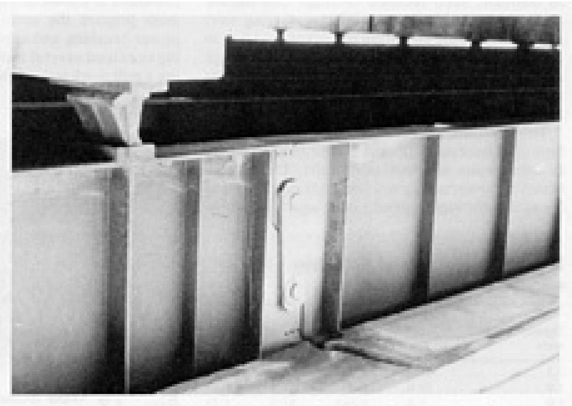

Fig. 20 Typical hanger pin assembly with bronze washer

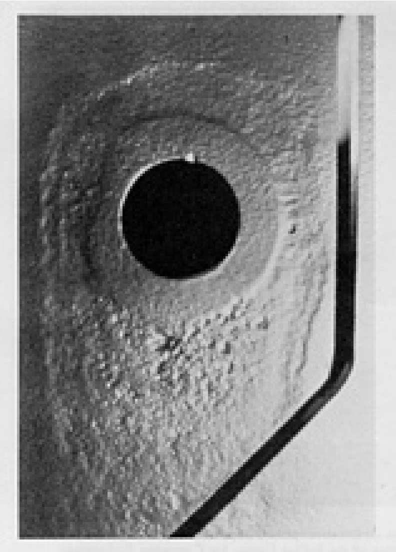

Fig. 21 View of blast-cleaned assembly showing effects of corrosion due to crevice attack and galvanic activity

Example 4: Packout Rust Formation, Bolting, and Sealing.

One of the major differences between a galvanized steel bolted structure, such as a transmission tower, and a weathering steel tower is the ability to tolerate loose bolts. In the case of a galvanized structure, moisture draining between a gusset plate and structural angle because of a loose bolt will cause little or no harm. In contrast, such retained drainage can initiate corrosion and rust formation in weathering steel joints, such as the condition of packout evident in Fig. 22. This condition can be overcome through the use of high-strength bolts; use of such bolts expands the area of clamping power over that of conventional bolts.

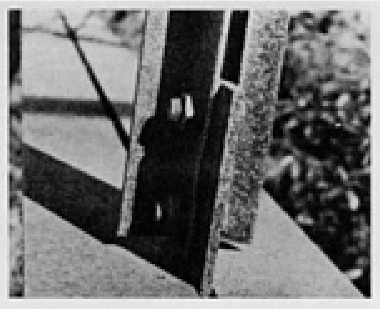

Fig. 22 Distortion caused by packout rust formation because excessive spacing between bolts permitted entry of moisture into joint

To overcome the possibility of packout formation, it is necessary to seal a joint effectively by an appropriate distribution of bolts. This is necessary for overcoming any tendency toward wicking action through capillary openings. The working guidelines for bolting, as discussed in Ref 58 and 59, deal with the establishment of bolt spacings and bolt-to-edge distances to provide adequate joint stiffness in order to avoid distortion due to packout corrosion products. Briefly, these guidelines provide that the pitch (spacing on a line of fasteners adjacent to a free edge of plates or shapes in contact with one another) should not exceed 14 times the thickness of the thinnest part and in any event should not exceed 180 mm (7 in.). The distance from the center of any bolt to the nearest free edge of plates or shapes in contact with one another should not exceed eight times the thickness of the thinnest part and in any event should not exceed 130 mm (5 in.). These factors are illustrated in Fig. 23.

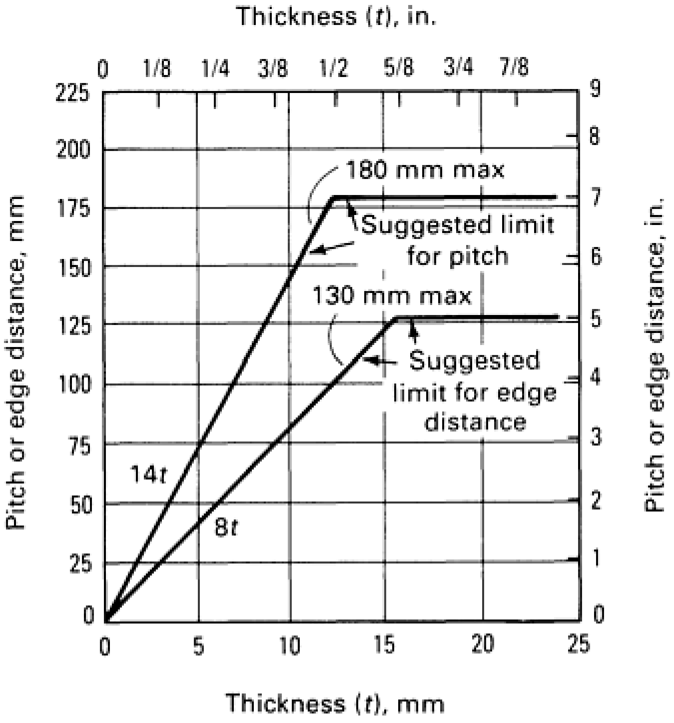

Fig. 23 Suggested spacing limits for joints in bolted weathering steel structures

At times, it would be wise to apply a caulk or sealant to the edges to ensure that an effective means for preventing the entry of moisture is used. Such a case is that shown in Fig. 24.

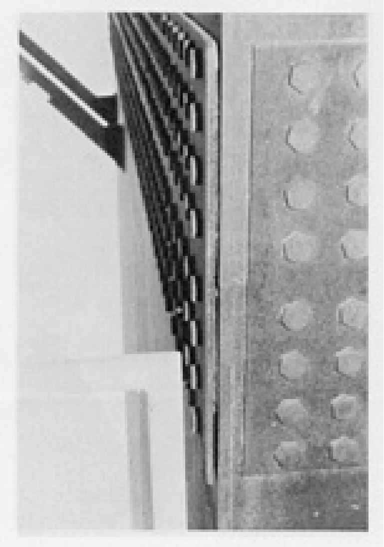

Fig. 24 Gusset plate that should be strip caulked to prevent entry of moisture. Note the possibility for wicking action.

Example 5: Protection of Buried Members.

When columns are located on concrete footers several feet below grade, they must not be installed in the unpainted condition. Such an action can result in moisture wicking upward from beneath the concrete pad and can create a condition of lamellar corrosion above grade. This condition is shown in Fig. 25. To avoid this, one must prepare the surface by blast

cleaning or power brushing and apply a coal tar epoxy coating to extend several inches above grade. Arranging a grill work and drainage system is a desirable means of drawing off rainwater drainage and melted snow.

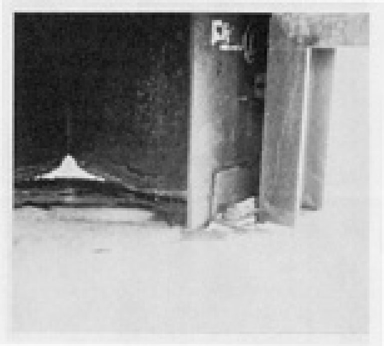

Fig. 25 Formation of lamellar rust due to moisture wicking upward from beneath concrete pad. The buried portion must be painted.

Example 6: Contact With Fire-Retardant Wood Panels.

A condition is often encountered in which a weathering steel curtain wall is placed over plywood panels that are treated with preservatives or fire retardants (Fig. 26). Because most fire-retardant compositions consist of inorganic salts capable of being leached from the panels if they become wet either through entry of water or through the maintenance of high relative humidities, it becomes necessary to insert a vapor barrier or effective sealant sheet, such as polyethylene. Alternatively, the interior face of the steel must be painted with a system capable of resisting the presence of water and the resulting salt leachate.

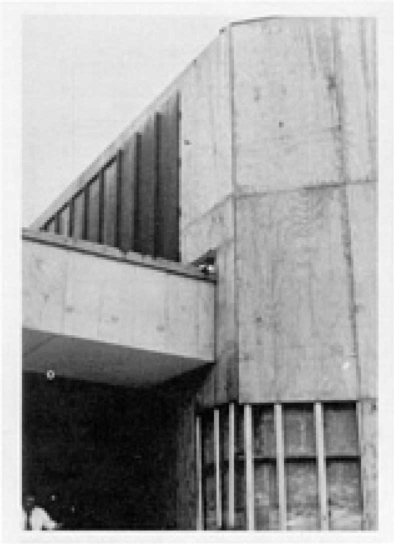

Fig. 26 Example of fire-retardant treated plywood panels that must be separated from the weathering steel cladding by application of a paint system capable of resisting ingredients moisture-leached from the plywood

The major cause of failure of weathering steel curtain walls is inside-out corrosion due to the intrusion of moisture. A primary reason is that the quality of the interior protective coating is inadequate for resisting the destructive effects of long-term or frequent contact with liquid water rather than moisture vapor. Another cause is the failure of certain types of foamed-in-place insulation to adhere completely over the entire interior surface of the curtain wall.

Example 7: Painted Weathering Steels.

Experience has demonstrated that paint, regardless of composition, will adhere better and give longer service when applied to an appropriately prepared weathering steel surface as compared to a carbon steel surface. This was demonstrated by exposing ten different paint systems over blast-cleaned panels of USS COR-TEN steel and carbon steel in the 25-m (80-ft) lot at Kure Beach, NC, for 15 years (Fig. 27).

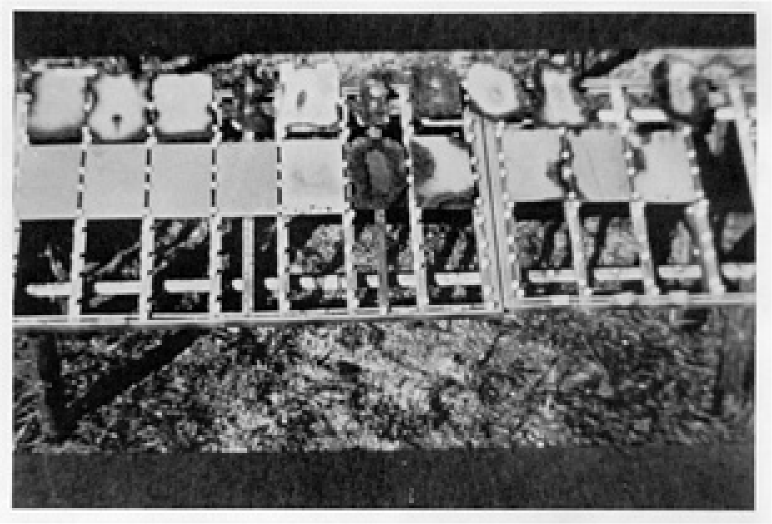

Fig. 27 Exposure test of ten paint systems applied to carbon steel panels (top) and weathering steel panels 25 m (80 ft) from ocean after 15 years. Courtesy of the LaQue Center for Corrosion Technology

The paint systems that failed on the (from left to right) fourth, seventh, and tenth carbon steel panels continued to function effectively on the weathering steel panels. The paint system that failed on the sixth carbon steel panel reached its true service life on the weathering steel panel; this permitted the exposed steel to develop its protective oxide film to resist the environment further. In addition, it can be seen that the integrity of the paint, regardless of its composition, is retained on all but the sixth and seventh weathering steel panels. From this test and other similar exposure tests, it is suggested, conservatively, that paint life over a weathering steel surface can be doubted.

Example 8: Steel Thickness for Curtain Walls.

Experience has demonstrated that if there is a desire to use a weathering steel as a curtain wall, the minimum thickness specified should be 18 gage (1.2141 mm, or 0.0478 in.). Thinner sections result in oil canning, which leads to irregular weathering, as noted in Fig. 28.

Fig. 28 Clad columns with less than 18-gage cover, resulting in oil canning

Example 9: Removing or Avoiding Stains.

Staining is due to the small particles of dried rust becoming detached as condensed dew or rain drains down the sides of a structure. The particles of rust will dry on window panes or become trapped in the surface roughness of concrete columns and sidewalks. These deposits can be readily removed from windows with household abrasives. Such stains can be removed from concrete using typical building supplier's products. These concrete stain removers are generally acidic in nature and eliminate the stain by removing an extremely thin layer of concrete.

There are several ways to avoid staining of adjacent materials. To avoid staining of building entrance walks, one can install an anodized aluminum channel or gutter to retain and divert any drainage products, as shown in Fig. 29. Another method is to install a firm plastic sheet beneath a structural member to act as a deflector to protect lower walls, as shown in Fig. 30. Where horizontal and vertical structural members project beyond vertical members, condensate drippage can be retained through the use of shrubbery beds.

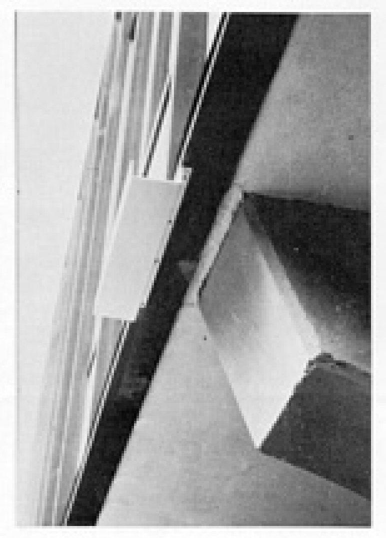

Fig. 29 Protection offered by anodized aluminum channel to retain and divert dew condensate drippage

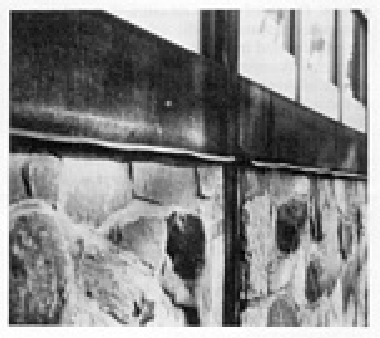

Fig. 30 Use of stiff rubberized sheeting beneath beam to divert drainage beyond stone wall

Example 10: Protection of Tower Legs and Lighting Standards.

A very important form of protection for transmission tower legs and lighting standards at ground level is to maintain a clean area free of grass, bushes, and field crops. All of these forms of plant life tend to maintain a damp environment for long periods and interfere with the development of the protective oxide film. They are especially damaging when covering bolts and nuts at the base of these towers around concrete footers; the bolts and nuts in these areas can lose section and weaken in just a few years.

Summary

Weathering steels, used within the limitations outlined in this section, are useful structural materials, falling midway between painted carbon steel and the stainless steels. Depending on environment conditions, they can be used in the unpainted or the painted condition. In the painted condition, weathering steels contribute synergistically to extending the service life of the protective coating and therefore to lessening maintenance costs.

The primary limitations involve frequent and long-term contact with water caused by the inadvertent creation of pockets and crevices that trap and retain moisture. Another limitation is that found on bridge structures in which insufficient attention is paid to preventing attack of the below-deck structural members by deicing salt solution leaking through poorly maintained expansion joint devices. Also, bridge structures located close to the Gulf Coast shoreline are subject to constant onshore breezes, which contact the structure and leave sea salt residues in places on the structure where they cannot be washed away by the rain.

Like any below-ground carbon steel structure, the weathering steels require a protective coating, as they do when constantly immersed in freshwater or seawater. The protective oxide coating can develop only under conditions of alternate wetting and drying that occur in normal day and night exposure.

To avoid the staining that results from the drainage of moisture that contains particles of rust, one must resort to the techniques of retention and diversion. Finally, care must be taken to protect field installations at ground level from the destructive effects of damp shrubbery, grass, and field crops. Clear space is necessary so that the structure can maintain a dry state, except for the usual periods of rain and snow.

Protection of Steel From Corrosion[*]

Corrosion protection is often an essential consideration in selecting carbon or alloy steel for a given structural application. Corrosion can reduce the load-carrying capacity of a component either by generally reducing its size (cross section) or by pitting, which not only reduces the effective cross section in the pitted region but also introduces stress raisers that may initiate cracks. Obviously, any measure that reduces or eliminates corrosion will extend the life of a component and increase its reliability.

Overall economics, environmental conditions, degree of protection needed for the projected life of the part, consequences of unexpected service failure, and importance of appearance are the chief factors that determine not only whether a steel

part needs to be protected against corrosion but also the most effective and economic method of achieving that protection. There are two methods of minimizing the corrosion of steels. The first is to separate the reacting phases, and the second is to reduce the reactivity of the reacting phases. The separation of the reacting phases can be accomplished by metallic, inorganic or organic coatings, and film-forming inhibitors. Reactivity can be reduced by alloying, anodic or cathodic protection, and chemical treatment of the environment. Some methods of protection combine two or more forms. For example, a baked epoxy paint applied over a chromate conversion coating on a galvanized steel part is, in reality, a combination of three forms. The epoxy paint provides a physical barrier to the corroding medium, the chromate conversion coating provides an inhibitor if the medium somehow penetrates the paint, and the galvanized coating (zinc) is an effective sacrificial anode (galvanic device) that diverts corrosion from the underlying steel part. A guide to the corrosion protection of carbon steels is provided in Table 11.

Table 11 Guide to corrosion prevention for carbon steels in various environments

Preventive method	Atmosphere	Soil	Freshwater	Seawater	Stream systems	Acids and pickling baths
Metal coatings: electroplating, galvanizing	Galvanizing very effective; plating with other metals used for both decorative appearance and corrosion protection	Galvanized steel widely used in drainage pipe and storm sewers	Galvanizing used in potable water	Not recommended	Not recommended	Not recommended
Painting: chemical treatment, priming, and painting	Economical and effective corrosion prevention	Seldom used	Fairly effective	Special paint systems used	Not recommended	Not recommended
Cathodic protection	Not recommended	Most economical and effective method, especially with organic coatings other than paint	Fairly effective with organic coatings	Very effective	Not recommended	Effective under special conditions
Inhibitors: liquid and vapor	Effective in closed areas	Not recommended	Effective in some applications, especially cooling waters	Fairly effective in some applications	Very effective	Very effective
Alloying additions to steel	Very effective, especially copper-bearing and HSLA steels	Not effective	Not effective	Only effective with much alloying	Chromium-molybdenum steels are very effective	Only effective with much alloying
Removal of oxygen from environment	Not applicable	Not recommended	Seldom used	Very effective, especially in desalination and hot seawater	Very effective	Not recommended
Removal of more noble metals; elimination of	Usually not necessary	Fairly effective	Effective	Necessary	Advisable	Not effective

galvanic couples						
Organic coatings other than paint	Sometimes used to replace painting	Used to advantage with cathodic protection	Fairly effective with cathodic protection	Used to advantage with cathodic protection	Not recommended	Have been used

In addition to the active forms of corrosion prevention described above, design and material selection are important to the overall corrosion performance of a part. Many exterior steel structures--highway guard rails and electric transmission towers, for example--have been designed so that rain does not collect on horizontal surfaces in depressions, or at joints, but washes freely from all exposed surfaces. When such structures are made from a weathering steel containing small amounts of certain alloying elements (ASTM A242 and ASTM A588 structural steels, for example), the need for a protective coating is eliminated. Normal atmospheric conditions cause the steel to develop an adherent protective oxide that has a pleasing color. Maintenance is almost totally unnecessary because any mars or scratches in the oxide coating are naturally and automatically repaired by normal oxidation of the damaged area. Only physical damage affecting the function of the structure must be corrected by maintenance or repair personnel.

Galvanic couples usually are not serious considerations for steel exposed to the atmosphere, but become very important when a strong electrolyte such as seawater is involved. The effects of galvanic couples are described in the articles "Corrosion of Alloy Steels" and "General Corrosion" (see the Section "Galvanic Corrosion") in this Volume.

Coatings

Many types of coatings are applied to enhance the corrosion resistance of carbon steels. Coating practices range from oiling for low-cost, temporary protection to vapor deposition for long-term corrosion, heat, and wear resistance. For economic reasons, the desired degree of protection must be determined before a coating is selected.

Effective temporary protection during shipment or storage can be obtained by coating the steel with mineral oil, solvents combined with inhibitors, emulsions of petroleum-base coatings, or waxes. These types of coatings are applied after acid pickling or between coating sequences, and they are not expected to provide long-term corrosion protection.

Surface preparation is important for all coating processes. Any oxide on the steel surface must be removed by pickling or blasting. Degreasing is necessary after oxide removal or when the steel has been given a temporary coating, and it can be accomplished by several means. More information on the cleaning and degreasing of steels is available in the article "Cleaning for Surface Conversion" in this Volume and in *Surface Engineering,* Volume 5 of the *ASM Handbook.* Ideally, the first step in the coating process should be started immediately after cleaning.

Hot-dip coating processes are used to apply coatings of zinc, aluminum, lead, tin, and some alloys of these metals to carbon steels. The hot-dip process consists of immersing the steel in a molten bath of the coating metal. Zinc coating (galvanizing) protects steel galvanically because the zinc is anodic to the steel base metal and therefore corrodes preferentially in most environments. Hot-dip galvanizing affords adequate atmospheric-corrosion protection to steel (see the section "Metallic Coated Steels" in this article and the articles "Hot Dip Coatings" and "Corrosion of Zinc" in this Volume). Aluminum hot-dip coatings (aluminizing) provide carbon steels with resistance to both corrosion and heat. In many environments, aluminum protects steel galvanically in much same way as zinc.

Zinc-aluminum and aluminum-zinc alloys are also applied to steel by hot dipping. Heating aluminized steel results in the formation of an iron-aluminum intermetallic compound that resists oxidation at temperatures up to about 800 °C (1500 °F). Aluminized steel is often used where heat resistance is required--for example, in automotive exhaust systems (see the

section "Metallic Coated Steels" in this article and the articles "Hot Dip Coatings" and "Corrosion in the Automotive Industry" in this Volume).

Hot-dip tin coatings provide a decorative and nontoxic barrier coating. Tin does not galvanically protect the steel substrate; for this reason, lacquers or other organic coatings are frequently used to fill pores in the tin coating and provide enhanced barrier protection. More information on tin coatings for steel is available in the article "Corrosion of Tin and Tin Alloys" in this Volume.

Hot-dip lead coatings are sometimes used on steel that will be exposed to sulfuric acid fumes or other aggressive chemical environments. Terne plate, a lead-tin alloy coating, gives more protection than pure lead coatings and is solderable (see the article "Corrosion of Lead and Lead Alloys" in this Volume).

Electroplated coatings are applied to steel for corrosion resistance, appearance, solderability, or other special requirements. A wide variety of materials are electroplated on steel, including zinc, aluminum, chromium (see the article "Corrosion of Electroplated Hard Chromium" in this Volume), copper, cadmium, tin, and nickel. Multilayer coatings can also be applied by electroplating; an example is the copper-nickel-chromium plating system used for bright automotive trim. More information on the electroplating process is available in *Surface Engineering,* Volume 5 of the *ASM Handbook.* The article "Electroplated Coatings" in this Volume also contains information on the corrosion resistance of various plating materials.

Clad Metals. Carbon steels can be bonded to more corrosion-resistant materials, such as copper and stainless steels, by cold roll bonding, hot roll bonding, hot pressing, explosion bonding, and extrusion bonding. The resulting lamellar composite material has specific properties not obtainable in a single material. Examples of various clad metal systems and guidelines for designing with clad metals are enumerated in the article "Corrosion of Clad Metals" in this Volume.

Thermal spray coatings provide effective long-term corrosion protection for steels in a wide range of corrosive environments. They are applied by one of several processes, including wire flame spraying, powder flame spraying, and electric arc spraying. Zinc, aluminum, and zinc-aluminum alloys are the most common coating materials applied by thermal spray techniques; austenitic stainless steels, aluminum bronzes, and MCrAlY coating materials have also been used for specific applications. For maximum corrosion resistance, thermal sprayed coatings are sealed with an organic topcoat. Thermal spray coatings are often used for corrosion protection in marine applications. More information on thermal spray coatings is available in the articles "Thermal Spray Coatings" and "Marine Corrosion" in this Volume.

Vapor-deposited coatings are sometimes used for the protection of steel, although the cost of such coatings can be prohibitive. In vapor deposition, whether it be physical vapor deposition or chemical vapor deposition, the coating material is transported to the substrate in the form of individual atoms or molecules. A wide range of coating materials can be applied by vapor deposition. If applied to a sufficient thickness, the coating is essentially pore free and dense, thus providing excellent barrier protection. A well-known application for vapor-deposited coatings on steel is ion vapor deposited aluminum coatings on steel aircraft and aerospace components (see the article "Corrosion in the Aircraft Industry" in this Volume). More information on materials for and applications of vapor-deposited coatings is available in the article "CVD/PVD Coatings" in this Volume.

Phosphate or chromate conversion coatings are used to enhance the corrosion resistance of steels. By themselves, they provide slightly better corrosion resistance than bare steel; more often, they are used in conjunction with another coating system. Conversion coatings are applied after hot-dip galvanizing and provide good corrosion protection when topcoated with an organic coating system. More information on conversion coatings for the protection of steel is available in the articles "Chromate Conversion Coatings" and "Phosphate Conversion Coatings" in this Volume.

Organic coatings (paints) are used more often for corrosion protection of steels than any other type of coating. Properly applied, they provide excellent protection at a relatively low cost. A wide variety of coating materials and application methods are available; these are discussed in detail in the section "Organic Coated Steels" in this article and in the article "Organic Coatings and Linings" in this Volume.

Ceramic coatings used to protect steel include silicate cements and porcelain enamels. Monolithic cement linings provide good resistance to chemicals and thermal insulation. They can be applied by casting or spraying. More information on these materials is available in the article "Chemical-Setting Ceramic Linings" in this Volume. Porcelain enamels are glass coatings that are fused onto the steel surface at or above 425 °C (800 °F) to provide a glassy coating with good corrosion resistance and high hardness. The composition of the enamel can be varied to provide desired

properties, such as improved resistance to alkalies. More information on porcelain enamels is available in the article "Porcelain Enamels" in this Volume.

Other nonmetallic materials are sometimes used as coatings or linings for steel in corrosion applications. These include rubbers (both natural and synthetic) and other elastomers and such plastic materials as epoxies, phenolics, and vinyls. A wide variety of properties and resistances to specific environments are available. Rubber linings have been used for many years in steel storage tanks for hydrochloric acid. Plastic linings are employed for plating tanks and similar applications. The articles "Corrosion in the Chemical Processing Industry," "Corrosion of Metal Processing Equipment," "Corrosion in the Pharmaceutical Industry," and "Corrosion in the Brewery Industry" in this Volume contain information on the use of these materials for the protection of steel.

Inhibitors

Inhibitors find their major uses in acid-pickling solutions, acidic service environments, steam systems, and neutral and near-neutral aqueous solutions. Inhibitors may be organic or inorganic compounds, and they are usually dissolved in aqueous environments. Inhibitors have been added to chemical conversion treatment baths and to paint primers. A few vapor-phase inhibitors are used in confined atmospheres (see the discussion "Packaging Applications" in this section) and in steam systems.

Some of the most effective inorganic inhibitors are chromates, nitrites, silicates, carbonates, phosphates, and arsenates (it should be noted that environmental concerns have significantly impacted the use of chromates). The organic inhibitors are many and include amines, heterocyclic nitrogen compounds, sulfur compounds (such as thioethers, thioalcohols, thioamides, thiourea, and hydrazine), some natural compounds (such as glue or proteins), and mixtures of two or more compounds. More detailed information on inhibitor types and applications can be found in the articles "Corrosion Inhibitors for Oil and Gas Production," "Corrosion Inhibitors for Crude Oil Refineries," and "Control of Environmental Variables in Water Recirculating Systems" in this Volume.

Corrosion Inhibitors in Acid Pickling. Mill scale is most often removed from steel by pickling in either sulfuric (H_2SO_4) or hydrochloric acid (HCl) solutions. Because pickling is essentially a chemical dissolution (corrosion) process, some of the underlying metal is inevitably removed from the surface along with the mill scale. Inhibitors are added to pickling baths to minimize metal loss, to minimize the extent of hydrogen pickup (which can lead to embrittlement), to protect the metal against pitting and poor surface quality, to reduce acid fumes, and to reduce acid consumption. Inhibitors prolong pickling time, but the benefits outweigh the increase in time. Table 12 gives mill scale removal rates in uninhibited H_2SO_4 and HCl. The removal rate is much higher for HCl but acid cost and acid consumption are lower for H_2SO_4.

Table 12 Mill scale removal rates in uninhibited aqueous acids

Concentration of acid, %	Removal rate [(a)], g/h	
	HCl	**H_2SO_4**
5	0.035	0.035
10	0.29	0.039
15	1.51	0.056

(a) At 18 °C (65 °F)

Acid-pickling inhibitors should be stable in the acid at all operating temperatures and must not stain or contaminate the steel. The natural compounds that have been used include bran flour, gelatin, glue, sulfonated coal tar products,

asphaltum, and wood tars. Synthetic compounds that have been used are nitrogen-base materials and their derivatives, pyridines, guanidines, aldehydes, and thioaldehydes and other sulfur-containing compounds.

Most inhibitors used for large-scale pickling are comparatively inexpensive technical grade chemicals that contain varying amounts and types of impurities. The inhibitive properties are often due to the presence of certain impurities rather than to the major constituent that determines the name of the product. When purified, many of these chemicals are ineffective as inhibitors. For example, various naphthalene sulfonic acids lose their inhibitive properties after purification by repeated recrystallization. Proteins and their breakdown products--the amino acids--can retard corrosion; however, purified proteins and amino acids are often found to be weaker inhibitors. The inhibitive properties of plant extracts are also due to the presence of natural nitrogen-containing bases known as alkaloids. Many of these--for example, brucine, strychnine, and papaverine--are very powerful corrosion inhibitors in sulfuric acid.

For a given metal, an inhibitor that is quite effective in one acid often has comparatively little influence in another acid of equal concentration. Thus, amines of high molecular weight retard corrosion of ferrous metals in hydrochloric acid far more effectively than in sulfuric acid. Proteins, on the other hand, are more effective in sulfuric acid.

Hydrogen Embrittlement. During pickling, hydrogen ions accumulate at the metal surface. The hydrogen ions combine to form molecules of hydrogen, which escape from the solution as bubbles. However, a few atoms penetrate the crystal lattice, where they may either diffuse through the metal and exit at the opposite surface or accumulate within the metal and embrittle it. Sometimes, as a result of high hydrogen pressures in subsurface pores, pickling blisters are formed on the surface.

Metal articles with polished surfaces absorb less hydrogen than those with rough, rusty, or scaled surfaces. Pickling in H_2SO_4 leads to much greater hydrogen pickup and more pronounced embrittlement than pickling in HCl of the same concentration. Inhibitors added to pickling solutions have a great effect on hydrogen pickup and its diffusion rate. Some inhibitors do not affect hydrogen pickup. In the presence of strong inhibitors, hydrogen absorption and diffusion is lowered to such an extent that quantitative results have no practical significance. It is important to recognize the inhibitors that strongly retard corrosion do not always lower the diffusion of hydrogen into the metal. For example, the comparatively weak inhibitor diethylaniline protects the steel effectively against hydrogen pickup when steel is pickled in 5 *N* H_2SO_4. On the other hand, when chemically pure pyridine is added to acids, the diffusion of hydrogen through the steel is appreciably enhanced despite effective inhibition against corrosion. Arsenic inhibitors also enhance the diffusion of hydrogen into steel.

Inhibitors act differently in nitric acid (HNO_3). Although the concentrated acid is a strong oxidizer, dilute solutions have more evident acidic properties. During pickling in uninhibited HNO_3, the HNO_3 is reduced to nitrous acid, which catalyzes further reduction to nitrous acid, which attacks ferrous metals. Hydrogen is consumed in producing nitrous acid and is not liberated at the metal surface; consequently, hydrogen embrittlement does not occur when steel is pickled in uninhibited HNO_3. A 0.007% solution of thiourea in a 1.5 *N* HNO_3 solution reduces the corrosion of carbon steel by 250 to 300 times. However, the mechanical properties after pickling are considerably impaired because thiourea hinders the reduction of HNO_3 to nitrous acid and causes hydrogen to be liberated at the metal surface along with other gases rather than being consumed within the acid solution.

Hydrazine, which is used as an oxygen scavenger, is an effective inhibitor because it is converted to hydrazoic acid, which decomposes the nitrous acid that forms. Potassium permanganate and potassium dichromate are also powerful inhibitors for HNO_3. The activity of these substances persists over a long period. For example, dichromate ions are active for several months in 1 *N* HNO_3 but they are persistent for only 10 h in 5 *N* HNO_3. Halides are also good inhibitors in HNO_3, potassium iodide being more effective than potassium bromide or potassium chloride. None of these inhibitors causes hydrogen embrittlement in HNO_3 solutions. More detailed information on hydrogen embrittlement is available in the articles "Environmentally Induced Cracking" and "Evaluation of Hydrogen Embrittlement" in this Volume.

Inhibitors in Acid Environments. The solution rate for steel in various acids depends on the surface finish of the steel, type and concentration of the acid, temperature, and the presence or absence of impurities that can either promote or inhibit corrosion. Generally, the corrosion rate of steel in HCl increases with acid concentration; however, in HNO_3 and H_2SO_4, the corrosion rate reaches a maximum and then decreases with increasing acid concentration. With HNO_3, the peak is at 6 *N;* with H_2SO_4, the peak is at 12 *N.*

The corrosion rate of steel in all types and concentrations of acid solutions tends to increase with carbon content as long as there is little or no change in the concentration of other alloying elements in the steel. In 4 *N* acetic acid, for example,

the corrosion rate of carbon steel is about 1.2 g/m^2/h for carbon steel containing 0.05% C and 2.8 g/m^2/h for 0.90% C. In 12 *N* H_2SO_4, the corrosion rate increases from 60 g/m^2/h for steel with 0.05% C to 120 g/m^2/h for steel with 0.90% C. In 16 *N* H_2SO_4, however, corrosion rates are the same regardless of carbon content, and the metal loss is less than 10 g/m^2/h.

Inhibitors are often used in acidic process fluids to reduce the rate of corrosion to a tolerable level, thus prolonging the life of steel components in contact with the process fluid. Sometimes, it is not possible to use a particular inhibitor because of an adverse effect on the process. Then, a different inhibitor can sometimes be used, even though it is not as effective as the optimum choice. With some processes, the use of any inhibitor would have an adverse effect on the process. In such cases, the only alternative to high corrosion rates and expensive maintenance programs is the use of corrosion-resistant materials, either as coatings or linings or as basic materials of construction.

Volatile Inhibitors. The protection of metals against atmospheric corrosion and in closed steam systems by means of volatile (vapor phase) inhibitors is one of the more recent, significant methods for combating metallic corrosion. For atmospheric corrosion, the method consists of saturating an enclosed storage space with vapors that enhance the corrosion resistance of the metal surface. Volatile inhibitors protect metals primarily by changing the kinetics of the corrosion reactions much the same as inhibitors in solution. On the basis of general inhibition theory gained through experience, the kinds of groups necessary to effect protection can be predicted. For steel, they are chromate, dichromate, benzoate, nitrite, phosphate, hydroxyl, and ammonia. Such salts as sodium nitrite and potassium chromate (which are exceptionally effective as contact inhibitors or passivators in solution) could, in principle, be used as volatile inhibitors if their vapor pressures were suitable. Therefore, if an inorganic compound contains a desirable protective group, an organic radical can be substituted for the inorganic metal so that an organic salt is obtained that will now possess the two desirable properties, namely volatility and a protective group. Often, it may not be possible to vaporize a protective group at ordinary temperatures, and means must be taken to reduce the vapor pressure of the compound.

Amines were the first group of chemical compounds that attracted attention as volatile inhibitors. Amines are obtained by the substitution of an organic radical for one hydrogen atom in the ammonia molecule. An amine can combine with water to form organic cations and hydroxyl anions. Thus, the medium is made more alkaline, and the corrosion of iron is reduced. It was assumed that the principal passivating effect is produced by the hydroxyl ion; however, electrochemical investigations have shown that the organic cation, not the hydroxyl anion, plays the more significant role in the passivation process. Aliphatic, alicyclic, and heterocyclic amines are more effective than aromatic amines; for example, cyclohexylamine, dicyclohexylamine, and monoethanolamine are very effective. These amines have significant shortcomings, however. Because their vapor pressures are too high, they cannot provide lasting protection.

Vapor pressure is one of the basic characteristics of volatile inhibitors. The higher the vapor pressure, the sooner an airtight storage space is saturated. Because it is not economically feasible to produce airtight systems, a less volatile inhibitor is not consumed as quickly and can ensure more lasting protection. On the other hand, because more time is required to attain a protective vapor concentration, steel parts may corrode before a protective concentration is reached. Most of the amines used with steel have a vapor pressure that is too high to provide lasting protection; therefore, it is necessary to reduce the vapor pressure of the amine, which can be done by converting the amine to a salt.

Packaging Applications. The major application utilizing vapor-phase inhibition has been the packaging of steel articles ranging from small hand tools to large coils of steel strip. Paper can be impregnated with varying quantities of inhibitor--0.2 to 2 g/m^2--depending on prevailing temperature and on the time a nonaggressive environment must be maintained. Packaging for long-term storage imposes volatility requirements that are different from those of packaging only for protection in transit. Paper impregnated with 0.2 g/m^2 of dicyclohexylamine nitrite is capable of conferring protection up to 10 years if the temperature does not exceed 23 °C (73 °F). However, protection is effective for only about 100 days at 75 °C (167 °F). It has been found that the logarithm of the effective service time of paper impregnated with inhibitor is inversely proportional to the temperature.

Various inhibitor compounds have been encapsulated and used in tablet form to protect various iron and steel articles in museum cabinets where humidity control was difficult. The same tablets are now being used in cardboard cartons employed for shipping numerous steel articles. Aqueous solutions of mixtures of these compounds are used to fog the holds of seagoing barges and to fog closed railroad cars and trucks carrying coiled steel, which supplements the impregnated paper wrapping. Paper wrapping can be eliminated by spraying the edges of lifts and coils of steel and fogging the atmosphere of the cargo container so as to offer short-term transit protection. Grease and oil films have been the conventional means for protecting coils of wire; this produces hazardous and unsightly oil residues on the floors of transit vehicles and warehouses. A dip into an aqueous solution of an inhibitor plus water-dispersable waxes results in a clean, dry product that is self-lubricating and merely requires dry warehouse storage.

Automotive Applications. Corrosion inhibitors are extensively used in that part of the automotive industry associated with the production and storage of parts. In addition, inhibitors are included in many automotive fluids, such as gasoline, antifreeze, and oil and brake fluids. The addition of inhibitors to rust-preventive compounds increases the protection provided by hydrophobic coatings. Organic compounds such as alcohol and ethylene glycol are the principal substances used to prevent engine cooling fluid from freezing in cold climates. Both substances undergo oxidation to form acidic products. The evaluation of corrosion inhibitors to prevent attack of metal parts by organic acids has become a complex problem. Many variables are involved, such as aeration, cooling system temperature, pressure, coolant velocity, impurities in the water, corrosion products, and galvanic couples, among other operating conditions. The concentration of inhibitor required to prevent corrosion is dependent on the impurities present in the water used. For example, ferrous metal corrosion can increase as the concentration of chloride ions is increased to 100 ppm and the concentration of sulfate ions to 300 ppm.

In both the United States and Europe, chromates were among the first corrosion inhibitors to be used. A significant portion of the inhibitor formulations presently used in the United States contains borates or combinations of borax and sodium silicate. However, the effectiveness of borates is reduced with increases in the concentrations of chloride and sulfate ions. Mixed inhibitor systems, such as benzoate-nitrite combinations, have been quite successful (5% sodium benzoate plus 0.3% sodium nitrite is effective in a 25% ethylene glycol solution). General Motors developed an antifreeze combination that included sodium nitrite, borax, sodium silicate, and trisodium phosphate, with each compound functioning in a special fashion. For example, nitrite was used to protect aluminum and solder; borate was used for its buffer action and reserve alkalinity, as well as for protection of ferrous metals. Silicate was used for general protection of all metals, phosphate for protection of ferrous metals, aluminum ions for their buffering action, sodium hydroxide for reserve alkalinity and mercapto-benzothiazole (MBT) for protection of copper and brass. There is also a need for cavitation protection in cooling systems made of aluminum; phosphates and silicates are helpful in this instance. Sodium silicate in amounts greater than 0.3% (by weight) added to undiluted ethylene glycol can produce gelling during storage. Additional information on prevention of automobile corrosion can be found in the article "Corrosion in the Automotive Industry" in this Volume.

Cathodic Protection

The most economical method for protecting underground or underwater steel structures from corrosion is usually cathodic protection. The use of cathodic protection for long-term corrosion prevention for underground pipelines, oil and gasoline tanks, offshore drilling rigs, well-head structures, steel piling, piers, bulkheads, offshore pipelines, gathering systems, drilling barges, and other underground and underwater structures is now a fairly standard procedure. In this method, a direct electrical current is applied to the steel structure. The direct current can be supplied by galvanic action from sacrificial anodes or by impressed current from a rectifier. Coatings of the coal tar or coal tar epoxy types or fusion-bonded epoxy powders are generally used on steel structures in conjunction with cathodic protection to lessen the amount of current needed. The current then must protect the steel only at holidays and flaws in the coatings. Detailed information on the principles of cathodic protection and the types of sacrificial anodes and impressed-current anodes can be found in the article "Cathodic Protection" in this Volume. Other articles that include discussions of the use of cathodic protection of steels include "Marine Corrosion," "Corrosion in Petroleum Production Operations," "Corrosion of Pipelines," and "Corrosion in Structures" in this Volume.

Metallic Coated Steels

Harvie H. Lee, Inland Steel Company

The main purpose for the application of a metallic coating to a steel substrate is for corrosion protection. Most metallic coatings are applied either by hot dipping into a molten bath of metal or by electroplating in an aqueous electrolyte. To a lesser extent, coatings are also applied by other methods, such as metal spraying, cementation, and metal cladding. A number of coating processes were reviewed in the section "Protection of Steel From Corrosion" in this article.

From the standpoint of corrosion protection of iron and steel, metallic coatings can be classified into two types--noble coatings and sacrificial coatings. Noble coatings such as lead, copper, or silver are noble in the galvanic series with respect to steel. For noble coatings, at areas with surface defects or porosity, the galvanic current accelerates attack of the base steel and eventually undermines the coating. Sacrificial coatings such as zinc or cadmium are anodic (more active) to steel. For sacrificial coatings at uncoated areas (pores), the direction of galvanic current through the electrolyte is from coating to the base steel; as a result, the base steel is cathodically protected. In general, the thicker the coating, the longer

the duration of cathodic protection. This section will emphasize hot-dipped zinc and aluminum coatings. More detailed information is provided in the articles "Hot Dip Coatings," "Corrosion of Zinc," and "Corrosion in the Automotive Industry" in this Volume.

Zinc-Base Coatings

Types. Zinc-coated steels are generally produced by either hot dipping or electroplating. The main difference between these two types of zinc coatings is in their coating structure. The hot-dip galvanized steel coatings consist of a layer of zinc-iron intermetallics at the steel/zinc interface (Ref 60). Typical coating microstructures with various intermediate layers are shown in Fig. 31. For galvanized sheet steel with better coating adhesion and good coating forming properties, the thickness of the intermetallic layers should be controlled below 20% of the total coating thickness. Control of intermetallic layer thickness can be achieved by adding 0.1 to 0.3% Al into the zinc bath; this addition retards the growth of the intermetallic layer.

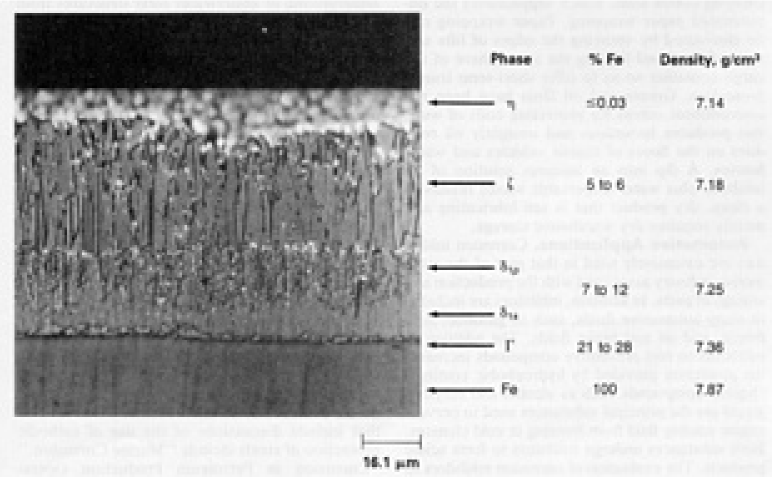

Fig. 31 Typical coating microstructure for prolonged immersion of carbon steel in prime western zinc at 450 °C (840 °F)

In the case of electrogalvanized steels, the coatings display a smooth, uniform, and spangle-free surface and do not have a zinc-iron intermetallic layer. Currently, almost all galvanized sheet steel in the United States is produced by continuous process. The two commercial processes used in the continuous hot-dip galvanizing of sheet steel are the Sendzimir process and the Cook-Norteman process.

In the Sendzimir process, the steel strip is heated in a high-temperature furnace consisting of an oxidizing atmosphere to remove organic oils and surface contaminants, followed by heating in a reducing furnace with a hydrogen-rich atmosphere to reduce the surface oxide layer and to anneal the steel substrate. The discharge end of the reducing furnace is below the surface of the zinc bath; this allows the continuous sheet to enter the bath without passing through a contaminating atmosphere. Precise control of oxidizing and reducing temperature is critical in developing and maintaining the cleanliness of the steel surface.

In the Cook-Norteman process, an in-line furnace is not used. The sheet is chemically cleaned by alkaline degreasing and acid pickling. After cleaning, the sheet is coated with a film of zinc ammonium chloride, dried, and preheated to less than 260 °C (500 °F) before entering the galvanizing bath.

Aqueous Corrosion of Galvanized Steel. Zinc is an amphoteric metal that corrodes in acid and alkaline solutions. The hydrogen ion concentration in water and aqueous solutions has a significant effect on the corrosion rate of zinc. This effect is shown in Fig. 32, which plots the average overall corrosion rate versus the hydrogen ion concentration expressed in terms of pH value (Ref 61). In the pH range of 6 to 12.5, a protective film is formed on the zinc surface, and the zinc corrodes very slowly. At pH values below 4 and above 12.5, the major form of attack on zinc is hydrogen evolution, and zinc corrodes very rapidly. The pH values for natural water and mild alkaline soap-bearing water fall within the safe range and are not corrosive toward zinc coatings. The corrosion rate is higher in soft water than in hard water, which often

forms a protective film. The corrosion rate of pure zinc in terms of weight losses ranges from 0.3 g/m^2/d in hard water to 2.7 g/m^2/d in distilled water. In aerated hot water, it has been observed that the polarity between the zinc coating and the base steel is reversed at 60 °C (140 °F) or above (Ref 62). In this case, zinc becomes a noble coating instead of a sacrificial coating and induces pitting of the bare steel. In seawater, zinc coatings corrode at approximately 0.025 mm/yr (1 mil/yr).

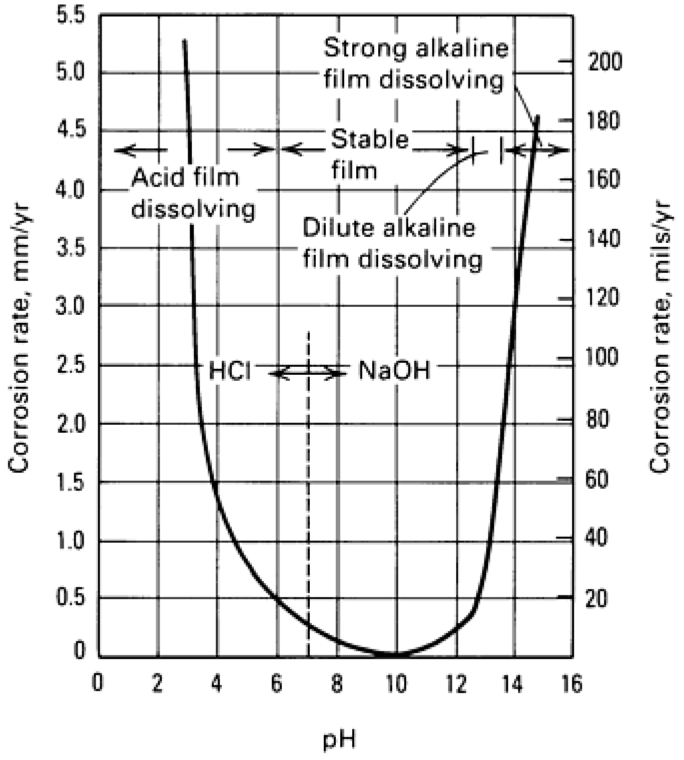

Fig. 32 Effect of pH value on the corrosion of zinc

Atmospheric Corrosion of Galvanized Steel. The corrosion rate of zinc coatings in outdoor exposure depends on the type of outdoor atmosphere involved. Factors such as the frequency and duration of moisture contact, the rate of drying, and the extent of industrial pollution in the air have significant effect on the corrosion rate. In general, the corrosion rate of zinc coatings in a rural atmosphere is very low. Seacoast atmospheres are less corrosive to zinc coating than industrial atmospheres.

A large-scale long-term test program was conducted on galvanized steel wire (both hot-dipped and electroplated) by ASTM (Ref 63). Carbon steel wires with different coating weights were exposed at several testing sites, including Pittsburgh, PA (severe industrial); Sandy Hook, NH (marine); Bridgeport, CT (industrial); State College, PA (rural); Lafayette, IN (rural); Ithaca, NY (rural); and Ames, IA (rural). After fifteen years of exposure at these sites, the average corrosion rates of the zinc coatings were obtained by dividing the coating weight (oz/ft^2) by the number of years of exposure before the first rust was observed. These rates are summarized in Table 13. The service life of the zinc coating appears to be in direct proportion to the weight of the coating. As shown in Table 13, the corrosion rate can range from 12 g/m^2/yr (0.04 oz/ft^2/yr) in a rural atmosphere (Ames, IA) to 104 g/m^2/yr (0.34 oz/ft^2/yr) in a severe industrial atmosphere (Pittsburgh, PA). The gage of the wire or the type of zinc coating (either hot-dipped or electro-deposited) within the test limits seems to have no effect on the corrosion rate of the zinc coating.

Table 13 Atmospheric-corrosion rates of zinc-coated wire

Test site	Type of atmosphere	Average corrosion rate	
		$g/m^2/yr$	**$oz/ft^2/yr$**
Pittsburgh, PA	Severe industrial	104	0.34
Sandy Hook, NJ	Marine (275 m, or 900 ft, from ocean)	40	0.13
Bridgepoint, CT	Industrial	40	0.13
State College, PA	Rural	18	0.06
Lafayette, IN	Rural	21	0.07
Ithaca, NY	Rural	18	0.06
Ames, IA	Rural	12	0.04

Source: Ref 63

In 1969, the atmospheric-corrosion behavior of hot-dip galvanized steel sheet was evaluated at three testing sites: a semi-industrial test site (Porter County, IN), a severe industrial test site (East Chicago, IN), and a marine test site (Kure Beach, NC, 250-m, or 800-ft, lot) (Ref 64). The galvanized steel used was 0.81 mm (0.032 in.) in thickness with an average coating weight of 168 g/m^2 (0.55 oz/ft^2). All test panels were 100 × 150 mm (4 × 6 in.) in size. Two panels were made into one sandwich-type test specimen for exposure so that the corrosion rate on the skyward and groundward side of each specimen could be evaluated independently. All specimens were exposed inclined 30° from the horizontal. Forty sandwich-type test specimens were placed at each of the three test sites. Specimens were removed at the conclusion of the exposure period of 6 months, 1 year, 2 years, 3 years, 4 years, and 5 years. The standard ASTM recommended practice G 1 was used in preparing, cleaning, and evaluating the specimens (Ref 65). The average weight loss data obtained from the skyward panels of each specimen were fitted to Eq 1.

Predictions of corrosion rates using Eq 1 are shown in Fig. 33. The correlation coefficients (R^2) shown demonstrate the high-quality fit of each curve in Fig. 33. These curves can be used to predict the service life of galvanized steel for a given coating thickness, or vice versa. For example, the predicted weight loss for a 10-year exposure, as shown in Fig. 33, is 121.6 g/m^2 (0.40 oz/ft^2) at the Porter County site, 290 g/m^2 (0.95 oz/ft^2) at the East Chicago site, and 103.3 g/m^2 (0.34 oz/ft^2) at the Kure Beach site.

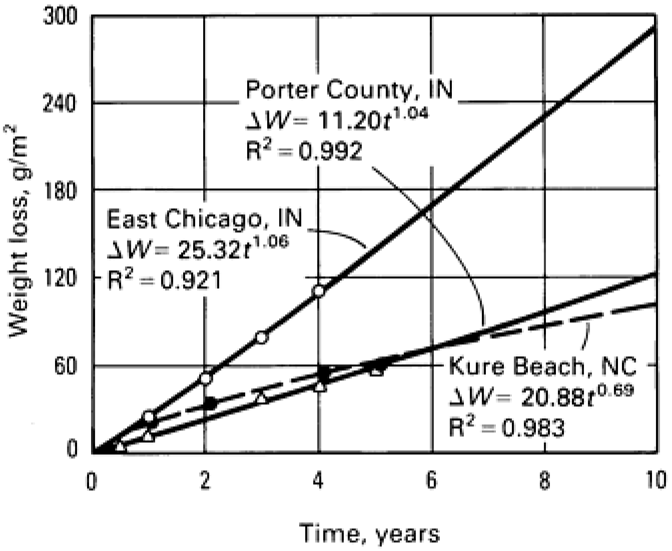

Fig. 33 Predictive equations for galvanized steel based on 5 years of exposure

Intergranular Corrosion of Galvanized Steel. It has been known since 1923 that zinc die casting alloys are susceptible to intergranular attack in an air-water environment (Ref 66). The adverse effect of intergranular corrosion of hot-dip galvanized steel was first observed in 1963, and was investigated at Inland Steel Company in 1972 (Ref 67). The observed effect associated with intergranular corrosion was termed delayed adhesion failure. Delayed adhesion failure is a deterioration in coating adhesion due to selective corrosion at grain boundaries. It was found that the small amount of lead normally added to commercial galvanizing spelters was a critical factor in the susceptibility of the zinc coating to intergranular attack. By using lead-free zinc spelter (<0.01% Pb), the damaging effect of intergranular corrosion was essentially eliminated.

For the continuous hot-dip galvanizing process, the main reason to add 0.07 to 0.15% Pb to zinc spelter was to produce a spangled coating and to lower the surface tension of the zinc bath in order to provide the necessary fluid properties to produce a ripple-free coating. It was found that by using antimony additions to the zinc spelter similar beneficial effects, such as those obtained by the use of lead additions, could be achieved without causing any detrimental effect with respect to intergranular corrosion. For galvanized coatings produced by electroplating process, no intergranular corrosion has been observed.

Aluminum-Base Coatings

Types. Aluminum coatings on steel are primarily produced by spraying or hot dipping. Spray coatings are mainly applied on structural steel by using a wire-type gun (see the article "Thermal Spray Coatings" in this Volume). Pure aluminum or aluminum alloy wires are continually melted in the oxygen-fuel gas flame and atomized by a compressed air blast that carries the melted metal particles to the prepared surface where they agglomerate to form a coating. The coating thickness is in the range of 0.08 to 0.2 mm (3 to 8 mils). Coatings are commonly sealed with organic lacquers or paints to delay the formation of visible surface rust.

Aluminum coatings on sheet steel are primarily produced by a continuous hot-dip process (the Sendzimir process). Molten baths of aluminum for hot dipping usually contain silicon in the range of 7 to 11% to retard the growth of a brittle iron-aluminum intermetallic layer. This alloy, which is one of the most fluid and easily cast aluminum alloys, forms a coating with a much thinner and more uniform alloy layer. This coated product, which has relatively good coating adhesion and forming properties, was commercially introduced in 1940; it is now identified as type I aluminized steel. A typical type I coating bath contains 9% Si, 87.5% Al, and 3.5% Fe.

Type II aluminized steel was commercially produced in 1954 with a coating consisting mainly of pure aluminum. This coating could withstand mild forming, such as corrugating and roll forming. A typical type II coating bath contains 97.5% Al, 2% Fe, and 0.5% Si.

Aqueous Corrosion of Aluminized Steels. In aqueous environments, pure aluminum or aluminum-silicon alloy coatings exhibit good general corrosive resistance. The coatings become passive in a pH range between 4 and 9 and corrode rapidly in acid or alkali solutions. These coatings tend to pit in environments containing chloride ions (Ref 68), particularly at crevice or stagnant areas where passivity breaks down through the action of a differential aeration cell.

In soft water, aluminum coatings exhibit a potential that is positive to steel; therefore, they act like a noble coating. In seawater or in aqueous environments containing Cl^- or SO_4^{2-}, the potential of aluminum coatings becomes active, and the polarity of aluminum-iron couples may reverse. Under these conditions, the aluminum coating is sacrificial and cathodically protects steel.

Atmospheric Corrosion of Aluminized Steel. The atmospheric-corrosion resistance of aluminum coatings is generally related to that of solid aluminum of the same thickness (see the article "Corrosion of Aluminum and Aluminum Alloys" in this Volume). The protection of steel by aluminum coating depends partly on cathodic protection and partly on the inert barrier layer of oxide film that forms on the metal surface. For thermally sprayed aluminum coatings, initial corrosion may produce slight superficial rust staining through pores in the coating. Subsequently, insoluble aluminum corrosion products block the pores and retard further corrosion of the coating.

When type I aluminized steel is exposed to the atmosphere, pitting corrosion can occur because of the difference in electrochemical potential between the silicon-rich phase and the aluminum matrix. The resulting corrosion product causes a red-brown blush discoloration on the metal surface (Ref 69). The corrosion product retards any further corrosion reaction. Type I panels have been exposed to a mild industrial atmosphere for over 40 years with no evidence of base metal corrosion.

For type II aluminum coating, the alloy layer is much thicker than that of the type I coating. Because of the protective nature of the oxide film formed on the coating surface, type II aluminum coatings have shown much better atmospheric-corrosion resistance than type I coatings.

In 1969, type I and type II aluminized steels were evaluated at three atmospheric-testing sites (Ref 64). This evaluation was part of the program outlined in the discussion "Zinc-Base Coatings" in this section. The weight loss data obtained from the skyward panels of each specimen were fitted to the same equation, $W = kt^n$, which has been used for hot-dipped zinc coatings. The results of this curve fitting, together with k and n values obtained for type I and type II aluminum coatings, are shown in Fig. 34 and 35 for all three test sites. Table 14 provides a summary of the predicted weight loss for type I and type II aluminized steel in comparison with hot-dip zinc coatings based on 5-year exposure data. As indicated in Table 14, the atmospheric-corrosion rate of aluminum coating (type I or type II) is equivalent to only 10 to 50% of the corrosion rate of zinc coating, depending on the type of atmosphere.

Table 14 Predicted weight loss after 10-year atmospheric exposure of hot-dip galvanized steel and type I and type II aluminized steel based on 5-year exposure data

Test site	Weight loss					
	Hot-dip galvanized		**Type I aluminized**		**Type II aluminized**	
	g/m^2	**mils**	**g/m^2**	**mils**	**g/m^2**	**mils**
Porter County, IN (semi-industrial)	121.6	0.64	14.7	0.2	8.5	0.12
East Chicago, IN (semi-industrial)	290.1	1.53	25.2	0.35	10.5	0.15

Organic Coated Steels

James H. Bryson, Inland Steel Company

Paint is applied to a steel sheet or a part for one or both of the following reasons: enhancement of the esthetic value of the product and/or preservation of structural integrity. The former goal is a consideration for the designer and will receive no further discussion in this section. The latter goal, however, will be discussed as it applies to prepainted steel.

This section will describe how paints deter corrosion, the prepainting process, the primary differences between prepaint paint formulations and postpaint formulations, considerations about part design, and selection criteria for the appropriate

paint system. More detailed information on organic coating materials can be found in the article "Organic Coatings and Linings" in this Volume and in the article "Painting" in *Surface Engineering,* Volume 5 of the *ASM Handbook.*

How Paint Films Deter Corrosion

In the presence of water and oxygen, iron corrodes to form iron oxides and hydroxides (see the discussion "Corrosion Film Formation and Breakdown" in the section "Carbon Steels" in this article). The corrosion rate is accelerated when electrolytic solutes, such as the chloride or sulfate salts of alkali metals, are present. Of course, temperature also increases the corrosion rate, and where possible, decreasing the service temperature will increase the service life of the part. However, because little can usually be done to change service temperature, the exclusion of one or more of the principal reactants (oxygen, water, or electrolytes) from the steel surface will help deter corrosion. Such exclusion of reactants is the purpose of the paint film.

There are primarily three methods of protection: barrier, passivation, and galvanic. In barrier protection, the paint film retards the diffusion of water, oxygen, or salts to the steel substrate. It has been demonstrated that the flow of water and oxygen through the film is rapid; therefore, the contribution of the coating to lowering the corrosion rate is the addition of a high electrolytic resistance (Ref 70). Flake-shaped pigment particles that leaf (overlap) can increase the path length a reactant must traverse before reaching the surface; this increases the effectiveness of the barrier film. Some aluminum and stainless steel pigments protect in this fashion. The reactivity of the steel surface can be decreased when the paint film contains passivating pigments such as chromate salts. Paints are also often pigmented with zinc for both barrier and galvanic protection. The zinc loading must be sufficiently high for interparticle contact, a condition that requires that the critical pigment volume be exceeded; that is, the pigment particles are not completely wetted by the paint vehicle. Although some galvanic protection is afforded, most of the protection is provided by the barrier formed by zinc corrosion products (Ref 71).

Prepaint Processing

Much of the painted steel used today is prepainted in coil form (coil coated) before shipment to fabricators. Modern, high-speed paint lines can process bare or coated steel strip, and can be used to apply a wide variety of organic coatings.

After decoiling, the first step in the prepaint process is to clean the steel strip with an alkaline detergent. The steel strip is then brushed with an abrasive roll to remove mill oils and grime and to reduce the level of an amorphous form of surface carbon indigenous to steel strip processing. High levels of surface carbon lower corrosion resistance (Ref 72). Cleaning is usually more effective on flat than on a formed part. Next, the strip is rinsed and pretreaded to improve paint adhesion and to reduce corrosion. A prepaint treatment may consist of phosphate coating or an organic pretreatment known as wash primer or etch primer. Such pretreatments are described in the article "Painting" in *Surface Engineering,* Volume 5 of the *ASM Handbook.* Following pretreatment, a paint is then applied and cured in an oven. Depending on the paint formulation and the paint line, the dwell time in the oven is generally between 20 and 50 s. A second coat may then be applied and cured.

Differences Between Prepaint and Postpaint

In formulating a paint designed for a prepaint application, the forming step must be considered. Aside from steel considerations, successful forming of the part will depend on the flexibility and the abrasion resistance of the coating. The paint film must be flexible enough to withstand the strains induced from bending without crazing, which may compromise corrosion resistance. In addition, in the forming stages, the bend radii are often more severe than in the final part.

The coating must also withstand the abrasive forces of handling and forming. For a given coating type, the harder the coating, the more abrasion resistant the coating will be. Unfortunately, flexibility and hardness are inversely related; that is, the more flexible the coating, the softer the coating.

A method for overcoming the problems associated with coating flexibility is covered in the discussion "Part Design Considerations" in this section. Flexibility and hardness are considerations only for the end use of postpainted parts, while forming and handling are also factors of concern in the formulation of a paint designed for precoating a steel strip.

The final dried paint thickness, or dry-film thickness, on a prepainted steel strip is usually no more than 0.025 mm (1 mil). Plastisols and organosols are the major exceptions. Therefore, the prepaint dry-film thickness is much less than the typical

dry-film thickness on a postpainted part. However, because of the method of application, the film is more evenly distributed; this results in significantly fewer areas of low dry-film thickness and the elimination of many of the appearance defects observed on finished postpainted parts. Many areas on postpainted parts will receive little or no paint because of the part shape. The formulations for prepaints are engineered to account for the lower dry-film thicknesses.

Part Design Considerations

When designing a part to be fabricated from prepainted steel, the maximum bend radius, the forming equipment, and the adjoining method must be considered. As mentioned earlier, the maximum bend radius is often smaller than that specified on the blueprint of the part. This radius should be as generous as the structural and decorative criteria will allow. In considering the part shape, the avoidance of catchment areas, where possible, will decrease failures due to corrosion.

The forming equipment should be well maintained to avoid marring the surface. Where possible, roll forming is preferable to stamping. In cases in which hard finishes in conjunction with tight radii (high flexibility) are required, the prepainted strip can be warm formed. In warm forming, the paint is heated into or above its glass transition temperature range. In this temperature range, the paint is softer and more flexible, thus allowing tighter radii to be achieved during forming. After cooling, the paint becomes harder and more abrasion resistant.

Lastly, the part require joining. Welding and mechanical fastening damage the paint film. Therefore, it is necessary to touch up the scars to restore corrosion resistance. Adhesive bonding eliminates the need for touch up of these damage areas. Taking these factors into account, prepainted steel has been successfully fabricated into finished or semifinished (requiring a post finish coat operation) parts in many automotive, appliances, or office furniture manufacturing plants. Prepainted parts have been produced on lines designed for their use and on existing lines, sometimes with no modification to the line.

Selection Guideline

As an aid to understanding the evaluation process, Table 15 compares various common coatings in several categories of performance. Changes in pigmentation and resin source for the vehicle can influence the rating by a factor of one or more. Table 15 is merely a guideline to the performance of these coatings. Comments from technical personnel at a paint company should be sought before making any decisions on paint selection.

Table 15 Relative rankings of various coatings in different performance categories

Category key: A, hardness; B, flexibility; C, humidity resistance; D, corrosion resistance to industrial atmospheres; E, salt spray; F, exterior durability, pigmented film; G, exterior durability, clear film; H, paint cure temperature, in °F; I, cost guide. Ratings key: 1, excellent; 2, good; 3, fair; 4, poor; H, high cost; M, moderate cost; L, low cost

Type	A	B	C	D	E	F	G	H	I
Silicone acrylic	1	3	2	2	2	2	1	450	H
Thermoset acrylic	2	2	1	2	1	2	2	430	M
Amine-alkyd	2	3	2	2	3	2	3	340	L
Silicone alkyd	2	3	2	2	2	1	2	420	H
Vinyl-alkyd	2	2	1	2	2	3	3	340	M
Straight epoxy	1	2	1	1	1	4	4	400	H
Epoxy-ester	2	2	1	2	1	4	4	400	M
Organosol	2	1	1	1	1	2	3	350	L
Plastisol	3	1	1	1	1	2	3	350	L
Polyester (oil-free)	1	2	1	2	1	2	3	400	M
Silicone polyester	2	2	1	2	1	1	2	450	H
Poly-vinyl fluoride	2	1	1	1	1	1	1	450	H
Poly-vinyl idene fluoride	2	1	1	1	1	1	1	450	H
Solution vinyl	2	1	1	2	1	2	3	300	M

The columns in Table 15 are self-explanatory, with the exception of those involving exterior durability and salt spray. Exterior durability is the resistance to weathering, particularly, the resistance to ultraviolet light. Ultraviolet light causes some coatings to chalk. Proper pigmentation will prevent this phenomenon for some coatings, and this can be determined by comparing the columns for pigmented and clear films.

Salt spray is not a predictor of service life and coatings cannot be compared for end use on this basis. However, salt spray does detect coating defects and can be put to good use for detecting induced flaws by comparing results for flat panels with those of panels with coating defects induced, for example, by forming or abrasion.

The first step in the evaluation is the selection of a steel mill and/or paint company that is willing and able to help evaluate the needs of the final product. These needs can be categorized as either preservice or service. The preservice

conditions involve forming, handling, and joining. The service conditions are those to which the customer exposes the product: humidity, temperature, corrosive agents, sunlight, and abrasion. Of course, the preservice conditions can affect the service life of the final product, and these effects should be evaluated.

The next step is the experimental design. The test program compares candidate materials to the current product, if possible. Evaluation in actual service conditions is often not possible because of time limitations. Therefore, accelerated and laboratory tests are needed (see the article "Laboratory Testing" in this Volume). From these results, acceptable candidates are identified and are included in the next level of tests. A set of suitable parts is identified for testing the candidates. After the parts are fabricated, they are inspected to determine whether coating damage occurred and whether corrosion resistance was compromised. In general, one material will not be superior in all aspects. Therefore, the desirable properties must be prioritized.

Advantages of Prepainted Steels

Although the above evaluation sequence may seem formidable, many manufacturers have found the use of prepainted steel to be productive and economical. The use of prepainted steel reduces or eliminates the problems of the waste treatment of the emissions from paint lines. The postpainting line is often the slow step in the process, and using prepainted steel increases output. Although the material cost of prepainted steel is higher than the bare metal, the final part cost is lower because of increased productivity and the reduction of other costs, such as emissions control. Although prepainted steel cannot replace postpainted steel in every application, prepainted steel has demonstrated its productive and economic advantages.

Corrosion of Alloy Steels

Thomas G. Oakwood, Inland Steel Research Laboratories

Introduction

ALLOY STEELS comprise a category of ferrous materials that exhibit mechanical properties superior to those of ordinary carbon steels as the result of additions of such alloying elements as chromium, nickel, and molybdenum. Total alloy content can range from 0.5 to 1% and up to levels just below that of stainless steels. For many alloy steels, the primary function of the alloying elements is to increase hardenability in order to optimize mechanical properties and toughness after heat treatment. In some cases, however, alloy additions are used to reduce environmental degradation under certain specified service conditions.

Alloy steels are used in a broad spectrum of applications. In some cases, corrosion resistance is a major factor in alloy selection; in other applications, it is only a minor consideration. The information available on the corrosion resistance of alloy steels is end-use oriented and often addresses rather specialized types of corrosion. As a result, this article will emphasize those applications where corrosion resistance is either a major factor in steel selection or where available data have shown that variations in alloy content or steel processing affect resistance to corrosion.

Many applications use steels with a relatively low alloy content. The steels involved include those designated by the American Iron and Steel Institute (AISI), ASTM, and the Society of Automotive Engineers (SAE) as standard alloy steels, as well as modifications of these grades. In addition, potential standard grades, formerly SAE EX (experimental) grades, are applicable, along with high-strength low-alloy (HSLA) and structural alloy steels. The primary function of the alloying element additions is to enhance hardenability and/or mechanical properties. As will be discussed later, small additions of some alloying elements will enhance corrosion resistance in moderately corrosive environments. In severe environments, however, the corrosion resistance of this group of steels is often no better than that of carbon steel (see the article "Corrosion of Carbon Steels" in this Volume).

Other applications require more highly alloyed steels that, in addition to achieving the necessary mechanical properties, provide increased resistance to specific types of corrosion in certain environments. In this group of steels, corrosion resistance is an important factor in alloy design (see the article "Corrosion of Stainless Steels" in this Volume).

An extensive collection of data on alloy steel products, which encompasses compositions, mechanical and physical properties, applications, and service characteristics, can be found in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1 of *ASM Handbook,* formerly 10th Edition *Metals Handbook.* Information on the metallographic preparation and microstructural interpretation of alloy steels is available in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.* Finally, fracture characteristics of alloy steels are reviewed in *Fractography,* Volume 12 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Corrosive Environments Encountered In The Use of Alloy Steels

Atmospheric corrosion is a factor in nearly all applications of alloy steels. It is the principal form of corrosion of concern in the automotive, off-highway equipment, machinery, construction, and aerospace industries. As will be discussed later, the atmospheric-corrosion resistance of various alloy steels, as well as the role of various alloying elements, depends on the severity of the environment. Corrosion rates vary as the environment is changed, for example, from rural to industrial.

Some industries that use alloy steels present certain specific corrosion problems. These include the production, refining, and distribution of oil and gas; energy conversion systems involving the combustion of fossil fuels; the chemical-process industries; and certain marine applications.

During the drilling and primary production of oil and gas, alloy steels are exposed to crude oil and gas formations containing varying amounts of hydrogen sulfide (H_2S), carbon dioxide (CO_2), water, and chloride compounds. High pressures and temperatures are also encountered in some cases. Refining operations subject low-alloy steels to environments containing both hydrogen and hydrocarbons. Transmission and distribution of oil and gas expose pipelines and piping systems to environments containing varying amounts of many of the constituents mentioned above.

In most cases, energy conversion systems involve consideration of the corrosion problems associated with the combustion of fossil fuels. Contaminants in coal, oil, and natural gas result in the accelerated attack of alloy steels at elevated temperatures. In steam-generating electric power plants, corrosion due to impurities in boiler feedwater and in high-pressure high-temperature steam needs to be addressed.

Alloy steels used in the construction of chemical-processing plants are subject to corrosion from a wide variety of environments. Compounds of chlorine, sulfur, ammonia (HN_3), and acids and alkalies are typical.

Finally, alloy steels are often used in marine environments involving direct contact with seawater. Applications include ship construction and offshore drilling equipment.

Atmospheric-Corrosion Resistance of Alloy Steels

As noted earlier, atmospheric-corrosion resistance is of concern in most of the applications for alloy steels. The atmospheric-corrosion resistance of alloy steels is a function of the specific environment and steel composition. Some of the data available describe the effects of various alloying elements on corrosion resistance; in other cases, specific alloy steel grades are addressed. Thus, the available information provides a general guide for the selection of an alloy steel based on overall alloy content.

Table 1 lists some of the results of a systematic study of 270 alloy steels. Experimental heats of steel involving systematic combinations of chromium, copper, nickel, silicon, and phosphorus were tested to determine their individual and joint contributions to corrosion resistance. Table 1 summarizes test results for composition whose performance established the value of specific concentrations of each of the five elements. These data were developed over 15.5 years in three environments: industrial (Kearny, NJ), semirural (South Bend, PA), and marine (Kure Beach, NC). The data show that the long-term atmospheric-corrosion of carbon steel can be reduced with a small addition of copper. Additions of nickel are also effective, and chromium in sufficient amounts is helpful if copper is present. The maximum resistance to corrosion was obtained in this study when alloy contents were raised to their highest levels.

(d) Estimated.

Figure 1 summarizes some of the results from industrial environments. The carbon steel corrosion rate becomes constant after about 5 years. The corrosion rate of the copper steel levels off to a constant value after about 3 years, and the high-strength low-alloy steel, which utilizes several alloy elements, exhibits a constant rate after approximately 2 years. Corrosion of the high-strength low-alloy steel eventually ceases. Table 2 compares the corrosion behavior of carbon steel, a copper steel, and ASTM types A242, A588, A514, and A517 low-alloy steels in a variety of environments. It is evident that the low-alloy steels exhibit significantly better performance than either carbon steel or the structural copper steel.

Although the data given above provide good estimates of average corrosion behavior, it is important to note that corrosion rates can increase significantly in severe environments. Table 3 lists corrosion rates for several steels exposed to various atmospheres in chemical plants. Comparison of these data with the industrial atmosphere data shown in Table 2 illustrates the significant increase in corrosion rate associated with severe environments. Table 3 does, however, demonstrate the effectiveness of increased alloy content on corrosion resistance.

Protective coatings offer a means of providing significant additional protection from atmospheric corrosion. Well-cleaned, primed, and painted steel can give good service in many applications (see the article "Organic Coatings and Linings" in this Volume).

Galvanizing is also used to provide protection even under conditions in which the corrosive environment is quite severe. This zinc coating is anodic and corrodes preferentially; this protects exposed steel surfaces existing at cut edges or other areas where breaks in the coating are found. Corrosion resistance increases with coating thickness. In mild environments, galvanized steels can be used with no further treatment. In more severe environments, galvanized steels can be painted. In some cases, a prior treatment is used to provide a zinc phosphate conversion coating over the zinc coating to improve paint adherence. Information on zinc-base coatings can be found in the articles"Hot Dip Coatings," "Organic Coatings and Linings," "Corrosion of Zinc," "Corrosion of Carbon Steels," and "Corrosion in the Automotive Industry" in this Volume.

Finally, electroplating, usually with chromium, can be used where decorative requirements must be met in addition to atmospheric-corrosion resistance. Detailed information is available in the aticles "Electroplated Coatings" and "Corrosion of Electroplated Hard Chromium" in this Volume.

Corrosion of Alloy Steels in Specific End-Use Environments

As with carbon steels, alloy steels are used in a wide variety of industrial applications. This section will review four major industries that rely heavily on alloy steel products. These include oil and gas production, energy conversion systems, marine applications, and chemical processing. Additional information is provided in the Section "Specific Industries and Environments" in this Volume.

Oil and Gas Production

Drilling and Primary Production. A variety of corrosion problems can be encountered in the drilling and primary production of oil and gas. These include weight loss corrosion, pitting corrosion, corrosion fatigue, stress-corrosion cracking, sulfide stress cracking, and hydrogen-induced cracking.

In relatively shallow wells, lower-strength carbon or carbon-manganese steels can be employed in many of the components used in drilling and primary production. Oil and gas deposits are often such that corrosion is limited to weight loss corrosion, which can be effectively controlled by chemical inhibition. For the case of deep wells, however, high-strength alloy steels are usually required. Furthermore, very hostile environments are often encountered--in particular, high H_2S levels. In the case of deep gas wells, for example, formations have been encountered with H_2S concentrations ranging from 28 to 46%. In addition, temperatures to 200 °C (390 °F) can be found, along with pressures to 140 MPa (20 ksi). Also, H_2S is often found in combination with chloride-containing brines and CO_2, which add to the harshness of the environment.

Although chemical inhibition is used even in deep wells to control weight loss corrosion (see the article "Corrosion Inhibitors for Oil and Gas Production" in this Volume), the presence of H_2S can still result in the embrittlement of high-strength steels. This phenomena, known as sulfide stress cracking (SSC), depends on H_2S concentration and temperature. An example is shown in Fig. 2. Figures 3 and 4 illustrate typical SSC data for alloy steels used in oil field tubular components. The data shown are for high-strength steels covered under the following American Petroleum Institute specifications:

- 5A: "Welded or Seamless Steel Pipe for Oil or Gas Well Casing, Tubing, or Drill Pipe"
- 5AC: "Welded or Seamless Steel Pipe with Restricted Yield-Strength Range for Oil or GasWell Casing or Tubing"
- 5AX: "High-Strength Seamless Steel Pipe for Oil or Gas Well Casing, Tubing, or Drill Pipe"

Certain proprietary grades are also included. As temperatures increase, some higher-strength steels can be used and resistance to SSC can be maintained. However, higher-strength steels are generally more susceptible to SSC than lower-strength steels.

Fig. 2 Sulfide stress corrosion cracking in a low-alloy steel. 100×

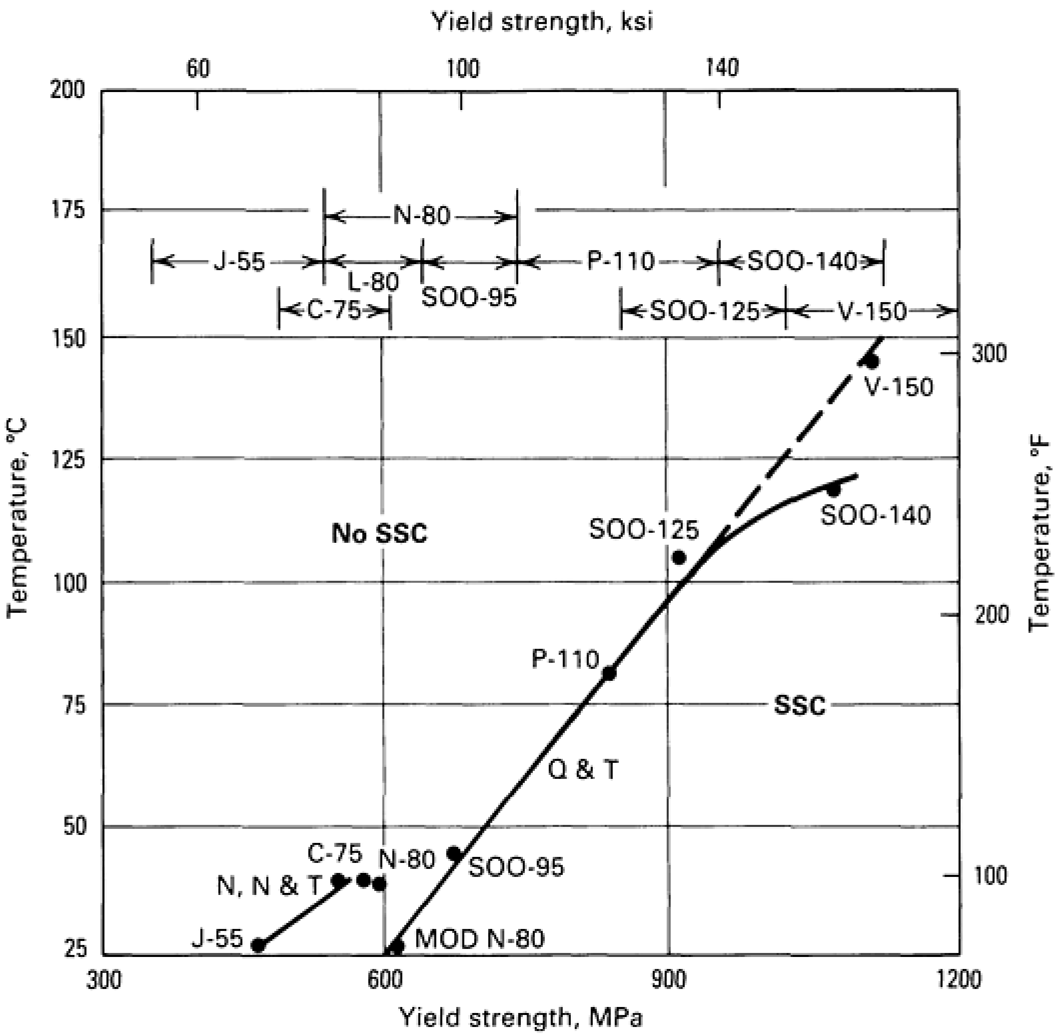

Fig. 3 Effect of temperature on SCC of high-strength steels. N, normalized; N & T, normalized and tempered; Q & T, quenched and tempered. Source: Ref 3

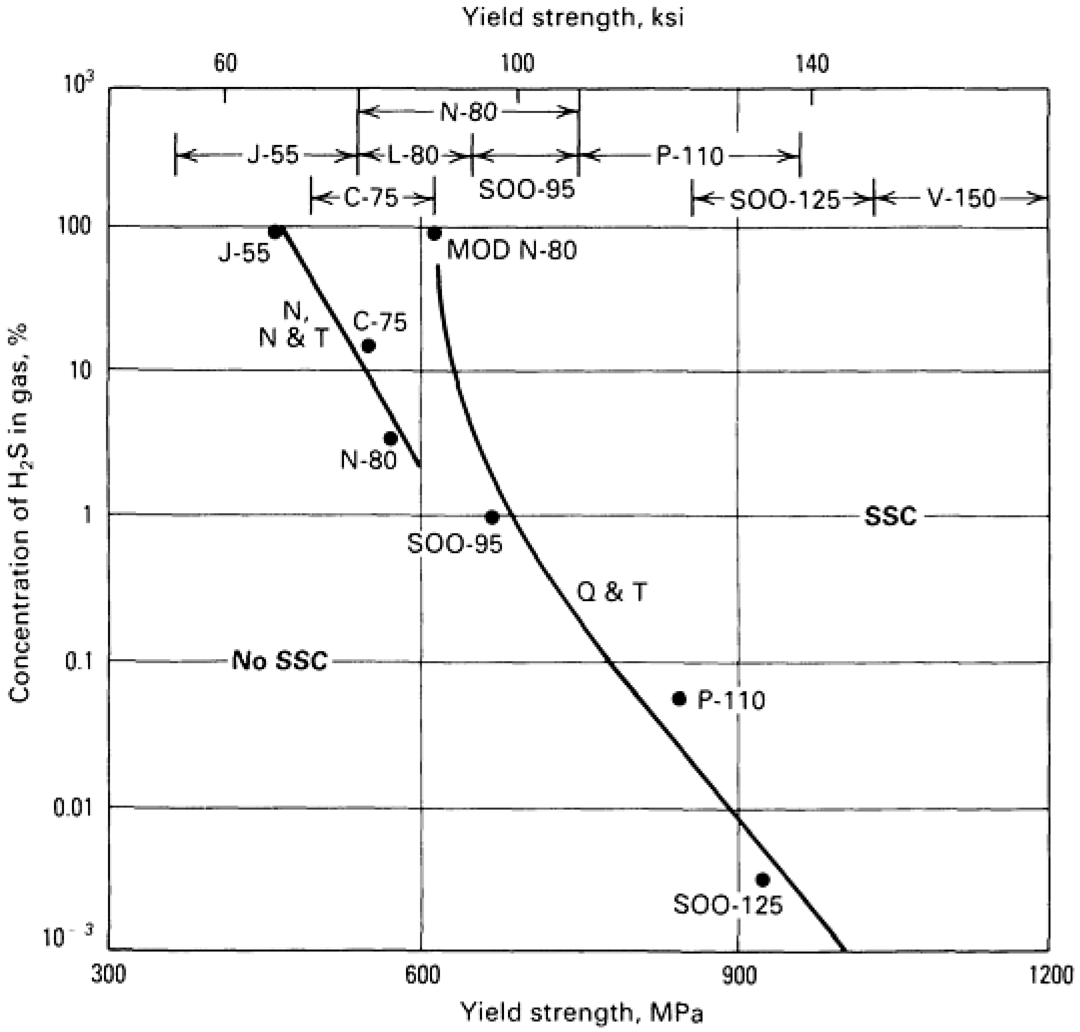

Fig. 4 Effect of H_2S concentration on SSC of high-strength steels. Source: Ref 3

Sulfide stress cracking resistance is influenced by steel microstructure, which in turn depends on steel composition and heat treatment. It has been observed that a martensitic structure provides better SSC resistance than other microstructures. Figure 5 illustrates this for a molybdenum-niobium modified AISI 4135 steel (compositions of the steels discussed in Fig. 5, 6, and 7 are given in Table 4). The data in Fig. 5(a) were developed by using simple beam specimens strained in three-point bending for measuring a critical stress, S_c, and the data in Fig. 5(b) were obtained from double-cantilever beam specimens strained by wedge opening loading for measuring a threshold stress intensity, K_{ISSC}. Thus, it is important to select an alloy steel that has sufficient hardenability to achieve 100% martensite for a given application.

Furthermore, proper tempering of martensite is essential in order to maximize SSC resistance. Figure 6 illustrates the effects of tempering temperature on SSC behavior. It is evident that higher tempering temperatures improve SSC performance. The presence of untempered martensite, however, is extremely detrimental to SSC resistance. This is illustrated in Fig. 7, which shows the effect of tempering above the Ac_1 temperature for molybdenum-niobium modified 4130 steels containing two levels of silicon. Water quenching from above the Ac_1 temperature results in untempered martensite with a subsequent loss in SSC resistance. It has also been found that the development of a fine prior-austenite grain size and the use of accelerated cooling rates after tempering improve SSC resistance. The necessity for adequate hardenability is quite evident when considering alloy steels for heavy section wellhead components. Figure 8 shows how the SSC resistance of conventional steels used in wellhead equipment can be improved through modifications in composition, which increase hardenability.

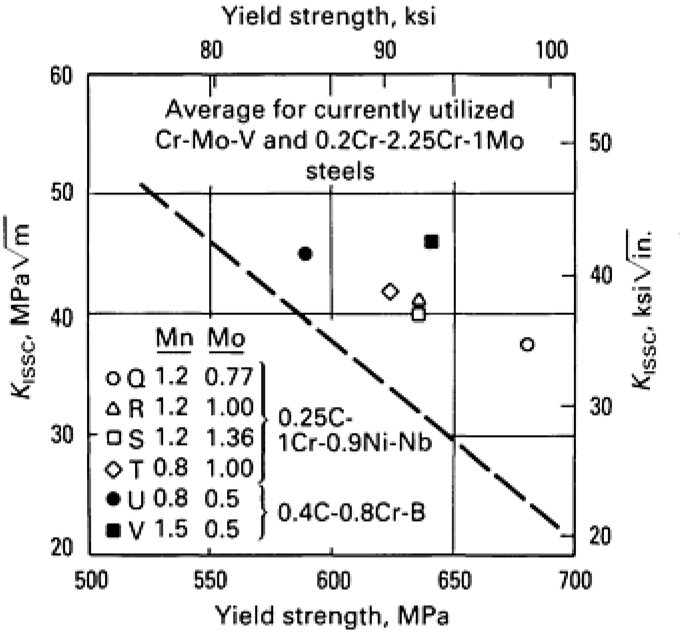

Fig. 8 Effects of molybdenum and manganese content on the SSC resistance of manganese-nickel-chromium-molybdenum-niobium and manganese-chromium-molybdenum-boron steels. Open symbols are 400-mm (16-

in.) section thickness; closed symbols are 250-mm (10-in.). Source: Ref 5

With the advent of enhanced oil recovery techniques, additional corrosion problems must be considered. Carbon dioxide injection is one method of displacing crude oil from a formation for increased recovery (CO_2 injection is discussed in the section "Problems Encountered and Protective Measures" of the article "Corrosion in Petroleum Production Operations" in this Volume). This method involves development of CO_2 source wells, that is, those having large quantities of CO_2-containing gas. The gas from these wells is processed, transported to the production reservoir, and injected. Corrosion in source wells and in production wells results from the highly acidic environment created when CO_2 and water are present. The presence of chlorides and H_2S adds to the aggressiveness of the environment. Furthermore, corrosion rates change as temperatures change.

Figures 9(a) to (d) illustrate the complexities of corrosion in CO_2 environments. In Fig. 9(a), the effects of increasing CO_2 concentration on weight loss corrosion at a temperature of 65 °C (150 °F) are shown. The lower-alloy steels show a slight increase in corrosion rate with increasing CO_2 concentration, but the higher-alloy materials show little or no dependence on CO_2 level. As chromium content increases, corrosion resistance improves at a given CO_2 level. At a temperature of 175 °C (350 °F), however, the corrosion resistance of the lower-alloy steels improves, but that of the higher-alloy steels remains the same or decreases (Fig. 9b). With the addition of significant amounts of chloride at 65 °C (150 °F), some of the higher-alloyed steels begin to show an increase in corrosion rate with increasing CO_2 level (Fig. 9c). An increase in chloride concentration, along with an increase in temperature, results in a significant decrease in the corrosion resistance of the more highly alloyed steels (Fig. 9d). Finally, if H_2S is present in CO_2-brine environments, the corrosion rate of lower-alloy steels can be expected to increase. This is illustrated in Table 5.

Table 5 Corrosion rate data for alloys exposed to seawater solutions at 175 °C (350 °F) with and without H_2S

The corrosion rate of various alloy steels in CO_2-brine-H_2S environments vary considerably with the specific environment encountered. As a result, control of the environment through chemical inhibition becomes an important tool, along with alloy selection, in reducing corrosion failures. Detailed information on corrosion and corrosion prevention in oil field operations is provided in the article "Corrosion in Petroleum Production Operations" in this Volume.

Petroleum Refining/Hydrocarbon Processing. A principal concern in petroleum refining and hydrocarbon processing is the problem of the interaction of hydrogen with the alloy steels used in these applications. Prolonged exposure to hydrogen, particularly at elevated temperatures, results in loss of ductility and premature failure. Figure 10 shows the delayed failure characteristics of an AISI 4340 steel resulting from cathodic charging of hydrogen. At higher tensile strengths, the effects of hydrogen become more severe.

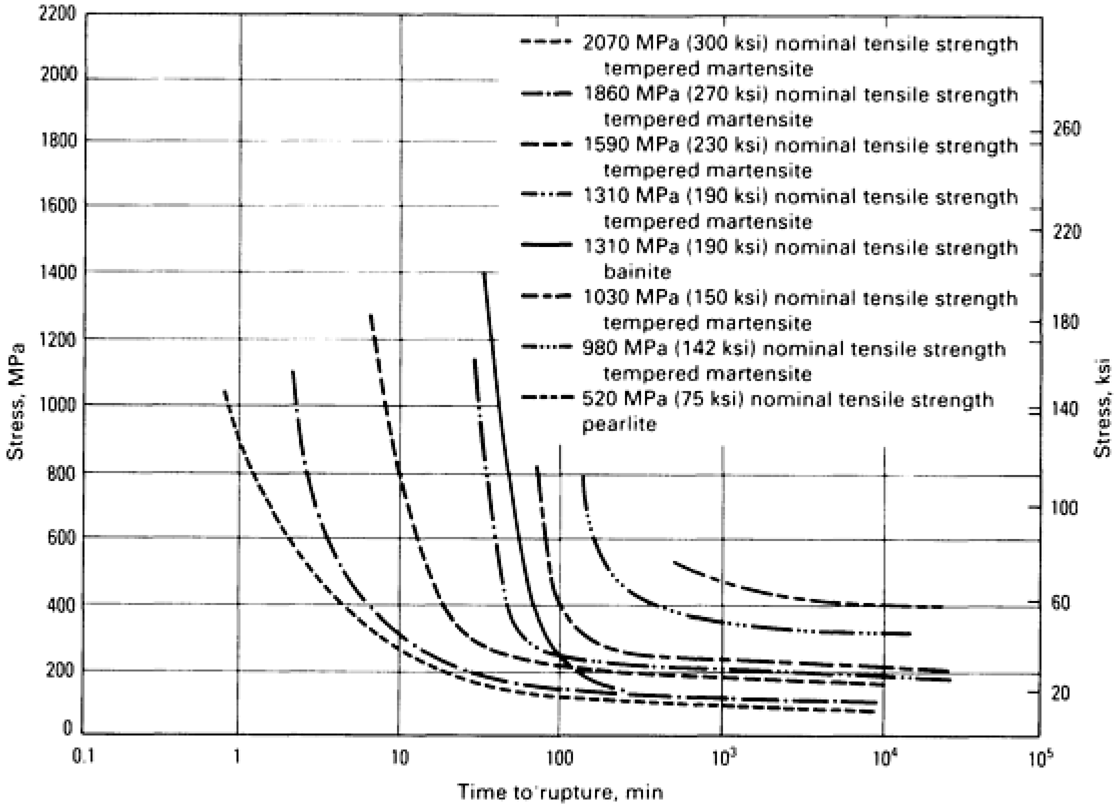

Fig. 10 Delayed-failure characteristics of unnotched specimens of an AISI 4340 steel during catholic charging with hydrogen under standardized conditions. Electrolyte: 4% H_2SO_4 in water. Poison: 5 drops/liter of cathodic poison composed of 2 g phosphorus dissolved in 40 mL CS_2. Current density: 1.2 mA/cm^2 (8 mA/in.^{2}). Source: Ref 7

The phenomenon often encountered in actual service is hydrogen attack. This involves the chemical reaction of hydrogen with metal carbides at elevated temperatures to form methane (CH_4). Because CH_4 cannot diffuse out of steel, an accumulation occurs, and this causes fissuring and blistering. The combined action of decarburization and fissuring results in loss of strength and ductility. The empirical limits on the use of alloy steels commonly used in a hydrogen environment are shown in Fig. 11. The Nelson diagrams shown are continually updated as additional service experience is acquired. Detailed information on corrosion problems and prevention in petroleum-refining operations is available in the articles "Corrosion in Petroleum Refining and Petrochemical Operations" and "Corrosion Inhibitors for Crude Oil Refineries" in this Volume.

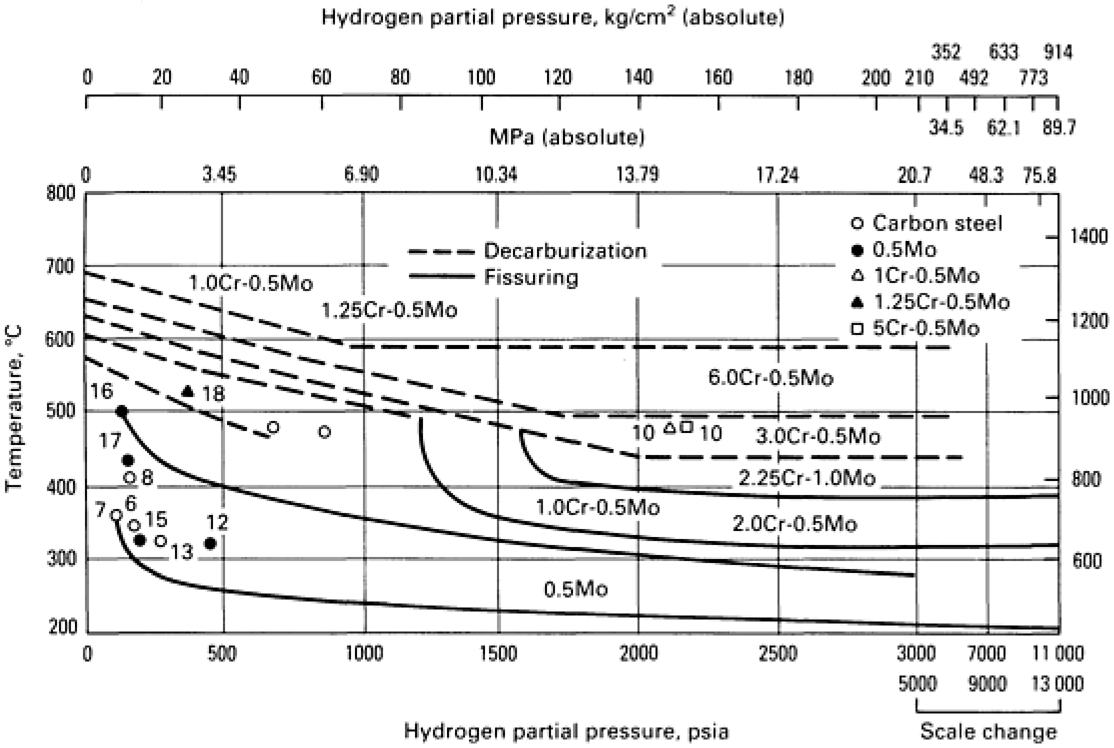

Fig. 11 Nelson curve defining safe upper limits for steels in hydrogen service. Source: Ref 7

Oil and Gas Transmission. The transmission of oil and gas involves consideration of the corrosion problems associated with linepipe steels. In addition to carbon steels, high-strength low-alloy steels are often used in pipeline service. Atmospheric corrosion, which has been discussed above, needs to be considered for exposed pipelines, and the corrosive actions of various soil formations must be addressed. A summary of an extensive study of the corrosion encountered by various alloy steels in several different types of soils is presented in Fig. 12(a) and 12(b). It is evident that factors such as soil pH, resistivity, degree od aeration, and level of acidity have more bearing on the severity of corrosion encountered than the alloy content of the steel. In some cases, increasing alloy content has a beneficial effect, but in other cases, it does not. In general, the use of protective coatings and cathodic protection offers the best means of reducing the level of corrosive attack.

Linepipe steels can be susceptible to a specialized form of hydrogen damage when H_2S is present in oil and gas. This type of embrittlement, known as hydrogen-induced cracking, results from the accumulation of hydrogen at internal surfaces within the steel. Examples include interfaces at nonmetallic inclusions and at microstructure constituents that differ significantly from the surrounding matrix. Martensite islands in a ferrite-pearlite matrix would be typical. Microcracks that form at these interfaces grow in a stepwise fashion toward the surface of the pipe, with the result being failure. Figure 13 illustrates an example of this type of cracking.

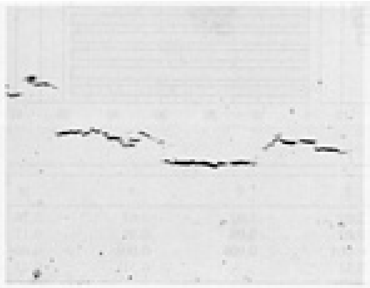

Fig. 13 Hydrogen-induced cracking in a linepipe steel. 30×

Very few failures due to hydrogen-induced cracking have been reported. However, they can be catastrophic, and considerable investigative work has been done to understand the nature of the problem and to develop preventive measures. Hydrogen-induced cracking can usually be prevented by control of the environment--for example, dehydration to remove water and through chemical inhibition. A number of metallurgical factors have also been identified that influence resistance to hydrogen-induced cracking and offer a means of reducing the susceptibility of linepipe steels to this form of embrittlement.

Two factors that influence the susceptibility of linepipe steels to hydrogen-induced cracking are steel cleanliness and degree of alloying element segregation. This might be expected, because the degree of steel cleanliness affects the volume fraction of nonmetallic inclusions present and therefore the number of interfaces available for the accumulation of hydrogen. Segregation of alloying elements can lead to the formation of low-temperature austenite decomposition products, thus providing additional sites for hydrogen accumulation.

Hydrogen-induced cracking has been found to be associated with manganese sulfide inclusions that have become elongated during hot rolling. Elongated silicate inclusions also provide interfaces for hydrogen accumulation. Laboratory tests have shown that reduction in the sulfur level of a linepipe steel reduces susceptibility to hydrogen-induced cracking. Reducing the sulfur content to levels of 0.002% or less can result in a significant improvement in resistance to hydrogen-induced cracking. It has also been observed that resistance to hydrogen-induced cracking can be improved through the use of sulfide shape control techniques. Calcium or rare-earth metals are added to the steel to form calcium or rare-earth sulfides. These inclusions are not plastic at hot working temperatures and therefore do not elongate during hot rolling.

The effects of various alloying elements on resistance to hydrogen-induced cracking are uncertain and somewhat controversial. The alloying element that has received the most attention is copper. Laboratory results have shown that copper can significantly reduce susceptibility to hydrogen-induced cracking. Apparently, the benefits of copper are realized only in environments with a pH of 4.5 to 4.8 and above. At pH levels less than this, copper has no effect on resistance to hydrogen-induced cracking. Detailed information on corrosion and corrosion prevention in linepipe steels can be found in the article "Corrosion of Pipelines" in this Volume.

Energy Conversion Systems

Fossil Fuel Power Systems. As noted earlier, corrosion problems associated with energy conversion systems often concern the combustion of fossil fuels (these corrosion problems are discussed in detail in the article "Corrosion in Fossil Fuel Power Plants" in this Volume). The most typical applications involve the operation of coal and oil-fired utility steam boilers. In these applications, corrosion due to boiler feedwater and high-temperature high-pressure steam must also be considered (see the section "Hot Corrosion in Coal- and Oil-Fired Boilers" in the article "Corrosion in Fossil Fuel Power Plants").

Combustion of fossil fuels can result in so-called fire-side corrosion, which is an elevated-temperature attack on metal surfaces stemming from the products of combustion. There are three general areas where external corrosion problems occur: the water wall or boiler tubes near the firing zone, the high-temperature superheater and reheater tubes, and the ductwork that handles the combustion flue gases.

Corrosion of the ductwork is a low-temperature attack that results mainly from acid condensation. Prevention of this corrosion depends primarily on maintaining flue gas temperatures and metal surface temperatures above acid dewpoints.

Corrosion on water wall, superheater, or reheater tubes results from fuel ash deposits at higher temperatures (see the section "Corrosion of Superheaters and Air Heaters" in the article "Corrosion in Fossil Fuel Power Plants" in this Volume). In these situations, the corrosive nature of fossil fuels varies considerably with the chemical composition of the fuel. It should be noted that many fuels are not especially corrosive. However, coals containing significant levels of sulfur and alkali metals are particularly damaging, as are oils that contain alkali metals, sulfur, and vanadium. These constituents have been identified as principal sources of corrosive attack in a number of studies involving the analysis of fuel ash deposits on boiler and superheater tubes.

In the case of coal combustion, corrosive attack results from complex chemical reactions involving sulfur and alkali metals (sodium and potassium) to form alkali sulfates. These alkali sulfates, along with sulfur trioxide (SO_3), react with the protective iron oxide. This reaction breaks down the iron oxide and forms a complex alkali iron sulfate. At temperatures of 425 to 480 °C (800 to 900 °F), this deposit can spall from the surface, exposing fresh iron for further attack. Such would be the case with water wall tubing. As temperatures increase to levels encountered by superheater or reheater tubing--for example, 565 to 705 °C (1050 to 1300 °F)--the complex sulfate becomes liquid and attacks the tubing directly. Figure 14 compares the corrosion behavior of two alloy steels and an austenitic stainless steel in this higher temperature range. The data were developed in a laboratory simulation that created the complex alkali iron sulfates. Corrosion rates increase with temperature until the sulfates become unstable, leading to a decrease in corrosion rate. Figure 15 illustrates weight loss data obtained from corrosion probes that were fabricated from various alloy steels and installed in a coal-fired steam boiler system. It is evident from both Fig. 14 and 15 that, although they can be used in these environments, alloy steels do not perform as well as stainless steels.

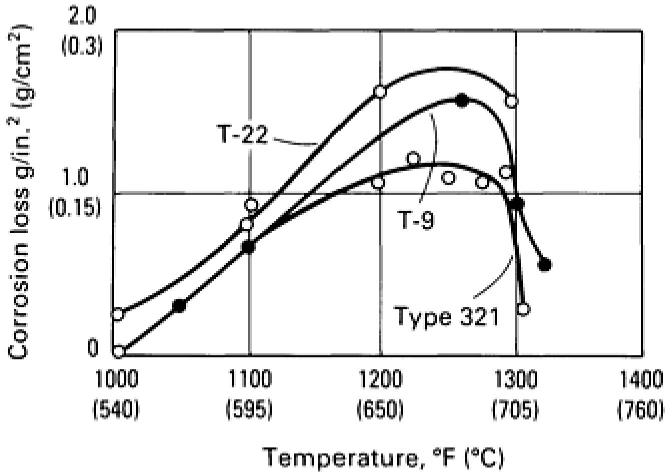

Fig. 14 Effect of alloying on corrosion rate of T-9 (8.0-10.0Cr, 0.90-1.10Mo), T-22 (1.9-2.6Cr, 0.87-1.13Mo), and type 321 (17-19Cr, 9-12Ni) alloy steels. Source: Ref 8

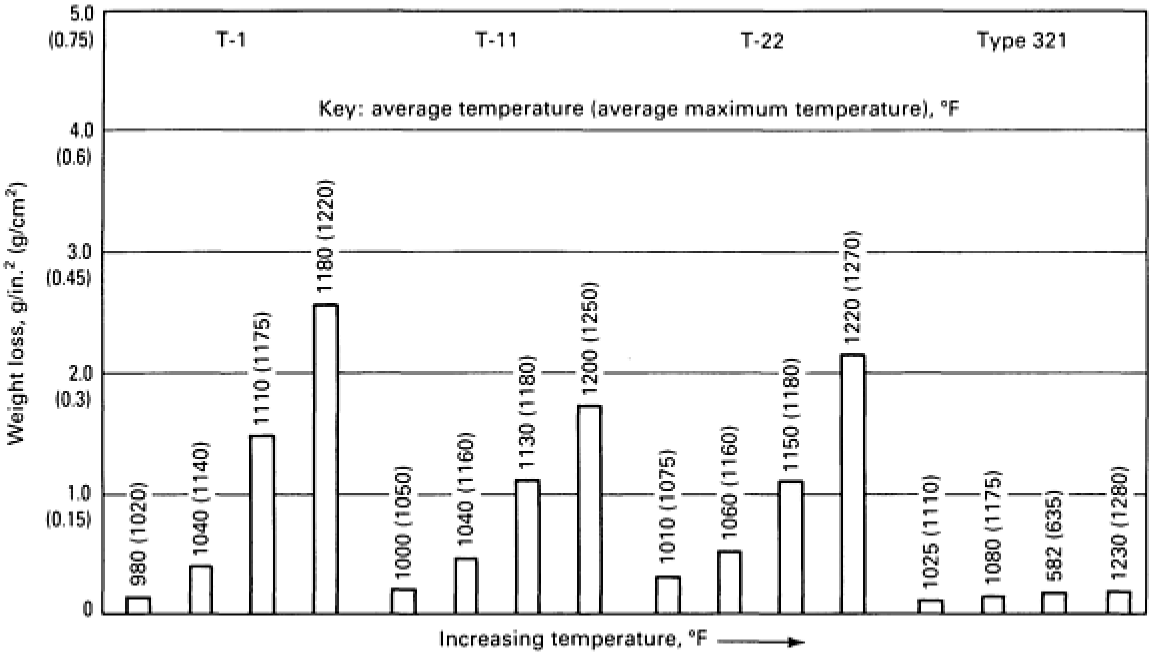

Fig. 15 Weight loss versus temperature data for corrosion probes made of alloy steels (T-1, T-11, T-22) and type 321 stainless steel. Source: Ref 9

Several courses of action are taken to prevent fire-side corrosion in coal-fired facilities. At the lower temperature encountered by water wall tubing, procedures are implemented to avoid spalling of combustion deposits. These procedures involve controlling fuel flow and combustion conditions to avoid impingement by particulate matter on critical metal surfaces. At higher temperatures, where liquid-phase attack can occur, protective shields have been used to maintain metal surfaces at temperatures above the corrosive range. The use of coal blending to counteract the corrosive nature of a given coal offers an additional means of corrosion prevention. Also, studies have shown that certain additives to coal are effective in reducing corrosion rates. Success has been achieved with kaolin, diatomaceous earth, and magnesium oxide or other alkaline earth oxides. These additives prevent the formation of complex alkali iron sulfates by forming stable compounds with one or more of their components. As noted earlier, the lower-alloy chromium-molybdenum steels have limited corrosion resistance to highly aggressive coals. Although some improvement can be achieved by using 9Cr-1Mo steels, such as T-9, maximum corrosion resistance requires the use of stainless steels.

In oil-fired boilers, the principal source of corrosion comes from a fluxing action of molten sodium-vanadium complexes with the protective oxide scale formed on metal surfaces. Although this can occur at lower temperatures if the current ratio of sodium to vanadium is present, this form of corrosion generally takes place at temperatures above 595 °C (1100 °F). Superheater and reheater tube corrosion rates of as much as 0.75 mm/yr (30 mils/yr) have been observed in field measurements.

An effective method of preventing oil ash corrosion is to remove vanadium, alkali metals, and sulfur chemically from the fuel. However this approach can be costly. Certain magnesium and calcium compounds have been found to be effective in reducing corrosion rates. These compounds form high melting point complexes with oil ash constituents. In terms of alloy steel selection, it has been found that the 9Cr-1M alloys exhibit excellent corrosion resistance to oil ash corrosion. In addition, modifications of these alloys with additional molybdenum and/or vadium provide high corrosion resistance and increased strength. Thus, for this application, alloy steels are available at a lower cost than stainless steels.

Steam/water side corrosion is another major problem encountered in fossil fuel power plants. In most cases, contaminant deposition reduces equipment efficiency and induces corrosion by a variety of mechanisms and is implicated in a variety of boiler tube failure mechanisms that are most common in water walls and economizers, which are often constructed from low-chromium ferritic steel such as ASTM A213 T11.

Water side deposits often begin as accumulations of corrosion products transported to the boiler from other parts of the system. The corrosion product deposit is porous, unlike the protective magnetite (Fe_3O_4) film. This porous deposit serves as a trap for corrosive impurities, such as caustic, chlorides, and acid sulfates.

Alloy steel boiler tube failures in steam-containing tubing have also almost exclusively been the result of contaminant entrainment within the steam. Chlorides, sulfates, and caustic are the most common contaminants. However, the growth of Fe_3O_4 on the inside tube surface can also be a secondary contributor to tube failure. If its rate of growth is excessive, this will act as a thermal barrier and cause the tube wall temperature to rise, sometimes above the point at which excessive creep damage will result in an overheating failure. Additional information is available in the section "Corrosion of Steam/Water Side Boilers" of the article "Corrosion in Fossil Fuel Power Plants" in this Volume.

Nuclear Power Systems. High-strength chromium-molybdenum and nickel-chromium-molybdenum alloy steels are also used in components for commercial light water reactors. For example, most modern light water reactor steam turbine rotors in the United States are made from 3.5NiCrMoV steel in conformance with the requirements of ASTM A471 (Class 1 through 9). A serious concern associated with steam turbine materials is that of stress-corrosion cracking (SCC), which has occurred in quenched-and-tempered and normalized-and-tempered low-alloy steels with a wide range of grain sizes. Metallurgical and environmental conditions that influence SCC behavior in low-alloy steels and methods of reducing or eliminating SCC are discussed in the section "Stress Corrosion Cracking in Steam Turbine Materials"of the article "Corrosion in the Nuclear Power Industry" in this Volume.

Wet steam erosion-corrosion of nuclear plant piping represents another serious problem that can lead to costly power outages and repairs. The most widely used material for U.S. nuclear plant wet steam piping has been carbon steel, which has shown a susceptibility to erosion-corrosion. With alloying additions of chromium, copper, and molybdenum, however, erosion-corrosion resistance can be significantly improved. In comparison to ordinary carbon steel, erosion-corrosion rates can be reduced by three times with carbon-molybdenum steel and more than ten times with chromium-molybdenum steels. Field experience has shown that 1.25Cr, 0.5Mo, and 2.25Cr-1Mo steels are virtually immune to erosion-corrosion in nuclear power plant applications. Data comparing the erosion-corrosion behavior of carbon and alloy steel piping material can be found in the section "Erosion-Corrosion in Wet Steam Flow" of the article "Corrosion in the Nuclear Power Industry" in this Volume.

Nuclear Waste Disposal. The disposal of high-level nuclear waste in deep underground repositories requires the development of waste packages that will keep the radioisotopes contained for periods of up to 1000 years. The primary geologic media currently being considered in the United States for repository siting are salt, basalt, tuff, and granite. A number of alloy steel and other iron-base materials are being considered for the structural barrier members of waste packages. Their uniform and nonuniform (pitting and intergranular) corrosion behavior and their resistance to SCC in aqueous environments relevant to salt media are under study at the Pacific Northwest Laboratory (Ref 10). These and the results of other studies on alternate nonferrous alloys are presented in the section "Corrosion of Containment Materials for Radioactive Waste Isolation" of the article "Corrosion in the Nuclear Power Industry" in this Volume.

Marine Applications

Carbon and alloy steels are extensively used for submerged or partly submerged structures--both in harbors (sea walls and piers, for example) and offshore (oil drilling platforms, for example). As will be shown in this section, however, low-alloy steels exhibit superior resistance to marine corrosion.

Marine structures exhibit five separate zones that are susceptible to corrosion at different rates, depending primarily on elevation above the tidal zone of depth of immersion in seawater. These zones are described below and are identified in Fig. 16, which also shows the usual relative corrosion rate associated with each zone:

- *Atmospheric zone:* The portion of the elevated structure subject to a marine atmosphere, including sea mist and high relative humidity, but without significant wetting by splash from waves
- *Splash zone:* The portion above the level of mean high tide that is subject to wetting by large droplets of seawater
- *Tidal zone:* The portion of the structure between mean high tide and mean low tide; it is alternately immersed in seawater and exposed to a marine atmosphere
- *Submerged zone:* The portion of the structure from about 0.3 to 1 m (1 to 3 ft) below mean low tide down to the mud line

- *Subsoil zone:* The portion below the mud line, where the structure has been driven into the ocean bottom

The effects of each of these zones on the corrosion behavior of alloy steels is reviewed below. More detailed information on marine atmospheres (zones 1 and 2, Fig. 16) and marine environments (zones 3 to 5) and the variables (such as salinity, temperature, pollutants, and biological activity) that influence corrosion can be found in the article "Marine Corrosion" in this Volume. A brief summary of some of the more influential variables is presented in Table 6.

Table 6 Corrosion factors for carbon and alloy steel immersed in seawater

Factor in seawater	Effect on iron and steel
Chloride ion	Highly corrosive to ferrous metals. Carbon steel and common ferrous metals cannot be passivated (sea salt is about 55% chloride).
Electrical conductivity	High conductivity makes it possible for anodes and cathodes to operate over long distances; thus, corrosion possibilities are increased, and the total attack may be much greater than that for the same structure in freshwater.
Oxygen	Steel corrosion is cathodically controlled for the most part. Oxygen, by depolarizing the cathode, facilitates the attack; thus, a high oxygen content increases corrosivity.
Velocity	Corrosion rate is increased, especially in turbulent flow. Moving seawater may destroy rust barrier and provide more oxygen. Impingement attack tends to promote rapid penetration. Cavitation damage exposes the fresh steel surface to further corrosion.
Temperature	Increasing ambient temperature tends to accelerate attack. Heated seawater may deposit protective scale or lose its oxygen; either or both actions tend to reduce attack.
Biofouling	Hard-shell animal fouling tends to reduce attack by restricting access of oxygen. Bacteria can take part in corrosion reaction in some cases.
Stress	Cyclic stress sometimes accelerates failure of a corroding steel member. Tensile stresses near yield also promote failure in special situations.
Pollution	Sulfides, which are normally present in polluted seawater, greatly accelerate attack on steel. However, the low oxygen content of polluted waters could favor reduced corrosion.
Silt and suspended sediment	Erosion of the steel surface by suspended matter in the flowing seawater greatly increases the tendency toward corrosion.
Film formation	A coating of rust or of rust and mineral scale (calcium and magnesium salts) will interfere with the diffusion of oxygen to the cathode surface, thus slowing the attack.

Atmospheric-Zone Corrosion. Low-alloy steels demonstrate greatly improved resistance to marine atmospheres compared to the resistance of carbon steels. The first indication that composition affects corrosion behavior was the observation that copper-bearing steels exhibit improved endurance in industrial atmospheres (Ref 12). It was later found that copper-bearing steels also perform better than plain carbon steels at ocean sites (Ref 11).

A number of marine corrosion studies have evaluated the benefits of copper, nickel, chromium, and phosphorus additions to steel (Ref 1, 13, 14, 15, 16, 17, 18). The benefit derived from the addition of copper to steel exposed to an industrial atmosphere has been attributed to the relatively insoluble basic sulfates from the SO_2 in the polluted air, which slowly develop a fine-grain, tightly adherent protective rust film (Ref 11). Additions of nickel, chromium, silicon, and phosphorus also promote relatively insoluble corrosion products (Ref 13). Chlorine has a deleterious effect on the protective rust layer an alloy steels, and the manner in which protective rust coats form in marine atmospheres is less understood than in the case of the industrial atmosphere. However, tests have shown that alloying additions to provide enhanced corrosion resistance in marine atmospheres. The effects of individual additions of copper, nickel, and chromium are shown in Fig. 17.

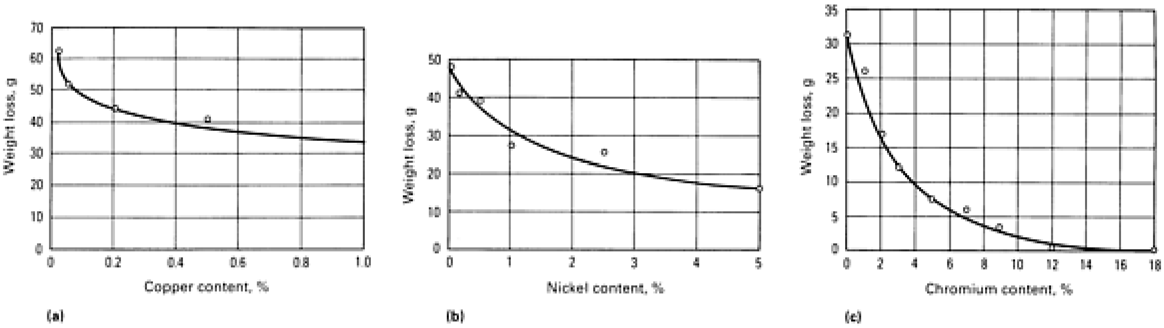

Fig. 17 Effect of alloying additions on the corrosion of steel in a marine atmosphere at Kure Beach, NC (90-month exposure). (a) Effect of copper (100 × 150 mm, or 4 × 6 in., specimen). (b) Effect of nickel (100 × 150 mm, or 4 × 6 in., specimen). (c) Effect of chromium (75 × l50 mm, or 3 × 6 in., specimen). Source: Ref 14

Tests performed at a 250-m (800-ft) lot at Kure Beach, NC, for 15.5 years indicated a corrosion rate of 7.6 μm (0.3 mil/yr) or less for copper-bearing and low-alloy steels (Ref 13). Table 7 identifies the compositions of the steels used in these tests and gives the weight losses determined. A wide range of compositions gave improved corrosion resistance. A

comparison of marine atmosphere corrosion of plain carbon, copper-bearing steel and two low-alloy steels is shown in Fig. 18. Data for a series of low-alloy steels with total alloy additions up to 3.5% are shown in Fig. 19. Additional information on the effects of various alloying additions to carbon steels can be found in the section "Weathering Steels" of the article "Corrosion of Carbon Steels" in this Volume.

Splash- and Tidal-Zone Corrosion. Low-alloy steel undergoes decidedly less corrosion at the splash zone (zone 2, Fig. 16) than carbon steel (Ref 11) does. Some experimental results comparing carbon and alloy steel 6 m (20 ft) specimens after 5 years of exposure to splash, seawater, and mud zones are presented in Table 8. At the 0.45- and 0.75-m (1.5- and 2.5-ft) levels, the loss in thickness for the carbon steel was three to six times higher than that for the low-alloy steels. A graphical comparison of the 5-year results for a plain carbon and an Fee-0.54Ni-0.5Cu-0.12P alloy steel is shown in Fig. 20. Other experiences with low-alloy steels, especially in exposures in which the wave action is vigorous, also indicate that they have considerable merit for splash-zone service (Ref 11).

Submerged Zone. Low-alloy steels exhibit corrosion rates in the range of about 65 to 125 μm/yr (2.5 to 5 mils/yr) when fully immersed in seawater (Ref 11). As such, low-alloy steels offer no particular advantage over carbon steel in applications involving submergence in the ocean. Examples of corrosion rates for plain carbon steel and low-alloy steels after 8 and 16 years in the Pacific Ocean near the Panama Canal are given in Table 9. The inferior corrosion performance

of alloy steels in seawater is due to the fact that the special conditions in the atmosphere, which lead to the formation of the protective rust films, do not operate in the submerged condition.

Low-alloy steels also develop deeper pits in seawater than carbon steels do. This is demonstrated by the 8-year results from the Panama-Pacific exposures given in Table 10. The total penetration calculated from the weight loss (column 1) is compared with the average of the 20 deepest pits (column 2) and with the deepest pit (column 3). Assuming that the average of the 20 deepest pits is a more significant criterion than the deepest pit, this average pitting value can be compared with the weight loss penetration. The ratio of these two values for low-carbon steel at the 4.25-m (14-ft) depth is 2.6. The range for the alloy steel, some of which have higher weight loss penetrations to start with, is 1.6 to 3.7. At the mean tide level, the factor is lower, as is the pit depth for many of the steels involved in the comparison.

(a) 1, calculated from weight loss; 2, average of 20 deepest pits; 3, deepest pit.

(b) Ratio of average of 20 deepest pits to weight loss penetration. The higher the number, the greater is the pitting tendency in relation to the corrosion rate.

(c) Completely perforated.

For a given strength, the designer would be tempted to specify a thinner wall for a low-alloy steel in a seawater application (Ref 11). Because the corrosion rate is higher, corrosion failure would be more rapid. Thus, from a design standpoint, the corrosion allowance for a low-alloy steel should be greater than that for a low-carbon steel. However, low-alloy steels have good strength characteristics, and if protective coatings were applied, these steels could be used to advantage. Cathodic protection must be applied with care for high-strength low-alloy steels because some tend to be more susceptible to hydrogen damage than carbon steel. Information on the cathodic protection of marine structures can be found in the article "Marine Corrosion" in this Volume and in Ref 21.

Burial Zone. Bottom conditions vary, but local attack is sometimes observed just above the mud zone or in the bottom mud itself (Ref 11). As in the soil, bottom mud is often aggressive to steel because of the presence of sulfate-reducing bacteria. For steel structures standing in the mud, the anodic and cathodic sites may be a considerable distance apart, and their locations may shift somewhat with time.

Galvanic corrosion in seawater is a matter of concern because the corroding medium has a fairly high conductivity. Service conditions can differ considerably because of solution composition, solute concentration, agitation, aeration, temperature, and purity of the metals, as well as corrosion product formation and biological growth, each of which can result in a different galvanic series.

In a structural joint, the ratio of the areas of two dissimilar metals has enormous influence on the corrosion rate of one of the members of the joint--the one that is more anodic in the galvanic series. The greater the ratio of the cathode to the anode, the greater the corrosion rate. A surprisingly small difference in solution potential can often result in a significant difference in corrosion rate. For example, tests were conducted in which carbon steel was coupled to itself and to ASTM A242 (type 1) high-strength low-alloy steel and type 410 stainless steel and in which ASTM A242 (type 1) high-strength low-alloy steel was coupled to itself and to type 410 stainless steel. The results of these tests after 6 months of immersion in seawater are given in Table 11. Coupling carbon steel to stainless steel in an anode-to-cathode ratio of 1:8 can result in an approximately eightfold greater corrosion loss for the carbon steel. Also important to design engineers is the significant increase in corrosion that occurs when carbon steel is coupled to high-strength low-alloy steel, despite the fact that their solution (galvanic) potentials are practically the same. An example of a carbon steel/alloy steel galvanic couple is shown in Fig. 21.

Table 11 Corrosion of members of couples in seawater after 6 months

Ship and Submarine Applications. The selection of alloy steels for ship and submarine hulls, structures, and deck railings is based on toughness, ductility, and weldability rather than corrosion performance. Protection from corrosion is generally supplied by coatings and cathodic protection, as discussed in the article "Marine Corrosion" in this Volume. Compositions of high-strength alloy steels used for ship and submarinestructural applications are given in Table 12. Of the compositions given, the corrosion resistance of ASTM A710 in both flowing and still seawater has been characterized (Ref 22). These results are given in Fig. 22(a) and 22(b) where ASTM A710 is compared with several other high-strength

steels as well as with carbon steel. The conclusion drawn from this study is that ASTM A710 exhibits corrosion resistance comparable to other high-strength and carbon steels.

Chemical-Processing Industry

Many factors influence corrosion in the chemical-processing industry. Temperature, pressure, and velocity of the process stream all affect corrosion, and minute amounts of contaminants can result in large increases in corrosion rates. The use of alloy steels in such environments is generally limited to static or low-velocity applications, such as storage tanks or low-velocity piping. Applications for bare steel are particularly limited. More often, some form of protection is used both to

protect the steel equipment and to maintain the purity of the product. Organic linings are commonly used for this purpose; the use of cathodic and anodic protection is also becoming more common. Some applications for alloy steels in the chemical-processing industry are listed below.

Sulfuric Acid. Steel tanks are used to store sulfuric acid at ambient temperatures at all concentrations to 101%. Corrosion can rapidly become catastrophic at these concentrations and at temperatures above 25 °C (75 °F). When product purity is of concern, anodic protection can be used to limit iron contamination over long storage periods (see the article "Anodic Protection" in this Volume). The addition of 0.1 to 0.5% Cu to steels used for sulfuric acid storage has been shown to reduce corrosion rates in acid concentrations to about 55%, but this beneficial effect has not been observed at concentrations greater than 60% (Ref 23).

Organic Acids. Alloy steel can be used for ambient-temperature storage of some high molecular weight organic acids, but steel is attacked rapidly by formic, acetic, and propionic acids.

Alkalies. Bare steel storage tanks are used for sodium hydroxide at concentrations to 50% and at temperatures to about 65 °C (150 °F). Where iron contamination of the product is of concern, spray-applied neoprene latex or phenolic-epoxy linings are used.

Anhydrous Ammonia. Low-alloy steel storage tanks have been used for many years for ammonia storage. Stress-corrosion cracking has been the primary corrosion problem in vessels used for ammonia storage. It has been shown in several investigations that high stresses and oxygen (air) contamination are the primary causes of such cracking and that the addition of 0.1 to 0.2% H_2O inhibits SCC in alloy steel storage vessels (Ref 24 24, 25, 26, 27, 28, 29).

Chlorine. Steel is used to handle dry chlorine, and corrosion rates are generally low. Ignition can be a problem, however, and the recommended maximum service temperature in this application is 150 °C (300 °F) (Ref 30). Steel is also used to handle refrigerated liquid chlorine, but care must be taken at potential leak sites. Chlorine from small leaks can be trapped beneath ice formed on the equipment; this will form corrosive wet chlorine gas. More information on the materials used in the chemical-processing industry is available in the article "Corrosion in the Chemical Processing Industry" in this Volume.

Corrosion of Stainless Steels

Ralph M. Davison, Avesta Stainless Inc.; Terry DeBold, Carpenter Technology Corporation; Mark J. Johnson, Allegheny Ludlum Steel Corporation

Introduction

STAINLESS STEELS are iron-base alloys containing at least 10.5% Cr. With increasing chromium content and the presence or absence of some ten to fifteen other elements, stainless steels can provide an extraordinary range of corrosion resistance. Various grades have been used for many years in environments as mild as open air in architectural applications and as severe as the chemically active product streams in the chemical-processing industries. Stainless steels are

categorized in five distinct families according to their crystal structure and strengthening precipitates. Each family exhibits its own general characteristics in terms of mechanical properties and corrosion resistance. Within each family, there is a range of grades that varies in composition, corrosion resistance, and cost.

Stainless steels are susceptible to several forms of localized corrosive attack. The avoidance of such localized corrosion is the focus of most of the effort involved in selecting stainless steels. Furthermore, the corrosion performance of stainless steels can be strongly affected by practices of design, fabrication, surface conditioning, and maintenance.

The selection of a grade of stainless steel for a particular application involves the consideration of many factors, but always begins with corrosion resistance. It is first necessary to characterize the probable service environment. It is not enough to consider only the design conditions. It is also necessary to consider the reasonably anticipated excursions or upsets in service conditions. The suitability of various grades can be estimated from laboratory tests or from documentation of field experience in comparable environments. Once the grades with adequate corrosion resistance have been identified, it is then appropriate to consider mechanical properties, ease of fabrication, the types and degree of risk present in the application, the availability of the necessary product forms, and cost.

Identification Systems for Stainless Steels

Grades of stainless steel are most commonly designated in one or more of the following ways: the American Iron and Steel Institute (AISI) numbering system, the Unified Numbering System (UNS), and proprietary designations. Other designations have been established by the national standards organizations of various major industrialized countries. These systems are generally similar to those of the United States, but there can be significant differences that must be taken into account when designing under these codes or using materials from these areas.

The AISI System. The most common designations are those of AISI, which recognizes grades as standard compositions on the basis of meeting criteria of total production and number of sources. Most of these grades have a three-digit designation in the 200, 300, or 400 series, and some have a one- or two-letter suffix that indicates a particular modification of the composition. There is a general association of the various microstructural families of grades with particular parts of the numbering series, but there are several significant exceptions to the system. Table 1 lists the AISI grades and their chemical analyses. Some proprietary designations are similar in structure to the AISI system, but are not standard grades. Also, commercial offerings of the standard grades may use the AISI number with some additional prefix or suffix to indicate the producer or a particular modification of the grade for a certain type of application.

(a) Maximum unless otherwise indicated; all compositions include balance of iron.

The UNS system was introduced in the 1970s to provide a systematic and encyclopedic listing of metal alloys, including the stainless steels. Although not perfect, the UNS numbering system has been successful in maintaining a degree of order during a period when many new grades were introduced. In Table 1, the AISI grades also have UNS designations. Most stainless steels--those having more than 50% Fe--have a UNS number that consists of the letter S followed by five digits. For the AISI grades, the first three digits usually correspond to an AISI number. The basic AISI grades have 00 as the last two digits, while the modifications of the most basic grades show some other two digits. There are some significant exceptions in the UNS system, just as there are in the AISI system.

These designations are not normally a sufficient basis for specifying a stainless steel. To purchase a particular grade and product form, it is advisable to consult aa comprehensive specification. American Society for Testing and Materials (ASTM) specifications, for example, are the most commonly used. These specifications usually define compositional limits; minimum mechanical properties; production, processing, and testing requirements; and in some cases particular corrosion performance requirements. Other standard specifications, such as those of the American Society of Mechanical Engineers (ASME), the National Association of Corrosion Engineers (NACE), the Technical Association of the Pulp and Paper Industry (TAPPI), or those of individual companies, may apply to certain types of equipment.

Proprietary Designations. In addition to the standard grades, there are well over 100 special grades that represent modifications, extensions, or refinements of the basic grades. In the early 1970s, the introduction of new stainless steel refining practices, most commonly argon-oxygen decarburization (AOD), greatly facilitated the production of stainless steels. In addition to permitting the use of lower-cost forms of alloy element additions, AOD also allows precise control of individual elements. This process also makes possible the economical removal of interstitial and tramp elements that are detrimental to corrosion resistance, mechanical properties, and processing.

Because of these capabilities, stainless steel producers have greatly extended the range of stainless steel grades. Very few of these grades have been accepted as AISI standards, but all were assigned UNS numbers when they were introduced into ASTM standards. Table 2 provides a representative sampling of these grades across the range of alloy content and corrosion resistance. Some of the grades are identified by common trade names or trademarks in order to facilitate understanding and to enhance the usefulness of this discussion. This listing is not intended to be exhaustive, and the omission of a grade does not indicate its disqualification from consideration.

(b) Nominal composition

Families of Stainless Steels

There are five major families of stainless steels, as defined by crystallographic structure. Each family is distinct with regard to its typical mechanical properties. Furthermore, each family tends to share a common nature in terms of resistance/susceptibility to particular forms of corrosion. However, within each family, it is possible to have a substantial range of composition. Therefore, each family is applicable to a broad range of corrosion environments.

Ferritic Stainless Steels. The simplest stainless steels contain only iron and chromium. Chromium is a ferrite stabilizer; therefore, the stability of the ferritic structure increases with chromium content. Ferrite has a body-centered cubic crystal structure, and it is characterized as magnetic and relatively high in yield strength but low in ductility and work hardenability. Ferrite shows an extremely low solubility for such interstitial elements as carbon and nitrogen. The ferritic grades exhibit a transition from ductile to brittle behavior over a rather narrow temperature range. At higher carbon and nitrogen contents, especially at higher chromium levels, this ductile-to-brittle transition can occur above ambient temperature. This possibility severely limited the use of ferritic grades before the use of AOD. The ferritic family was then limited to AISI type 446 for oxidation-resistant applications and to AISI types 430 and 434 for such corrosion applications as automotive trim. The fact that these grades were readily sensitized to intergranular corrosion as a result of welding or thermal exposure further limited their use.

With AOD, it was possible to reduce the levels of carbon and nitrogen significantly. The activity of carbon and nitrogen could further be reduced by the use of stabilizers, which are highly reactive elements, such as titanium and niobium, that precipitate the remaining interstitials. This newer generation of ferritic stainless steels includes AISI type 444 and the more highly alloyed ferritic grades shown in Table 2. With control of interstitial elements, it is possible to produce grades with unusually high chromium and molybdenum contents. At these low effective carbon levels, these grades are tougher and more weldable than the first generation of ferritic stainless steels. Nevertheless, their limited toughness generally restricts use of these grades to sheet or lighter-gage tubulars.

Ferritic stainless steels are highly resistant and are in some cases immune to chloride stress-corrosion cracking (SCC). These grades are frequently considered for thermal transfer applications.

The same properties and advantages are also responsible for the extraordinary development of the lowest-alloyed grade of the ferritics, AISI type 409. This grade, developed for automotive muffler and catalytic converter service, has gained in technical sophistication. It is increasingly used in automotive exhaust systems and in other moderately severe atmospheric-exposure applications.

Austenitic Stainless Steels. The detrimental effects of carbon and nitrogen in ferrite can be overcome by changing the crystal structure to austenite, a face-centered cubic crystal structure. This change is accomplished by adding austenite stabilizers--most commonly nickel but also manganese and nitrogen. Austenite is characterized as nonmagnetic, and it is usually relatively low in yield strength with high ductility, rapid work-hardening rates, and excellent toughness. These

desirable mechanical properties, combined with ease of fabrication, have made the austenitic grades, especially AISI type 304, the most common of the stainless grades. Processing difficulties tend to limit increases in chromium content; therefore, improved corrosion resistance is usually obtained by adding molybdenum. The use of nitrogen as an intentional alloy addition stabilizes the austenite phase, particularly with regard to the precipitation of intermetallic compounds. With the nitrogen addition, it is possible to produce austenitic grades with up to 6% Mo for improved corrosion resistance in chloride environments. Other special grades include the high-chromium grades for high-temperature applications and the high-nickel grades for inorganic acid environments.

The austenitic stainless steels can be sensitized to intergranular corrosion by welding or by longer-term thermal exposure. These thermal exposures lead to the precipitation of chromium carbides in grain boundaries and to the depletion of chromium adjacent to these carbides. Sensitization can be greatly delayed or prevented by the use of lower-carbon L-grades (<0.03% C) or stabilized grades, such as AISI types 321 and 347, which include additions of carbide-stabilizing elements (titanium and niobium, respectively).

The common austenitic grades, AISI types 304 and 316, are especially susceptible to chloride SCC. All austenitic stainless steels exhibit some degree of susceptibility, but several of the high-nickel high-molybdenum grades are satisfactory with respect to stress-corrosion attack in most engineering applications.

Martensitic Stainless Steels. With lower chromium levels and relatively high carbon levels, it is possible to obtain austenite at elevated temperatures and then, with accelerated cooling, to transform this austenite to martensite, which has a body-centered tetragonal structure. Just as with plain carbon and low-alloy steels, this strong, brittle martensite can be tempered to favorable combinations of high strength and adequate toughness. Because of the ferrite-stabilizing character of chromium, the total chromium content, and thus the corrosion resistance, of the martensitic grades is somewhat limited. In recent years, nitrogen, nickel, and molybdenum additions at somewhat lower carbon levels have produced martensitic stainless steels of improved toughness and corrosion resistance.

The duplex stainless steels can be thought of as chromium-molybdenum ferritic stainless steels to which sufficient austenite stabilizers have been added to produce steels in which a balance of ferrite and austenite is present at room temperature. Such grades can have the high chromium and molybdenum responsible for the excellent corrosion resistance of ferritic stainless steels as well as the favorable mechanical properties of austenitic stainless steels. In fact, the duplex grades with about equal amounts of ferrite and austenite have excellent toughness and their strength exceeds either phase present singly.

First-generation duplex grades, such as AISI type 329, achieved this phase balance primarily by nickel additions. These early duplex grades have superior properties in the annealed condition, but segregation of chromium and molybdenum between the two phases as re-formed after welding often significantly reduced corrosion resistance. The addition of nitrogen to the second generation of duplex grades restores the phase balance more rapidly and minimizes chromium and molybdenum segregation without annealing. The newer duplex grades combine high strength, good toughness, high corrosion resistance, good resistance to chloride SCC, and good production economy in the heavier product forms.

The precipitation-hardening stainless steels are chromium-nickel grades that can be hardened by an aging treatment at a moderately elevated temperature. These grades may have austenitic, semiaustenitic, or martensitic crystal structures. Semiaustenitic structures are transformed from a readily formable austenite to martensite by a high-temperature austenite-conditioning treatment. Some grades use cold work to facilitate transformation. The strengthening effect is achieved by adding such elements as copper and aluminum, which form intermetallic precipitates during aging. In the solution-annealed condition, these grades have properties similar to those of the austenitic grades and are therefore readily formed. Hardening is achieved after fabrication within a relatively short time at 480 to 620 °C (900 to 1150 °F). The precipitation-hardened grades must not be subjected to further exposure to elevated temperature by welding or environment, because the strengthening can be lost by overaging of the precipitates. The precipitation-hardened grades have corrosion resistance generally comparable to that of the chromium-nickel grades.

Mechanism of Corrosion Resistance

The mechanism of corrosion protection for stainless steels differs from that for carbon steels, alloy steels, and most other metals. In these other cases, the formation of a barrier of true oxide separates the metal from the surrounding atmosphere. The degree of protection afforded by such an oxide is a function of the thickness of the oxide layer, its continuity, its coherence and adhesion to the metal, and the diffusivities of oxygen and metal in the oxide. In high-temperature oxidation, stainless steels use a generally similar model for corrosion protection. However, at low temperatures, stainless

steels do not form a layer of true oxide. Instead, a passive film is formed. One mechanism that has been suggested is the formation of a film of hydrated oxide, but there is not total agreement on the nature of the oxide complex on the metal surface. However, the oxide film should be continuous, nonporous, insoluble, and self-hearing if broken in the presence of oxygen.

Passivity exists under certain conditions for particular environments. The range of conditions over which passivity can be maintained depends on the precise environment and on the family and composition of the stainless steel. When conditions are favorable for maintaining passivity, stainless steels exhibit extremely low corrosion rates. If passivity is destroyed under conditions that do not permit restoration of the passive film, then stainless steel will corrode much like a carbon or low-alloy steel.

The presence of oxygen is essential to the corrosion resistance of a stainless steel. The corrosion resistance of stainless steel is at its maximum when the steel is boldly exposed and the surface is maintained free of deposits by a flowing bulk environment. Covering a portion of the surface--for example, by biofouling, painting, or installing a gasket--produces an oxygen-depleted region under the covered region. The oxygen-depleted region is anodic relative to the well-aerated boldly exposed surface, and a higher level of alloy content in the stainless steel is required to prevent corrosion.

With appropriate grade selection, stainless steel will perform for very long times with minimal corrosion, but an inadequate grade can corrode and perforate more rapidly than a plain carbon steel will fail by uniform corrosion. Selection of the appropriate grade of stainless steel is then a balancing of the desire to minimize cost and the risk of corrosion damage by excursions of environmental conditions during operation or downtime.

Confusion exists regarding the meaning of the term passivation. It is not necessary to chemically treat a stainless steel to obtain the passive film; the film forms spontaneously in the presence of oxygen. Most frequently, the function of passivation is to remove free iron, oxides, and other surface contamination. For example, in the steel mill, the stainless steel may be pickled in an acid solution, often a mixture of nitric and hydrofluoric acids (HNO_3-HF), to remove oxides formed in heat treatment. Once the surface is cleaned and the bulk composition of the stainless steel is exposed to air, the passive film forms immediately.

Effects of Composition

Chromium is the one element essential in forming the passive film. Other elements can influence the effectiveness of chromium in forming or maintaining the film, but no other element can, by itself, create the properties of stainless steel. The film is first observed at about 10.5% Cr, but it is rather weak at this composition and affords only mild atmospheric protection. Increasing the chromium content to 17 to 20%, as typical of the austenitic stainless steels, or to 26 to 29%, as possible in the newer ferritic stainless steels, greatly increases the stability of the passive film. However, higher chromium may adversely affect mechanical properties, fabricability, weldability, or suitability for applications involving certain thermal exposures. Therefore, it is often more efficient to improve corrosion resistance by altering other elements, with or without some increase in chromium.

Nickel, in sufficient quantities, will stabilize the austenitic structure; this greatly enhances mechanical properties and fabrication characteristics. Nickel is effective in promoting repassivation, especially in reducing environments. Nickel is particularly useful in resisting corrosion in mineral acids. Increasing nickel content to about 8 to 10% decreases resistance to SCC, but further increases begin to restore SCC resistance. Resistance to SCC in most service environments is achieved at about 30% Ni. In the water ferritic grades, in which the nickel addition is less than that required to destabilize the ferritic phase, there are still substantial effects. In this range, nickel increases yield strength, toughness, and resistance to reducing acids, but it makes the ferritic grades susceptible to SCC in concentrated magnesium chloride ($MgCl_2$) solutions.

Manganese in moderate quantities and in association with nickel additions will perform many of the functions attributed to nickel. However, total replacement of nickel by manganese is not practical. Very high manganese steels have some unusual and useful mechanical properties, such as resistance to galling. Manganese interacts with sulfur in stainless steels to form manganese sulfides. The morphology and composition of these sulfides can have substantial effects on corrosion resistance, especially pitting resistance.

Molybdenum in combination with chromium is very effective in terms of stabilizing the passive film in the presence of chlorides. Molybdenum is especially effective in increasing resistance to the initiation of pitting and crevice corrosion.

Carbon is useful to the extent that it permits hardenability by heat treatment, which is the basis of the martensitic grades, and that is provides strength in the high-temperature applications of stainless steels. In all other applications, carbon is detrimental to corrosion resistance through its reaction with chromium. In the ferritic grades, carbon is also extremely detrimental to toughness.

Nitrogen is beneficial to austenitic stainless steels in that it enhances pitting resistance, retards the formation of the chromium-molybdenum σ phase, and strengthens the steel. Nitrogen is essential in the newer duplex grades for increasing the austenite content, diminishing chromium and molybdenum segregation, and for raising the corrosion resistance of the austenitic phase. Nitrogen is highly detrimental to the mechanical properties of the ferritic grades and must be treated as comparable to carbon when a stabilizing element is added to the steel.

Effects of Processing, Design, Fabrication, and External Treatments

Corrosion failures in stainless steels can often be prevented by suitable changes in design or process parameters and by use of the proper fabrication technique or treatment. The solution to a corrosion problem is not always to upgrade the stainless steel. It is of course very important to establish the types of corrosion that may occur in a given service environment, and if failure does occur, it is important to establish the type of corrosion that caused the failure in order that the proper preventive measures can be implemented.

Heat Treatment

Improper heat treatment can produce deleterious changes in the microstructure of stainless steels. The most troublesome problems are carbide precipitation (sensitization) and precipitation of various intermetallic phases, such as σ, χ, and laves(η).

Sensitization, or carbide precipitation at grain boundaries, can occur when austenitic stainless steels are heated for a period of time in the range of about 425 to 870 °C (800 to 1600 °F). Time at temperature will determine the amount of carbide precipitation. When the chromium carbides precipitate in grain boundaries, the area immediately adjacent is depleted of chromium. When the precipitation is relatively continuous, the depletion renders the stainless steel susceptible to intergranular corrosion, which is the dissolution of the low-chromium layer or envelope surrounding each grain. Sensitization also lowers resistance to other forms of corrosion, such as pitting, crevice corrosion, and SCC.

Time-temperature-sensitization curves are available that provide guidance for avoiding sensitization and illustrate the effect of carbon content on this phenomenon (Fig. 1). The curves shown in Fig. 1 indicate that a type 304 stainless steel with 0.062% C would have to cool below 595 °C (1100 °F) within about 5 min to avoid sensitization, but a type 304L with 0.030% C could take about 20 h to cool below 480 °C (900 °F) without becoming sensitized. These curves are general guidelines and should be verified before they are applied to various types of stainless steels.

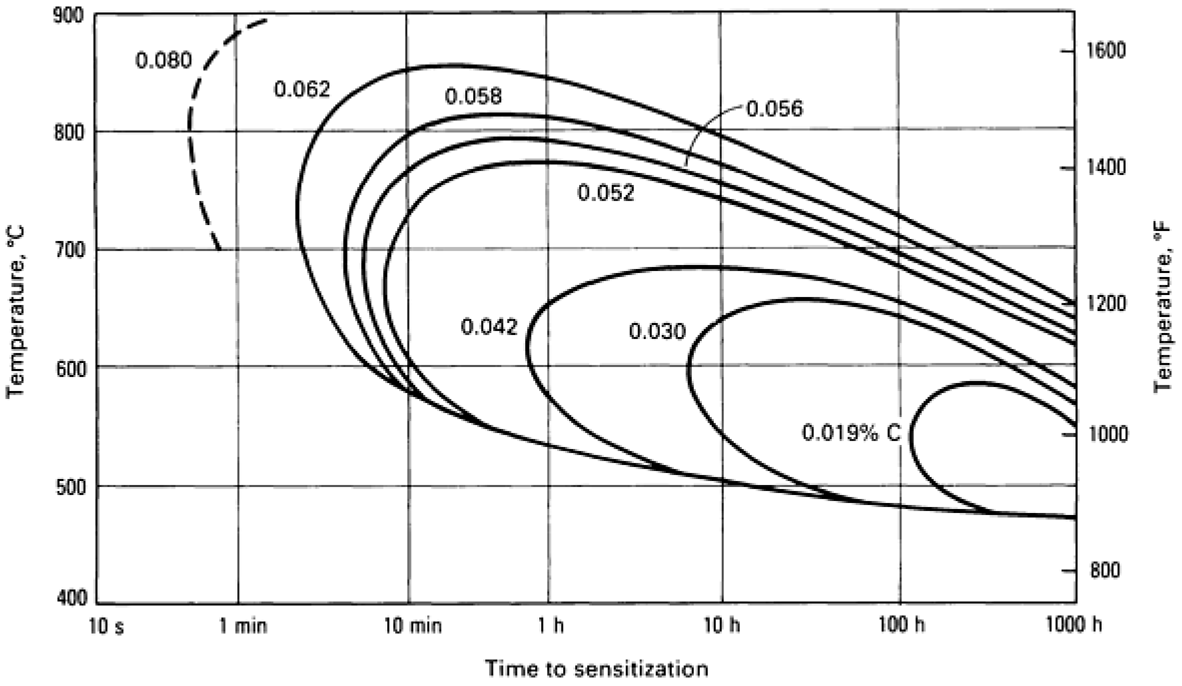

Fig. 1 Time-temperature-sensitization curves for type 304 stainless steel in a mixture of $CuSO_4$ and H_2SO_4 containing free copper. Curves show the times required for carbide precipitation in steels with various carbon contents. Carbides precipitate in the areas to the right of the various carbon content curves.

Another method of avoiding sensitization is to use stabilized steels. Such stainless steels contain titanium and/or niobium. These elements have an affinity for carbon and form carbides readily; this allow the chromium to remain in solution even for extremely long exposures to temperatures in the sensitizing range. Type 304L can avoid sensitization during the relatively brief exposure of welding, but it will be sensitized by long exposures.

Annealing is the only way to correct a sensitized stainless steel. Because different stainless steels require different temperatures, times, and quenching procedures, the user should contact the material supplier for such information. A number of tests can detect sensitization resulting from carbide precipitation in austenitic and ferritic stainless steels. The most widely used tests are described in ASTM standards A 262 and A 763 (Ref 1, 2). More detailed information on sensitization of stainless steels can be found in the article "Metallurgically Influenced Corrosion" in this Volume.

Precipitation of Intermetallic Phases. Sigma-phase precipitation and precipitation of other intermetallic phases also increase susceptibility to corrosion. Sigma phase is a chromium-molybdenum-rich phase that can render stainless steels susceptible to intergranular corrosion, pitting, and crevice corrosion. It generally occurs in higher-alloyed stainless steels (high-chromium high-molybdenum stainless steels). Sigma phase can occur at a temperature range between 540 and 900 °C (1000 and 1650 °F). Like sensitization, it can be corrected by solution annealing. Precipitation of intermetallic phase in stainless steels is also covered in detail in the article "Metallurgically Influenced Corrosion."

Cleaning Procedures. Any heat treatment of stainless steel should be preceded and followed by cleaning. Steel should be cleaned before heat treating to remove any foreign material that may be incorporated into the surface during the high-temperature exposure. Carbonaceous materials on the surface could result in an increase in the carbon content on the surface, causing carbide precipitation. Salts could cause excessive intergranular oxidation. Therefore, the stainless steel must be clean before it is heat treated.

After heat treatment, unless an inert atmosphere was used during the process, the stainless steel surface will be covered with an oxide film. Such films are not very corrosion resistant and must be removed to allow the stainless steel to form its passive film and provide the corrosion resistance for which it was designed. There are numerous cleaning methods that may be used before and after heat treating. An excellent guide is ASTM A 380 (Ref 3).

Welding

The main problems encountered in welding stainless are the same as those seen in heat treatment. The heat of welding (portions of the base metal adjacent to the weld may be heated to 430 to 870 °C, or 800 to 1600 °F) can cause sensitization and formation of intermetallic phases, thus increasing the susceptibility of stainless steel weldments to intergranular corrosion, pitting, crevice corrosion, and SCC. These phenomena often occur in the heat-affected zone of the weld. Sensitization and intermetallic phase precipitation can be corrected by solution annealing after welding. Alternatively, low carbon or stabilized grades may be used.

Another problem in high heat input welds is grain growth, particularly in ferritic stainless steels. Excessive grain growth can increase susceptibility to intergranular attack and reduce toughness. Thus, when welding most stainless steels, it is wise to limit weld heat input as much as possible. More detailed information on welding of stainless steels and the problems encountered can be found in the article "Corrosion of Weldments" in this Volume.

Cleaning Procedure. Before any welding begins, all materials, chill bars, clamps, hold down bars, work tables, electrodes, and wire, as well as the stainless steel, must be cleaned of all foreign matter. Moisture can cause porosity in the weld that would reduce corrosion resistance. Organic materials, such as grease, paint, and oils, may result in carbide precipitation. Copper contamination may cause cracking. Other shop dirt can cause weld porosity and poor welds in general. Information on cleaning is available in Ref 3.

Weld design and procedure are very important in producing a sound corrosion-resistant weld. Good fit and minimal out-of-position welding will minimize crevices and slag entrapment. The design should not place welds in critical flow areas. When attaching such devices as low-alloy steel support and ladders on the out side of a stainless steel tank, a stainless steel intermediate pad should be used. In general, stainless steels with higher alloy content than type 316 should be welded with weld metal richer in chromium, nickel, and molybdenum than the base metal. Every attempt should be made to minimize weld spatter.

After welding, all weld spatter, slag, and oxides should be removed by brushing, blasting, grinding, or chipping. All finishing equipment must be free of iron contamination. It is advisable to follow the mechanical cleaning and finishing with a chemical cleaning. Such a cleaning will remove any foreign particles that may have been embedded in the surface during mechanical cleaning without attacking the weldment. Procedures for such cleaning or descaling are given in Ref 3, and more information on welding of stainless steels is available in the article "Welding of Stainless Steels" in *Welding, Brazing, and Soldering,* Volume 6 of *ASM Handbook.*

Surface Condition

To ensure satisfactory service life, the surface condition of stainless steels must be given careful attention. Smooth surfaces, as well as freedom from surface imperfections, blemishes, and traces of scale and other foreign material, reduce the probability of corrosion. In general, a smooth, highly polished, reflective surface has greater resistance to corrosion. Rough surfaces are more likely to catch dust, salts, and moisture, which tend to initiate localized corrosive attack.

Oil and grease can be removed by using hydrocarbon solvents or alkaline cleaners, but these cleaners must be removed before heat treatment. Hydrochloric acid (HCl) formed from residual amounts of trichloroethylene, which is used for degreasing, has caused severe attack of stainless steels. Surface contamination may be caused by machining, shearing, and drawing operations. Small particles of metal from tools become embedded in the steel surface and, unless removed, may cause localized galvanic corrosion. These particles are best removed by the passivation treatments described below. Additional information on cleaning and descaling of stainless steel is available in Ref 3 and in the article "Surface Engineering of Stainless Steels" in *Surface Engineering,* Volume 5 of *ASM Handbook.*

Shotblasting or sandblasting should be avoided unless iron-free silica is used; metal shot, in particular, will contaminate the stainless steel surface. If shotblasting or shotpeening with metal grit is unavoidable, the parts must be cleaned after blasting or peening by immersing them in an HNO_3 solution, as noted above.

Passivation Techniques

During handling and processing operations, such as machining, forming, tumbling, and lapping, particles of iron, tool steel, or shop dirt may be embedded in or smeared on the surfaces of stainless steel components. These contaminants may reduce the effectiveness of the natural oxide (passive) film that forms on stainless steels exposed to oxygen at low temperatures (the formation of these passive films is discussed in the section "Mechanism of Corrosion Resistance" in this article). If allowed to remain, these particles may corrode and produce rustlike spots on the stainless steel. To prevent this

condition, semifinished or finished parts are given a passivation treatment. This treatment consists of cleaning and then immersing stainless steel parts in a solution of HNO_3 or of HNO_3 plus oxidizing salts. The treatment dissolves the embedded or smeared iron, restores the original corrosion-resistant surface, and maximizes the inherent corrosion resistance of the stainless steel.

Cleaning. Each workpiece to be passivated must be cleaned thoroughly to remove grease, coolant, or other shop debris (Ref 4). A worker will sometimes eliminate the cleaning step based on the reasoning that the cleaning and passivation of a grease-laden part will occur simultaneously by immersing it in an HNO_3 bath. This assumption is mistaken. The grease will react with the HNO_3 to form gas bubbles, which collect on the surface of the workpiece and interfere with passivation. Also, contamination of the passivating solution (particularly with high levels of chlorides) can cause flash attack, which results in a gray or black appearance and deterioration of the surface.

To avoid such problems, each part should be wiped clean of any large machining chips or other debris. More tenacious deposits should be removed by brushing with a stainless steel wire brush, grinding, polishing with an iron-free abrasive, or sandblasting. Tools and materials used for these processes should be clean and used only for stainless steels. Machining, forming, or grinding oils must be removed in order for passivation to be effective. Cleaning should begin with solvent cleaning, which may be followed by alkaline soak cleaning and thorough water rinsing. Optimum results are obtained in passivation when the parts to be treated are as clean as they would have to be for plating. When large parts or bulky vessels are to be cleaned, it may be necessary to apply cleaning liquids by means of pressure spray; exterior surfaces may be cleaned by immersion or swabbing.

Passivating. After cleaning, the workpiece can be immersed in the passivating acid bath. As shown in Table 3, the composition of the acid bath depends on the grade of stainless steel. The 300-series stainless steels can be passivated in 20 vol% HNO_3. A sodium dichromate ($Na_2Cr_2O_7·2H_2O$) addition or an increased concentration of HNO_3 is used for less corrosion-resistant stainless steels to reduce the potential for flash attack.

Source: Ref 4

The procedure suggested for passivating free-machining stainless steels is somewhat different from that used for nonfree-machining grades (Ref 4). This is because sulfides of sulfur-bearing free-machining grades, which are totally or partially removed during passivation, create microscopic discontinuities in the surface of the machined part. Even normally efficient water rinses can leave residual acid trapped in these discontinuities after passivation. This acid can then attack the surface of the part unless it is neutralized or removed. For this reason, a special passivation process, referred to as the alkaline-acid-alkaline method, is suggested for free-machining grades.

The following steps should be followed when passivating free-machining stainless steels with the alkaline-acid-alkaline technique:

- After degreasing, soak the parts for 30 min in 5 wt% sodium hydroxide (NaOH) at 70 to 80 °C (160 to 180 °F)
- Water rinse
- Immerse the part for 30 min in 20 vol% HNO_3 plus 22 g/L (3 oz/gal) $Na_2Cr_2O_7 \cdot 2H_2O$ at 50 to 60 °C (120 to 140 °F)
- Water rinse
- Immerse for 30 min in 5 wt% NaOH at 70 to 80 °C (160 to 180 °F)
- Water rinse and dry

Testing is often performed to evaluate the passivated surface. For example, 400-series, precipitation-hardening, and free-machining stainless steels are often tested in a cabinet capable of maintaining 100% humidity at 35 °C (95 °F) for 24 h. Material that is properly passivated will be virtually free of rust, although light staining may occur (Ref 1). Austenitic 300-series grades can be evaluated using a technique given in ASTM Standard Method A 380 (Ref 3). This test consists of swabbing the part with a copper sulfate ($CuSO_4 \cdot 5H_2O$)/sulfuric acid (H_2SO_4) solution; wetness should be maintained for 6 min (Ref 4). Free iron, if present, plates out the copper from the solution, and the surface develops a copper cast or color. Precautions for this procedure and details on additional tests for detecting the presence of iron on passivated surfaces are outlined in Ref 3 and 4. Information on passivation treatments for corrosion-resistant steels is also available in Federal Specification QQ-P-35B (Ref 5).

Design

Corrosion can often be avoided by suitable changes in design without changing the type of steel. The factors to be considered include joint design, surface continuity, and concentration of stress. Designs that tend to concentrate corrosive media in a small area should be avoided. For example, tank inlets should be designed such that concentrated solutions are mixed and diluted as they are introduced (Fig. 2). Otherwise, localized pockets of concentrated solutions can cause excessive corrosion.

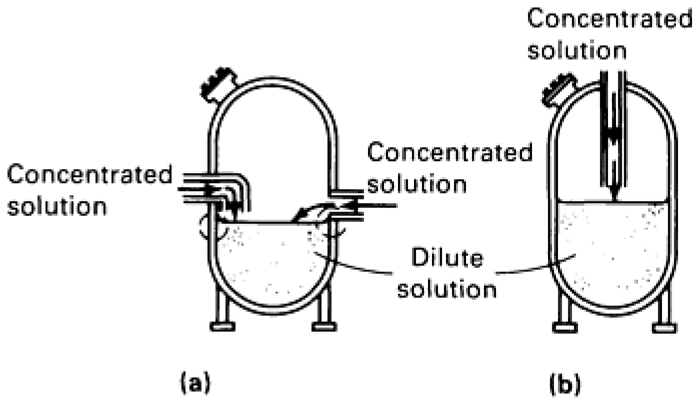

Fig. 2 Poor (a) and good (b) designs for vessels used for mixing concentrated and dilute solutions. Poor design causes concentration and uneven mixing of incoming chemicals along the vessel wall (circled areas). Good design allows concentrated solutions to mix away from vessel walls.

Poor design of heaters can create similar problems, such as those that cause hot spots and thus accelerate corrosion. Heaters should be centrally located (Fig. 3). If a tank is to be heated externally, heaters should be distributed over as large a surface area as possible, and circulation of the corrosive medium should be encouraged, if possible.

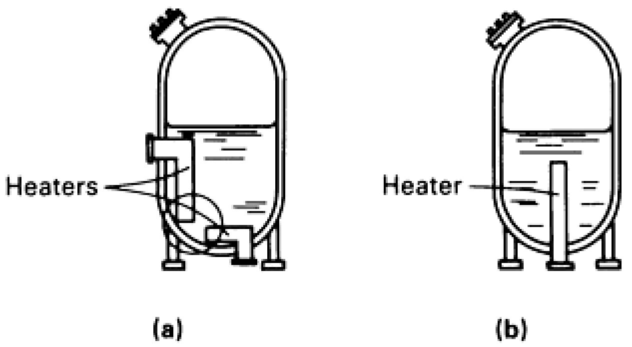

Fig. 3 Poor (a) and good (b) designs for heating of solutions. Poor design creates hot spots (circled area) that may induce boiling under the heater at the bottom of the vessel or may cause deposits to form between heaters and vessel walls. Good design avoids hot spots and pockets in which small volumes of liquid can become trapped between the heater and the vessel wall.

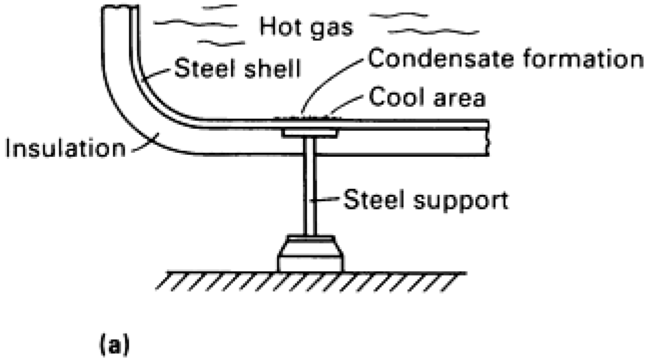
Hot gases that are not corrosive to stainless steel may form corrosive condensates on the cold portions of a poorly insulated unit. Proper design or insulation can prevent such localized cooling (Fig. 4). Conversely, vapors from noncorrosive liquids may cause attack; exhausts and overflows should be designed to prevent hot vapor pockets (Fig. 5). In general, the open ends of inlets, outlets, and tubes in heat exchangers should be flush with tank walls or tubesheets to avoid buildup of harmful corrodents, sludges, and deposits (Fig. 6). This is also true of tank bottom and drainage designs (Fig. 7).



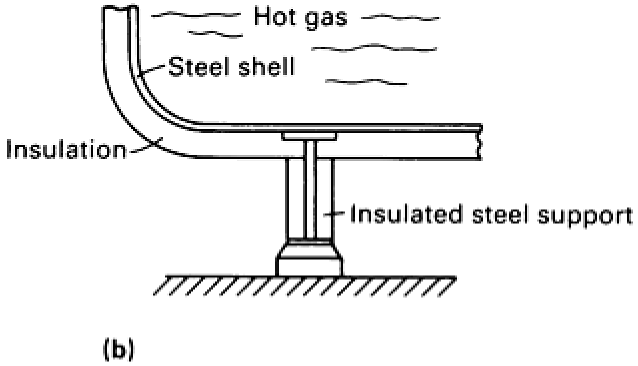


Fig. 4 Design to prevent localized cooling. In the poor design (a), the uninsulated steel support radiates heat, which causes a cool area on the steel shell. In (b), the steel support is insulated to prevent temperature decrease at the base of the shell.

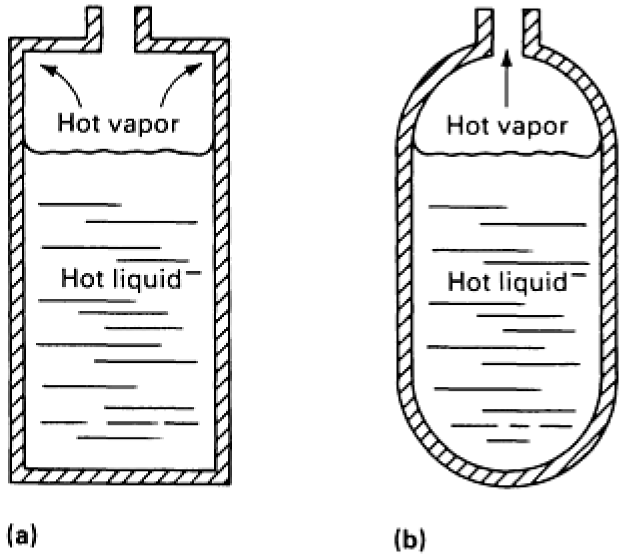

Fig. 5 Poor (a) and good (b) designs for vessels holding both liquid and vapor phases. Sharp corners and protruding outlet end in (a) allow hot gases to become trapped in the vapor space. This is avoided in (b) by using rounded corners and mounting the vessel outlet pipe flush.

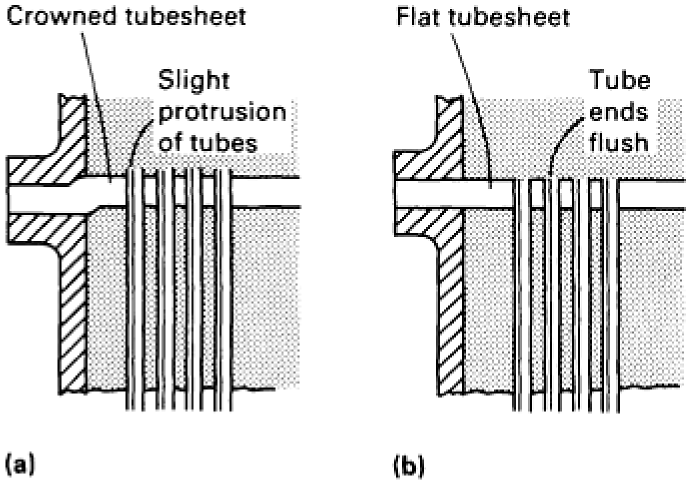

Fig. 6 Poor (a) and good (b) designs for tube/tubesheet assemblies. Crowned tubesheet and protruding tubes in (a) allow buildup of corrosive deposits; in (b), tubesheet is flat and tubes are mounted flush.

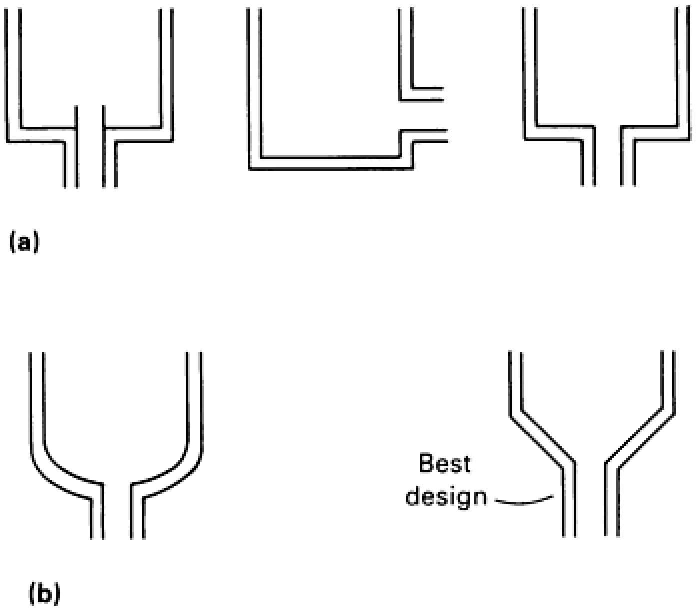

Fig. 7 Examples of poor (a) and good (b) designs for drainage, corners, and other dead spaces in vessels. Sharp corners and protruding outlet pipes in (a) can cause buildup of corrosive deposits and crevice corrosion; these design features are avoided in (b).

Tanks and tank supports should be designed to prevent or minimize corrosion due to spills and overflows (Fig. 8). A tank support structure may not be as corrosion resistant as the tank itself, but it is a very important part of the unit and should not be made vulnerable to spilled corrodents.

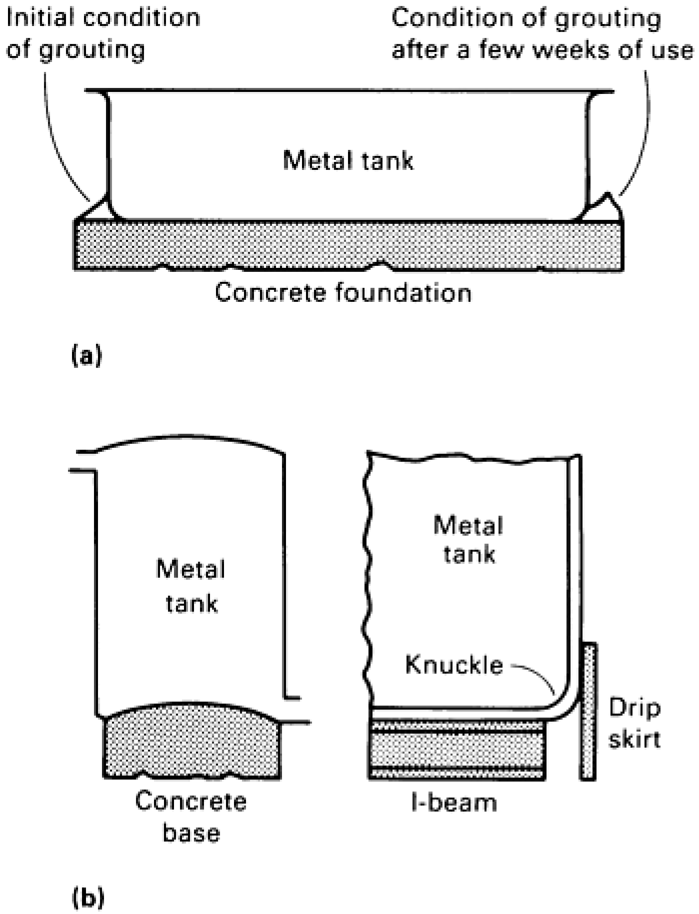

Fig. 8 Design for preventing external corrosion from spills and overflows. (a) Poor design. (b) Good designs

Designs that increase turbulence or result in excessive flow rates should be avoided where erosion-corrosion may be a problem (Fig. 9). Gaskets in flanges should fit properly, intrusions in a flow stream should be avoided, and elbows should be given a generous radius. Finally, crevices should be avoided. Where crevices cannot be avoided, they should be sealed by welding, soldering, or the use of caulking compounds or sealants. Additional information is available in the article "Design Details to Minimize Corrosion" in this Volume.

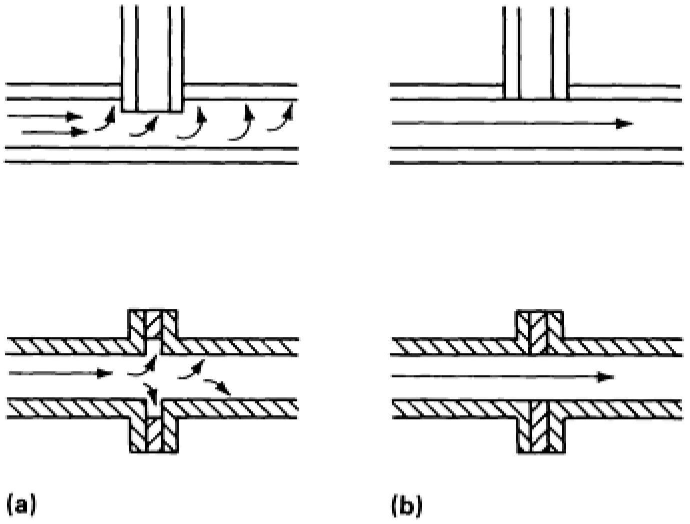

Fig. 9 Designs for preventing excessive turbulence. (a) Poor designs (both top and bottom figures). (b) Good designs (both top and bottom figures)

Forms of Corrosion of Stainless Steels

The various forms of corrosive attack will be briefly discussed in this section. Detailed information on each of these forms of corrosion is available in the Section "Forms of Corrosion" in this Volume.

General (uniform) corrosion of a stainless steel suggests an environment capable of stripping the passive film from the surface and preventing repassivation. Such an occurrence could indicate an error in grade selection. An example is the exposure of a lower-chromium ferritic stainless steel to a moderate concentration of hot sulfuric acid (H_2SO_4).

Galvanic corrosion results when two dissimilar metals are in electrical contact in a corrosive medium. As a highly corrosion-resistant metal, stainless steel can act as a cathode when in contact with a less noble metal, such as steel. The corrosion of steel parts--for example, steel bolts in a stainless steel construction--can be a significant problem. However, the effect can be used in a beneficial way for protecting critical stainless steel components within a larger steel construction. In the case of stainless steel connected to a more noble metal, consideration must be given to the active-passive condition of the stainless steel. If the stainless steel is passive in the environment, galvanic interaction with a more noble metal is unlikely to produce significant corrosion. If the stainless steel is active or only marginally passive, galvanic interaction with a more noble metal will probably produce sustained rapid corrosion of the stainless steel without repassivation. The most important aspect of galvanic interaction for stainless steels is the necessity of selecting fasteners and weldments of adequate corrosion resistance relative to the bulk material, which is likely to have a much larger exposed area.

Pitting is localized attack that can produce penetration of a stainless steel with almost negligible weight loss to the total structure. Pitting is associated with a local discontinuity of the passive film. It can be a mechanical imperfection, such as an inclusion or surface damage, or it can be a local chemical breakdown of the film. Chloride is the most common agent for initiation of pitting. Once a pit is formed, it in effect becomes a crevice; the local chemical environment is substantially more aggressive than the bulk environment. This explains why very high flow rates over a stainless steel surface tend to reduce pitting corrosion; the high flow rate prevents the concentration of corrosive species in the pit. The stability to the passive film with respect to resistance to pitting initiation is controlled primarily by chromium and molybdenum. Minor alloying elements can also have an important effect by influencing the amount and type of inclusions (for example, sulfides) in the steel that can act as pitting sites.

Pitting initiation can also be influenced by surface condition, including the presence of deposits, and by temperature. For a particular environment, a grade of stainless steel may be characterized by a single temperature, or a very narrow range of temperatures, above which pitting will initiate and below which pitting will not initiate. It is therefore possible to select a grade that will not be subject to pitting attack if the chemical environment and temperature do not exceed the critical levels. If the range of operating conditions can be accurately characterized, a meaningful laboratory evaluation is possible. Formation of deposits in service can reduce the pitting temperature.

Although chloride is known to be the primary agent of pitting attack, it is not possible to establish a single critical chloride limit for each grade. The corrosivity of a particular concentration of chloride solution can be profoundly affected by the presence or absence of various often chemical species that may accelerate or inhibit corrosion. Chloride concentration may increase where evaporation or deposits occur. Because of the nature of pitting attack--rapid penetration with little total weight loss--it is rate that any significant amount of pitting will be acceptable in practical applications.

Crevice corrosion can be considered a severe form of pitting. Any crevice, whether the result of a metal-to-metal joint, a gasket, fouling, or deposits, tends to restrict oxygen access, resulting in attack. In practice, it is extremely difficult to prevent all crevices, but every effort should be made to do so. Higher-chromium, and especially higher-molybdenum, grades are more resistant to crevice attack. Just as there is a critical pitting temperature for a particular environment, there is also a critical crevice temperature. This temperature is specific to the geometry and nature of the crevice and to the precise corrosion environment for each grade. The critical crevice temperature can be useful in selecting an adequately resistant grade for particular applications.

Intergranular corrosion is a preferential attack at the grain boundaries of a stainless steel. It is generally the result of sensitization. This condition occurs when a thermal cycle leads to grain-boundary precipitation of a carbide, nitride, or intermetallic phase without providing sufficient time for chromium diffusion to fill the locally depleted region. A grain-boundary precipitate is not the point of attack; instead, the low-chromium region adjacent to the precipitate is susceptible.

Sensitization is not necessarily detrimental unless the grade is to be used in an environment capable of attacking the region. For example, elevated-temperature applications for stainless steel can operate with sensitized steel, but concern for intergranular attack must be given to possible corrosion during downtime when condensation might provide a corrosive medium. Because chromium provides corrosion resistance, sensitization also increases the susceptibility of chromium-depleted regions to other forms of corrosion, such as pitting, crevice corrosion, and SCC. The thermal exposures required to sensitize a steel can be relatively brief, as in welding, or can be very long, as in high-temperature service.

Stress-corrosion cracking is a corrosion mechanism in which the combination of a susceptible alloy, sustained tensile stress, and a particular environment leads to cracking of the metal. Stainless steels are particularly susceptible to SCC in chloride environments; temperature and the presence of oxygen to aggravate chloride SCC of stainless steels. Most ferritic and duplex stainless steels are either immune or highly resistant to SCC. All austenitic grades, especially AISI types 304 and 316, are susceptible to some degree. The highly alloyed austenitic grades are resistant to sodium chloride. (NaCl) solutions, but crack readily in $MgCl_2$ solutions. Although some localized pitting or crevice corrosion probably precedes SCC, the amount of pitting or crevice attack may be so small as to undetectable. Stress corrosion is difficult to detect while in progress, even when pervasive, and can lead to rapid catastrophic failures of pressurized equipment.

It is difficult to alleviate the environmental conditions that lead to SCC. The level of chlorides required to produce stress corrosion is very low. In operation, there can be evaporative concentration or a concentration in the surface film on a heat-rejecting surface. Temperature is often a process parameter, as in the case of a heat exchanger. Tensile stress is one parameter that might be controlled. However, the residual stresses associated with fabrication, welding, or thermal cycling, rather than design stresses, are often responsible for SCC, and even stress-relieving heat treatments do not completely eliminate these residual stresses.

Erosion-Corrosion. Corrosion of a metal or alloy can be accelerated when there is an abrasive removal of the protective oxide layer. This form of attack is especially significant when the thickness of the oxide layer is an important factor in determining corrosion resistance. In the case of a stainless steel, erosion of the passive film can lead to some acceleration of attack.

Oxidation. Because of their high chromium contents, stainless steels tend to be very resistant to oxidation. Important factors to be considered in the selection of stainless steels for high-temperature service are the stability of the composition and microstructure of the grade upon thermal exposure and the adherence of the oxide scale upon thermal cycling. Because many of the stainless steels used for high temperatures are austenitic grades with relatively high nickel contents, it is also necessary to be alert to the possibility of sulfidation attack.

Corrosion in Specific Environments

Selection of a suitable stainless steel for a specific environment requires consideration of several criteria. The first is corrosion resistance. Alloys are available that provide resistance to mild atmospheres (for example, type 430) or to many food-processing environments (for example, type 304 stainless). Chemicals and more severe corrodents require type 316 or a more highly alloyed material, such as 20Cb-3. Factors that affect the corrosivity of an environment include the concentration of chemical species, pH, aeration, flow rate (velocity), impurities (such as chlorides), and temperature, including effects from heat transfer.

The second criterion is mechanical properties, or strength. High-strength materials often sacrifice resistance to some form of corrosion, particularly SCC.

Third, fabrication must be considered, including such factors as the ability of the steel to be machined, welded, or formed. Resistance of the fabricated article to the environment must be considered--for example, the ability of the material to resist attack in crevices that cannot be avoided in the design.

Fourth, total cost must be estimated, including initial alloy price, installed cost, and the effective life expectancy of the finished product. Finally, consideration must be given to product availability.

Many applications for stainless steels, particularly those involving heat exchangers, can be analyzed in terms of a process side and a water side. The process side is usually a specific chemical combination that has its own requirements for a stainless steel grade. The water side is common in many applications. This section will discuss the corrosivity of various environments for stainless steels.

Atmospheric Corrosion

The atmospheric contaminants most often responsible for the rusting of structural stainless steels are chlorides and metallic iron dust. Chloride contamination may originate from the calcium chloride ($CaCl_2$) used to make concrete or from exposure in marine or industrial locations. Iron contamination may occur during fabrication or erection of the structure. Contamination should be minimized, if possible.

The corrosivity of different atmospheric exposures can vary greatly and can dictate application of different grades of stainless steel. Rural atmospheres, uncontaminated by industrial fumes or coastal salt, are extremely mild in terms of corrosivity for stainless steel, even in areas of high humidity. Industrial or marine environments can be considerably more severe.

Table 4 demonstrates that resistance to staining can depend on the specific exposure. For example, several 300-series stainless steels showed no rust during long-term exposures in New York City. On the other hand, staining was observed after much shorter exposures at Niagara Falls in a severe industrial-chemical environment near plants producing chlorine of HCl.

Table 4 Atmospheric corrosion of austenitic stainless steels at two industrial sites

Type[(a)]	New York City (industrial)		Niagara Falls (industrial-chemical)	
	Exposure time, years	**Specimen surface evaluation**	**Exposure time, years**	**Specimen surface evaluation**
302	5	Free from rust stains	$<\frac{2}{3}$	Rust stains
302	26	Free from rust stains	. . .	. . .
304	26	Free from rust stains	<1	Rust stains
304	. . .	. . .	6	Covered with rust spots and pitted
347	26	Free from rust stains	. . .	. . .
316	23	Free from rust stains	$<\frac{2}{3}$	Slight stains
316	. . .	. . .	6	Slight rust spots, slightly pitted
317	. . .	. . .	$<\frac{2}{3}$	Slight stains
317	. . .	. . .	6	Slight stains

310	. . .	. . .	6	Rust spots; pitted

(a) Solution-annealed sheet, 1.6 mm ($\frac{1}{16}$ in.) thick

Although marine environments can be severe, stainless steels often provides good resistance. Table 5 compares AISI 300-series stainless steels after a 15-year exposure to a marine atmosphere 250 m (800 ft) from the ocean at Kure Beach, NC. Materials containing molybdenum exhibited only extremely slight rust stain, and all grades were easily cleaned to reveal a bright surface. Type 304 stainless steel may provide satisfactory resistance in many marine applications, but more highly alloyed grades are often selected when the stainless is sheltered from washing by the weather and is not cleaned regularly.

Table 5 Corrosion of AISI 300-series stainless steels in a marine atmosphere

Based on 15-year exposures 250 m (800 ft) from the ocean at Kure Beach, NC

AISI type	Average corrosion rate		Average depth of pits		Appearance[a]
	mm/yr	**mils/yr**	**mm**	**mils**	
301	<2.5 × 10^{-5}	<0.001	0.04	1.6	Light rust and rust stain on 20% of surface
302	<2.5 × 10^{-5}	<0.001	0.03	1.2	Spotted with rust stain on 10% of surface
304	<2.5 × 10^{-5}	<0.001	0.028	1.1	Spotted with slight rust stain on 15% of surface
321	<2.5 × 10^{-5}	<0.001	0.067	2.6	Spotted with slight rust stain on 15% of surface
347	<2.5 × 10^{-5}	<0.001	0.086	3.4	Spotted with moderate rust stain on 20% of surface
316	<2.5 × 10^{-5}	<0.001	0.025	1.0	Extremely slight rust stain on 15% of surface
317	<2.5 × 10^{-5}	<0.001	0.028	1.1	Extremely slight rust stain on 20% of surface

(a) All stains easily removed to reveal bright surface.

Type 302 and 304 stainless steels have had many successful architectural applications. Type 430 stainless steel has been used in many locations, but there have been problems. For example, type 430 stainless steel rusted in sheltered areas after only a few months' exposure in an industrial environment. They type 430 stainless steel was replaced by type 302, which provide satisfactory service. In more aggressive environments, such as marine or severely contaminated atmospheres, type 316 stainless steel is especially useful.

Stress-corrosion cracking is generally not a concern when austenitic or ferritic stainless steels are used in atmospheric exposures. Several austenitic stainless steels were exposed to a marine atmosphere at Kure Beach, NC. Annealed and quarter-hard wrought AISI types 201, 301, 302, 304, and 316 stainless steels were not susceptible to SCC. In the as-welded condition, only type 301 stainless steel experienced failure. Following sensitization at 650 °C (1200 °F) for 1.5 h and furnace cooling, failures were obtained only for materials with carbon contents of 0.043% or more (Ref 8).

Stress-corrosion cracking must be considered when quench-hardened martensitic stainless steels or precipitation-hardening grades are used in marine environments or in industrial locations where chlorides are present. Several hardenable stainless grades were exposed as U-bends 25 m (80 ft) from the ocean at Kure Beach, NC. Most samples were cut longitudinally, and two alloys received different heat treatments to produce different hardness or strength levels. The

results of the study (Table 6) indicated that Custom 450 stainless and stainless alloy 355 resisted cracking. Stainless alloy 355 failed in this type of test when fully hardened; resistance was imparted by the 540-°C (1000-°F) temper. Precipitation-hardenable grades are expected to exhibit improved corrosion resistance when higher aging temperatures (lower strengths) are used.

Table 6 SCC of U-bend test specimens 25 m (80 ft) from the ocean at Kure Beach, NC

Alloy	Final heat treatment	Hardness, HRC	Specimen orientation	Time to failure of each specimen, days[(a)]
Custom 450	Aged at 480 °C (900 °F)	42	Transverse	NF, NF, NF, NF, NF
Type 410	Tempered at 260 °C (500 °F)	45	Longitudinal	379, 379, 471
	Tempered at 550 °C (1025 °F)	35	Longitudinal	4, 4
Alloy 355	Tempered at 540 °C (1000 °F)	38	Longitudinal	NF, NF, NF
15Cr-7Ni-Mo	Aged at 510 °C (950 °F)	49	Longitudinal	1, 1, 1
17Cr-4Ni	Aged at 480 °C (900 °F)	42	Longitudinal	93, 129, NF
	Aged at 620 °C (1150 °F)	32	Longitudinal	93, 129, NF
14Cr-6Ni	Aged at 480 °C (900 °F)	39	Longitudinal	93, 872, NF

Source: Ref 9

(a) NF, no failure in over 4400 days for Custom 450 and 1290 days for the other materials.

Resistance to SCC is of particular interest in the selection of high-strength stainless steels for fastener applications. Cracking of high-strength fasteners is possible and often results from hydrogen generation due to corrosion or contact with a less noble material, such as aluminum. Resistance to SCC can be improved by optimizing the heat treatment, as noted above.

Fasteners for atmospheric exposure have been fabricated from a wide variety of alloys. Type 430 and unhardened type 410 stainless steels have been used when moderate corrosion resistance is required in a lower-strength material. Better-than-average corrosion resistance has been obtained by using 305 and Custom Flo 302HQ stainless steels when lower strength is acceptable.

Corrosion in Waters

Waters may vary from extremely pure to chemically treated water to highly concentrated chloride solutions, such as brackish water or seawater, further concentrated by recycling. This chloride content poses the danger of pitting or crevice attack of stainless steels. When the application involves moderately increased temperatures, even as low as 45 °C (110 °F), and particularly when there is heat transfer into the chloride-containing medium, there is the possibility of SCC. It is useful to consider water with two general levels of chloride content: freshwater, which can have chloride levels up to approximately 600 ppm, and seawater, which encompasses brackish and severely contaminated waters. The corrosivity of

a particular level of chloride can be strongly affected by the other chemical constituents present, making the water either more or less corrosive.

Permanganate ion (MnO_4^-), which is associated with the dumping of chemicals, has been related to pitting of type 304 stainless steel. The presence of sulfur compounds and oxygen or other oxidizing agents can affect the corrosion of copper and copper alloys, but does not have very significant effects on stainless steels at ambient or slightly elevated temperatures (up to approximately 250 °C or 500 °F).

In freshwater, type 304 stainless steel has provided excellent service for such items as valve parts, weirs, fasteners, and pump shafts in water and wastewater treatment plants. Custom 450 stainless steel has been used as shafts for large butterfly valves in potable water. The higher strength of a precipitation-hardenable stainless steel permits reduced shaft diameter and increased flow. Type 201 stainless steel has seen service in revetment mats to reduce shoreline erosion in freshwater. Type 316 stainless steel has been used as wire for microstrainers in tertiary sewage treatment and is suggested for waters containing minor amounts of chloride.

Seawater is a very corrosive environment for many materials. Stainless steels are more likely to be attacked in low-velocity seawater or at crevices resulting from equipment design or attachment of barnacles. Type 304 and 316 stainless steels suffer deep pitting if the seawater flow rate decreases below about 1.5 m/s (5 ft/s) because of the crevices produced by fouling organisms. However, in one study, type 316 stainless steel provided satisfactory service as tubing in the heat recovery section of a desalination test plant with relatively high flow rates (Ref 10).

The choice of stainless steel for seawater service can depend on whether or not stagnant conditions can be minimized or eliminated. For example, boat shafting of 17Cr-4Ni stainless steel has been used for trawlers where stagnant exposure and the associated pitting would not be expected to be a problem. When seagoing vessels are expected to lie idle for extended periods of time, more resistant boat shaft materials, such as 22Cr-13Ni-5Mn stainless steel, are considered. Boat shafts with intermediate corrosion resistance are provided by 18Cr-2Ni-12Mn and high-nitrogen type 304 (type 304HN) stainless steels.

The most severe exposure conditions are often used in seawater test programs. In one example of such data, flat-rolled specimens of 11 commercially available alloys with several mill finishes were exposed to seawater (Table 7). Triplicate samples were prepared with plastic multiple-crevice washers, each containing 20 plateaus or crevices. These washers were affixed to both sides of each panel by using a torque of either 2.8 or 8.5 N ·m (25 or 75 in. · lb). The panels were exposed for up to 90 days in filtered seawater flowing at a velocity of less than 0.1 m/s (<0.33 ft/s).

Table 7 Crevice corrosion indexes of several alloys in tests in filtered seawater

Mill-finished panels exposed for 30, 60, and 90 days to seawater at 30 °C (85 °F) flowing at <0.1 m/s (<0.33 ft/s); crevice washers tightened to 2.8 or 8.5 N · m (25 or 75 in. · lb)

Alloy	UNS Designation	Number of sides (S) attacked[(a)]	Maximum pit depth (D)		Crevice corrosion index (S × D)
			mm	**mils**

Source: Ref 11

(a) Total number of sides was 18.

(b) Also showed tunneling attack perpendicular to the upper edge, or attack at edges.

(c) Perforated by attack from both sides.

The results given in Table 7 show the number of sides that experienced crevice attack and the maximum attack depth at any crevice for that alloy. A crevice corrosion index (CCI) was calculated by multiplying the maximum attack depth times the number of sides attacked. This provided a ranking system that accounts for both initiation and growth of attack. Lower values of the CCI imply improved resistance.

Attack in the above test does not mean that materials with high CCIs cannot be used in seawater. For examples, 22Cr-13Ni-5Mn stainless steel with a CCI of 20 has proved to be a highly resistant boat shaft alloy. Some of the more resistant materials in the above tests have been used for utility condenser tubing. These alloys include MONIT, AL-29-4C, 254SMO, Sea-Cure, and AL-6XN.

The possibility of galvanic corrosion must be considered if stainless steel is to be used in contact with other metals in seawater. Figure 10 provides corrosion potentials in flowing seawater for several materials. Preferably, only those materials that exhibit closely related electrode potentials should be coupled to avoid attack of the less noble material. Galvanic differences have been used to advantage in the cathodic protection of stainless steel in seawater. Crevice corrosion and pitting of austenitic type 302 and 316 stainless steels have been prevented by cathodic protection, but type 410 and 430 stainless steels develop hydrogen blisters at current densities below those required for complete protection.

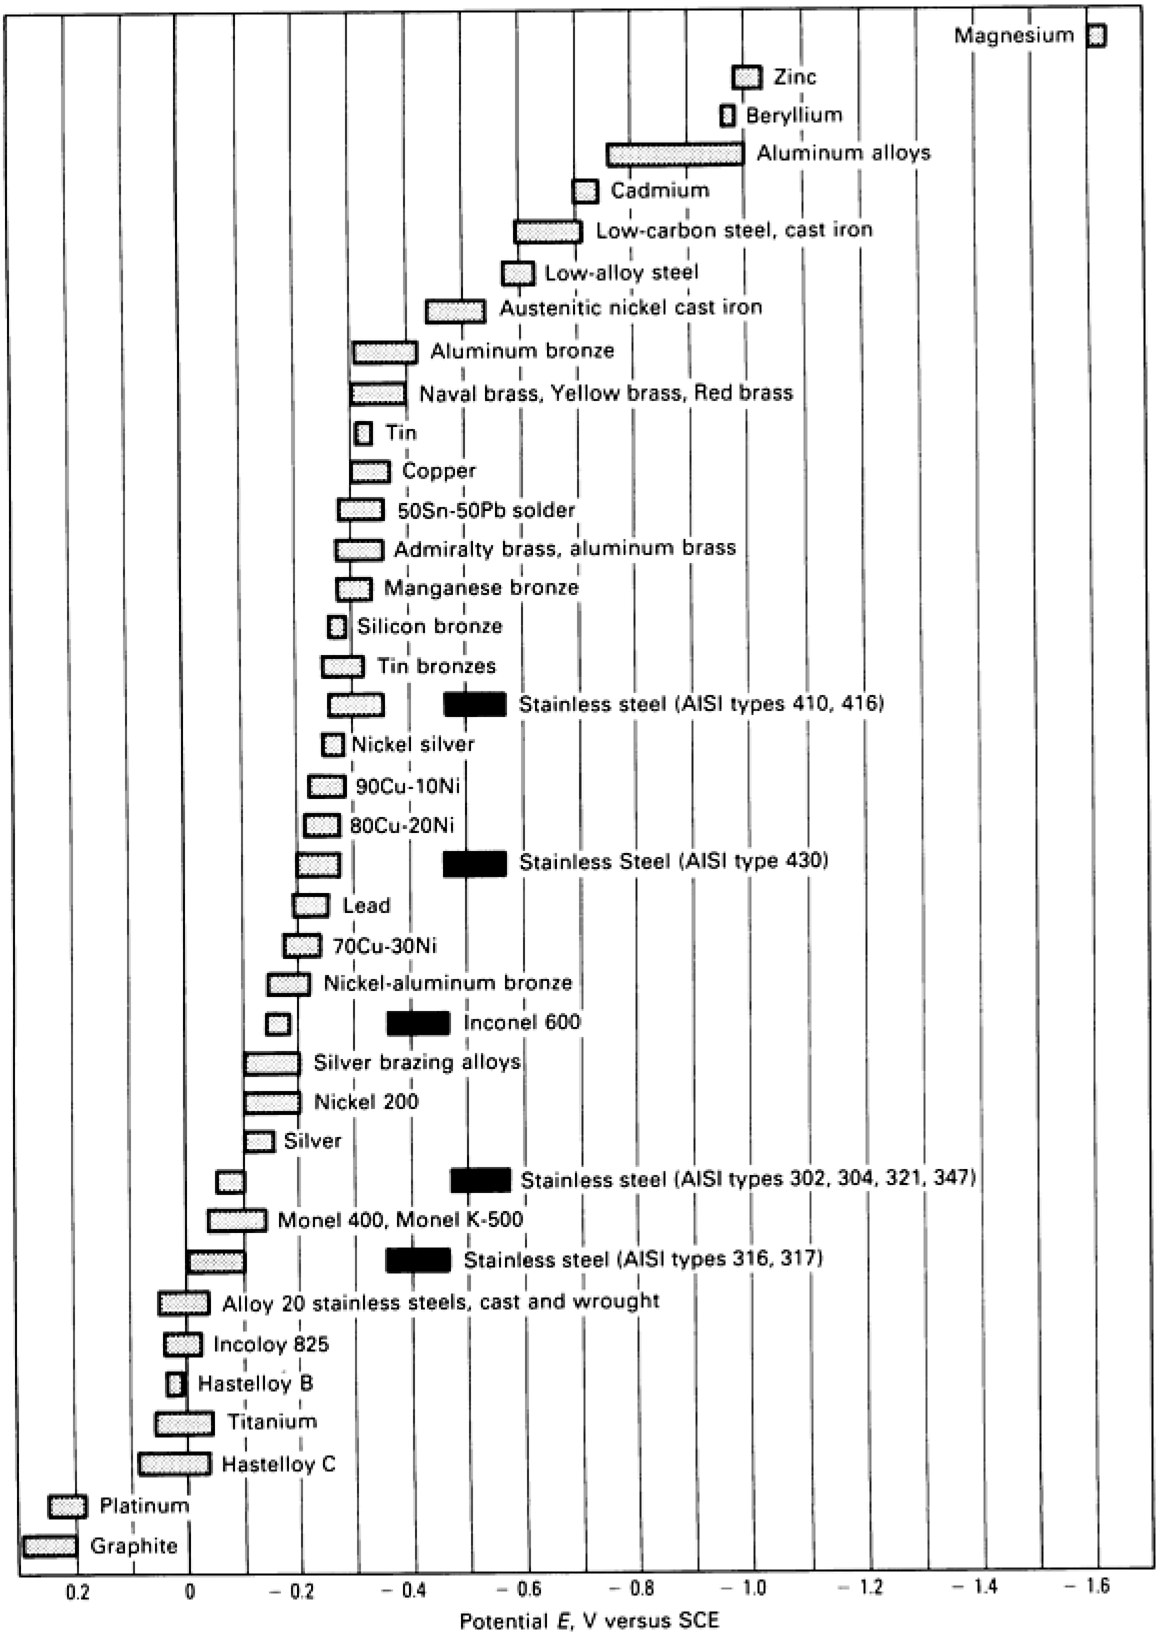

Fig. 10 Corrosion potentials of various metals and alloys in flowing seawater at 10 to 25 °C (50 to 80 °F). Flow rate was 2.5 to 4 m/s (8 to 13 ft/s); alloys are listed in order of the potential versus SCE that they exhibited. Those metals and alloys indicated by a black bar may become active and exhibit a potential near -0.5 V versus SCE in low velocity or poorly aerated water and in shielded areas. Source: Ref 12

Other factors that should be noted when applying stainless steels in seawater include the effects of high velocity, aeration, and temperature. Stainless steels generally show excellent resistance to high velocities, impingement attack, and cavitation in seawater. Also, stainless steels provide optimum service in aerated seawater because a lack of aeration at a specific site often leads to crevice attack. Very little oxygen is required to maintain the passive film on a clean stainless surface. Increasing the temperature from ambient to about 50 °C (120 °F) often reduces attack of stainless steels, possibly because of differences in the amount of dissolved oxygen, changes in the surface film, or changes in the resistance of the boldly exposed sample area (Ref 13). Further temperature increases can result in increased corrosion, such as SCC.

Corrosion in Chemical Environments

Selection of stainless steels for service in chemicals requires consideration of all forms of corrosion, along with impurity levels and degree of aeration. When an alloy with sufficient general corrosion resistance has been selected, care must be taken to ensure that the material will not fail by pitting or SCC due to chloride contamination. Aeration may be an important factor in corrosion, particularly in cases of borderline passivity. If dissimilar-metal contact or stray currents occur, the possibility of galvanic attack or hydrogen embrittlement must be considered.

Alloy selection also depends on fabrication and operation details. If a material is to be used in the as-welded or stress-relieved condition, it must resist intergranular attack in service after these thermal treatments. In chloride environments, the possibility of crevice corrosion must be considered when crevices are present because of equipment design or the formation of adherent deposits. Higher flow rates may prevent the formation of deposits, but in extreme cases may also cause accelerated attack due to erosion or cavitation. Increased operating temperatures generally increase corrosion. In heat transfer applications, higher metal wall temperatures result in higher rates than expected from the lower temperature of the bulk solution. These are other items may require consideration in the selection of stainless steels, yet suitable materials continue to be chosen for a wide variety of chemical plant applications (see the article "Corrosion in the Chemical Processing Industry" in this Volume).

Some generalizations can be made regarding the performance of various categories of stainless steels in certain types of chemical environments. These observations relate to the compositions of the grades. For example, the presence of nickel and copper in some austenitic grades greatly enhances resistance to H_2SO_4 compared to the resistance of the ferritic grades. However, combinations of chemicals that are encountered in practice can be either more or less corrosive than might be expected from the corrosivity of the individual components. Testing in actual or simulated environments is always recommended as the best procedure for selecting a stainless steel grade. Additional information describing service experience is available from alloy suppliers.

Mineral Acids. The resistance of stainless steel to acids depends on the hydrogen ion (H^+) concentration and the oxidizing capacity of the acid, along with such material variables as chromium content, nickel content, carbon content, and heat treatment (Ref 14). For example, annealed stainless steel resists strong HNO_3 in spite of the low pH of the acid, because HNO_3 is highly oxidizing and forms a passive film due to the chromium content of the alloy. On the other hand, stainless steels are rapidly attacked by strong HCl because a passive film is not easily attained. Even in strong HNO_3, stainless steels can be rapidly attacked if they contain sufficient carbon and are sensitized. Oxidizing species, such a ferric salts, result in reduced general corrosion in some acids, but can cause accelerated pitting attack if chloride ions (Cl^-) are present.

Nitric Acid. As noted above, stainless steels have broad applicability in HNO_3 primarily because of their chromium content. Most AISI 300-series stainless steels exhibit good or excellent resistance in the annealed condition in concentrations from 0 to 65% up to the boiling point. Figure 11 illustrates the good resistance of type 304 stainless steel, particularly when compared with the lower-chromium type 410 stainless steel. More severe environments at elevated temperatures require alloys with higher chromium. In HNO_3 cooler-condensers, such stainless alloys as 7-Mo PLUS (UNS S32950) and 2RE10 (UNS S31008), are candidates for service.

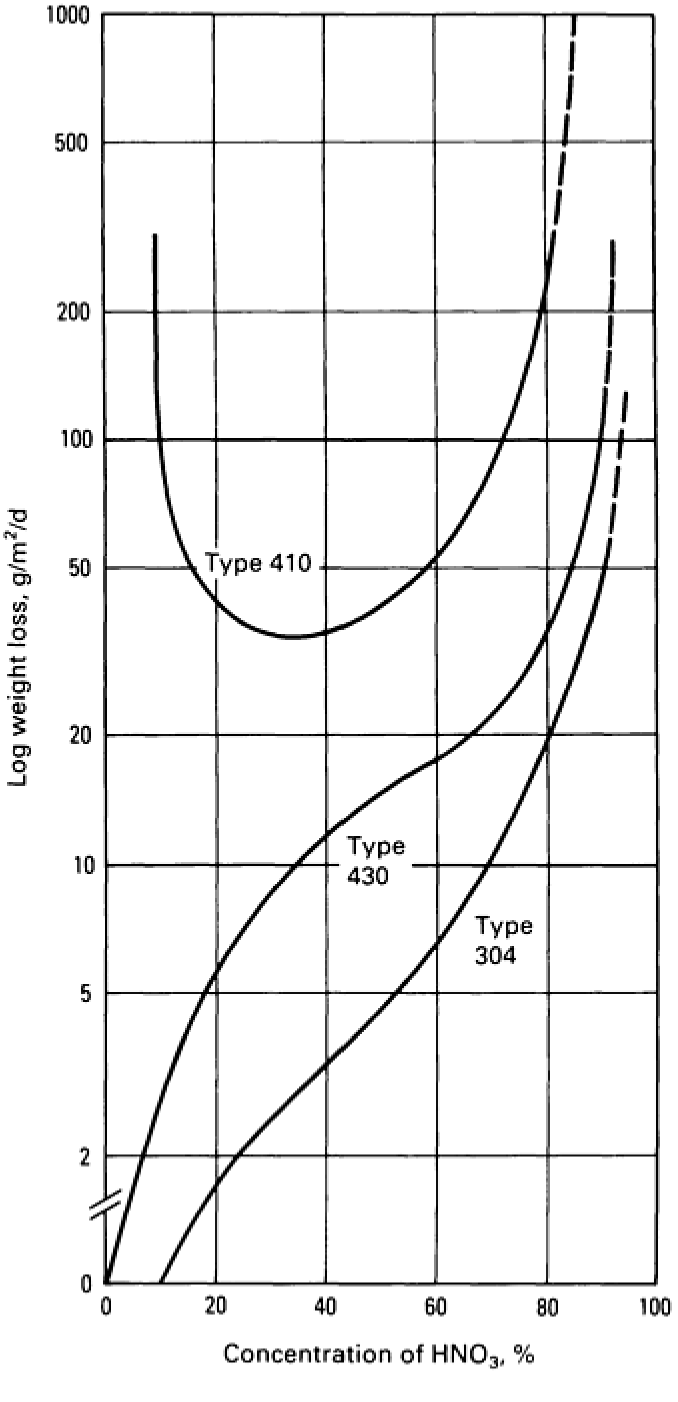

Fig. 11 Corrosion rates of various stainless steels in boiling HNO_3. Source: Ref 15

In sulfuric acid, stainless steels can approach the borderline between activity and passivity. Conventional ferritic grades, such as type 430, have limited use in H_2SO_4, but the newer ferritic grades containing higher chromium and molybdenum (for example, 28% Cr and 4% Mo) with additions of at least 0.25% Ni have shown good resistance in boiling 10% H_2SO_4 (Ref 16), but corrode rapidly when acid concentrations is increased.

The conventional austenitic grades exhibit good resistance in very dilute or highly concentrated H_2SO_4 at slightly elevated temperatures. Acid of intermediate concentration is more aggressive, and conventional grades have very limited utility. Resistance of several stainless steels in up to about 50% H_2SO_4 is shown in Fig. 12. Aeration or the addition of oxidizing species can significantly reduce the attack of stainless steels in H_2SO_4. This occurs because the more oxidizing environment is better able to maintain the chromium-rich passive oxide film.

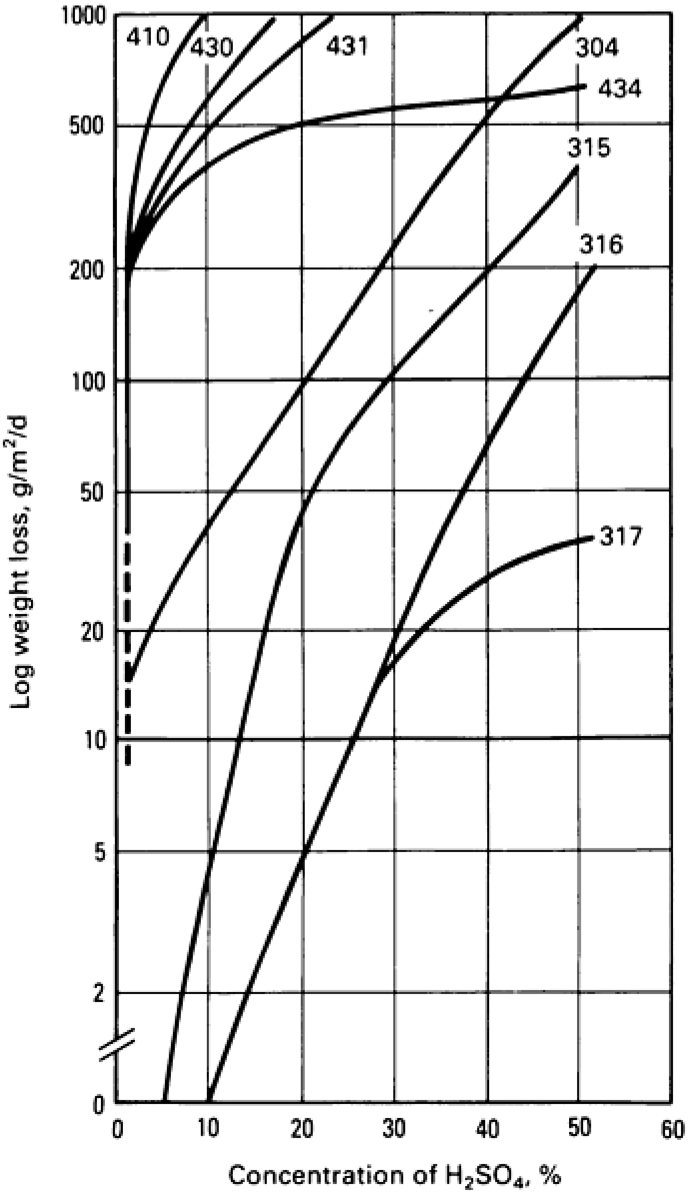

Fig. 12 Corrosion rates of various stainless steels in underaerated H_2SO_4 at 20 °C (70 °F). Source: Ref 15

Improved resistance to H_2SO_4 has been obtained by using austenitic grades containing high levels of nickel and copper, such as 20Cb-3 stainless steel. In addition to reducing general corrosion, the increased nickel provides resistance to SCC. Because of its resistance to these forms of corrosion, 20Cb-3 stainless steel has been used for valve springs in H_2SO_4 service.

Phosphoric Acid. Conventional straight-chromium stainless steels have very limited general corrosion resistance in phosphoric acid (H_3PO_4) and exhibit lower rates only in very dilute or more highly concentrated solutions. Conventional austenitic stainless steels provide useful general corrosion resistance over the full range of concentrations up to about 65 °C (150 °F); use at temperatures up to the boiling point is possible for acid concentrations up to about 40%.

In commercial applications, however, wet-process H_3PO_4 environments include impurities derived from the phosphate rock, such as chlorides, fluorides, and H_2SO_4. These three impurities accelerate corrosion, particularly pitting or crevice corrosion in the presence of the halogens. Higher-alloyed materials than the conventional austenitic stainless steels are required to resist wet-process H_3PO_4. Candidate materials include alloy 904L, alloy 28, 20Cb-3, 20Mo-4, and 20Mo-6 stainless steels.

Hydrochloric Acid. Stainless steels are generally not used for HCl service, except perhaps for very dilute solutions at room temperature. Stainless materials can be susceptible to accelerated general corrosion, SCC, and pitting in HCl environments.

Sulfurous Acid. Although sulfurous acid (H_2SO_3) is a reducing agent, several stainless steels have provided satisfactory service in H_2SO_3 environments. Conventional austenitic stainless steels have been used in sulfite digestors, and type 316, type 317, 20Cb-3, and cast Alloy Casting Institute alloys CF-8M and CN-7M stainless steels have seen service in wet sulfur dioxide (SO_2) and H_2SO_3 environments. Cast stainless steels are discussed in the article "Corrosion of Cast Steels" in this Volume, Service life is improved by eliminating crevices, including those from settling of suspended solids, or by using molybdenum-containing grades. In some environments, SCC is also a possibility.

Organic acids and compounds are generally less aggressive than mineral acids because they do not ionize as completely, but they can be corrosive to stainless steels, especially when impurities are present. The presence of oxidizing agents in the absence of chlorides can reduce corrosion rates.

Acetic Acid. Corrosion rates for several stainless steels in acetic acid are listed in Table 8. Resistance to pure acetic acid has been obtained by using type 316 and 316L stainless steels over all concentrations up to the boiling point. Type 304 stainless steel may be considered in all concentrations below about 90% at temperatures up to the boiling point. Impurities present in the manufacture of acetic acid, such as acetaldehyde, formic acid, chlorides, and propionic acid, are expected to increase the attack of stainless steels. Chlorides may cause pitting or SCC.

Table 8 Corrosion of austenitic stainless steels in boiling glacial acetic acid

Data are from averaged results of 11-, 12-, and 21-day field tests.

AISI type	Corrosion rate	
	mm/yr	**mils/yr**
304	0.46	18
321	1.19	47
347	1.04	41
308	1.35	53
310	0.99	39
316	0.015	0.6

Formic acid is one of the more aggressive organic acids, and corrosion rates can be higher in the condensing vapor than in the liquid. Type 304 stainless steel has been used at moderate temperatures. However, type 316 stainless steel or higher alloys, such as 20Cb-3, are often preferred, and high-alloy ferritic stainless steels containing 26% Cr and 1% Mo or 29% Cr and 4% Mo also show some promise.

Other Organic Acids. The corrosivity of propionic and acrylic acids at a given temperature is generally similar to that of acetic acid. Impurities are important and may strongly affect the corrosion rate. In citric and tartaric acids, type 304 stainless steels has been used for moderate temperatures, and type 316 has been suggested for all concentrations up to the boiling point.

Organic Halides. Most dry organic halides do not attack stainless steels, but the presence of water allows halide acids to form and can cause pitting or SCC. Therefore, care should be exercised when using stainless steels in organic halides to ensure that water is excluded.

Other Organic Compounds. Type 304 stainless steel has generally been satisfactory in aldehydes, in cellulose acetate at lower temperatures, and in fatty acids up to about 150 °C (300 °F). At higher temperatures, these chemicals require type 316 or 317. Type 316 stainless steel is also used in amines, phthalic anhydride, tar, and urea service.

Stainless steels have been used in the plastic and synthetic fiber industries. Type 420 and 440C stainless steels have been used as plastic mold steels. More resistant materials, such as Custom 450, have been used for extruding polyvinyl chloride (PVC) pipe. Spinnerettes, pack parts, and metering pumps of Custom 450 and Custom 455 stainless steels have been used in the synthetic fiber industry to produce nylon, rayon, and polyesters.

Alkalies. All stainless steels resist general corrosion by all concentrations of sodium hydroxide (NaOH) up to about 65 °C (150 °F). Type 304 and 316 stainless steels exhibit low rates of general corrosion in boiling NaOH up to nearly 20% concentration. Stress-corrosion cracking of these grades can occur at about 100 °C (212 °F). Good resistance to general corrosion and SCC in 50% NaOH at 135 °C (275 °F) is provided by E-Brite and 7-Mo stainless steels (Ref 18). In ammonia (NH_3) and ammonium hydroxide (NH_4OH), stainless steels have shown good resistance at all concentrations up to the boiling point.

Salts. Stainless steels are highly resistant to most neutral or alkaline nonhalide salts. In some cases, type 316 is preferred for its resistance to pitting, but even the higher-molybdenum type 317 stainless steel is readily attacked by sodium sulfide (Na_2S) solutions.

Halogen salts are more corrosive to stainless steels because of the ability of the halide ions to penetrate the passive film and cause pitting. Pitting is promoted in aerated or mildly acidic oxidizing solutions. Chlorides are generally more aggressive than the other halides in their ability to cause pitting.

Gases. At lower temperatures, most austenitic stainless steels resist chlorine or fluorine gas if the gas is completely dry. The presence of even small amounts of moisture results in accelerated attack, especially pitting and possibly SCC.

Oxidation. At elevated temperatures, stainless steels resist oxidation primarily because of their chromium content. Increased nickel minimizes spalling when temperature cycling occurs. Table 9 lists generally accepted maximum safe service temperatures for wrought stainless steels. Maximum temperatures for intermittent service are lower for the austenitic stainless steels, but are higher for most of the martensitic and ferritic stainless steels listed.

Table 9 Generally accepted maximum service temperatures in air for AISI stainless steels

Source: Ref 19

Contamination of the air with water and Co_2 often increases corrosion at elevated temperatures. Increased attack can also occur because of sulfidation as a result of SO_2 H_2S, or sulfur vapor.

Carburization of stainless steels can occur in carbon monoxide (CO), methane, (CH_4), and other hydrocarbons. Carburization can also occur when stainless steels contaminated with oil or grease are annealed without sufficient oxygen to burn off the carbon. This can occur during vacuum or inert gas annealing as well as open air annealing of oily parts with shapes that restrict air access. Chromium, silicon, and nickel are useful in combating carburization.

Nitriding can occur in dissociated NH_3 at high temperatures. Resistance to nitriding depends on alloy composition as well as NH_3 concentration, temperature, and pressure. Stainless steels are readily attacked in pure NH_3 at about 540 °C (1000 °F).

Liquid Metals. The 18-8 stainless steels are highly resistant to liquid sodium or sodium-potassium alloys. Mass transfer is not expected up to 540 °C (1000 °F) and remains at moderately low levels up to 870 °C (1600 °F). Accelerated attack of stainless steels in liquid sodium occurs with oxygen contamination, with a noticeable effect occurring at about 0.02% oxygen by weight (Ref 14).

Exposure to molten lead under dynamic conditions often results in mass transfer in common stainless alloy systems. Particularly severe corrosion can occur in strongly oxidizing conditions. Stainless steels are generally attacked by molten aluminum, zinc, antimony, bismuth, cadmium, and tin.

Corrosion in Various Applications

Every industry features a variety of applications encompassing a range of corrosion environments. This section will characterize the experience of each industry according to the corrosion problems most frequently encountered and will suggest appropriate grade selections.

Food and Beverage Industry. Stainless steels have been relied upon in these applications because of the lack of corrosion products that could contaminate the process environment and because of the superior cleanability of the stainless steels. The corrosion environment often involves moderately to highly concentrated chlorides on the process side, often mixed with significant concentrations of organic acids. The water side can range from steam heating to brine cooling. Purity and sanitation standards require excellent resistance to pitting and crevice corrosion.

Foods such as vegetables represent milder environments and can generally be handled by using type 304 stainless steel. Sauces and pickle liquors, however, are more aggressive and can pit even type 316 stainless steel. For improved pitting resistance, such alloys as 22Cr-13Ni-5Mn, 904L, 20Mo-4, 254SMO, AL-6XN, and MONIT stainless steels should be considered.

At elevated temperatures, materials must be selected for resistance to pitting and SCC in the presence of chlorides. Stress corrosion must be avoided in heat transfer applications, such as steam jacketing for cooking or processing vessels or in heat exchangers. Cracking may occur from the process or water side or may initiate outside the unit under chloride-containing insulation. Brewery applications of austenitic stainless steels have been generally successful except for a number of cases of SCC of high-temperature water lines. The use of ferritic or duplex stainless steels is an appropriate remedy for the SCC. More information on this subject is available in the article "Corrosion in the Brewery Industry" in this Volume.

Stainless steel equipment should be cleaned frequently to prolong its service life. The equipment should be flushed with freshwater, scrubbed with a nylon brush and detergent, the rinsed. On the other hand, consideration should be given to the effect of very aggressive cleaning procedures on the stainless steels, as in the chemical sterilization of commercial dishwashers. In some cases, it may be necessary to select a more highly alloyed stainless steel grade to deal with these brief exposures to highly aggressive environments.

Conventional AISI grades provide satisfactory service in many food and beverage applications. Type 304 stainless steel is widely used in the dairy industry, and type 316 finds application as piping and tubing in breweries. These grades, along with type 444 and Custom 450 stainless steels, have been used for chains to transfer food through processing equipment. Machined parts for beverage-dispensing equipment have been fabricated from type 304, 304L, 316, 316L, and 303Al MODIFIED, 302HQ-FM, and 303BV stainless steels. When the free-machining grades are used, it is important to passivate and rinse properly before service in order to optimize corrosion resistance.

Food-handling equipment should be designed without crevices in which food can become lodged. In more corrosive food products, extra-low-carbon stainless steels should be used when possible. Improved results have been obtained when equipment is finished with a 2B (general-purpose cold-rolled) finish rather than No. 4 (general-purpose polished) finish. Alternatively, an electropolished surface may be considered.

Pharmaceutical Industry. The production and handling of drugs and other medical applications require exceedingly high standards for preserving the sterility and purity of process streams. Process environments can include complex organic compounds, strong acids, chloride solutions comparable to seawater, and elevated processing temperatures. Higher-alloy grades, such as type 316 or higher, may be necessary instead of type 304 in order to prevent even superficial corrosion. Electropolishing may be desirable in order to reduce or prevent adherent deposits and the possibility of underdeposit corrosion. Superior cleanability and ease of inspection make stainless steel the preferred material.

The 18-8 stainless grades have been used for a wide variety of applications from pill punches to operating tables. However, care is required in selecting stainless steels for pharmaceutical applications because small amounts of contamination can be objectionable. For example, stainless steel has been used to process vitamin C, but copper must be eliminated because copper in aqueous solutions accelerates the decomposition of vitamin C. Also, stainless is not used to handle vitamin B_6 hydrochloride, even though corrosion rates may be low, because trace amounts of iron are objectionable (see the Section "Specialty Steels and Heat-Resistant Alloys" in *Properties and Selection: Irons, Steels, and High-Performance Alloys,* Volume 1, *ASM Handbook*).

The effects of temperature and chloride concentration must be considered. At ambient temperature, chloride pitting of 18Cr-8Ni stainless steel may occur, but SCC is unlikely. At about 65 °C (150 °F) or above, SCC of austenitic grades must be considered. Duplex alloys, such as 7-Mo PLUS, alloy 2205, and Ferralium 225 possess improved resistance to SCC in elevated-temperature chloride environments. Ferritic grades with lower nickel content, such 18Cr-2Mo stainless steel, provide another means of avoiding chloride SCC. Additional information on the use of stainless steels in the pharmaceutical industry is available in the article "Corrosion in the Pharmaceutical Industry"in the Volume.

Stainless steels have also found application as orthopedic implants. Material is required that is capable of moderately high strength and resistance to wear and fretting corrosion, along with pitting and crevice attack. Vacuum-melted type 316 stainless steel has been used for temporary internal fixation devices, such as bone plates, screws, pins and suture wire. Higher purity improves electropolishing, and increased chromium (17 to 19%) improves corrosion resistance.

In permanent implants, such as artificial joints, very high strength and resistance to wear, fatigue, and corrosion are essential. Cobalt- or titanium-base alloys are used for these applications. More information on this subject is available in the article "Corrosion of Metallic Implants and Prosthetic Devices" in this Volume.

Oil and Gas Industry. Stainless steels were not frequently used in oil and gas production until the tapping of sour reservoirs (those containing hydrogen sulfide, H_2S) and the use of enhanced recovery systems in the mid-1970s. Sour environments can result in sulfide stress cracking (SCC) of susceptible materials. This phenomenon generally occurs at ambient or slightly elevated temperatures; it is difficult to establish an accurate temperature maximum for all alloys. Factors affecting SSC resistance include material variables, pH, H_2S concentration, total pressure, maximum tensile stress, temperature, and time. A description of some of these factors, along with information on materials that have demonstrated resistance to SSC, is available in Ref 20.

The resistance of stainless steels to SSC improves with reduced hardness. Conventional materials, such as type 410, 430, and 304 stainless steels, exhibit acceptable resistance at hardnesses below 22HRC. Specialized grades, such as 22Cr-13Ni-5Mn, Custom 450, 20Mo-4, and some duplex stainless steels, have demonstrated resistance at higher hardnesses. Duplex alloy 2205 has been used for its strength and corrosion resistance as gathering lines for CO_2 gas before gas cleaning. Custom 450 and 22Cr-13Ni-5Mn stainless steels have seen service as valve parts. Other grades used in these environments include 254SMO and alloy 28, particularly for chloride and sulfide resistance, respectively.

In addition to the lower-temperature SSC, resistance to cracking in high-temperature environments is required in many oil field applications. Most stainless steels, including austenitic and duplex grades, are known to be susceptible to elevated-temperature cracking, probably by a mechanism similar to chloride SCC. Failure appears to be accelerated by H_2S and other sulfur compounds. Increased susceptibility is noted in material of higher yield strength, for example, because of the high residual tensile stresses imparted by some cold-working operations.

The above discussion is pertinent to the production phase of a well. However, drilling takes place in an environment of drilling mud, which usually consists of water, clay, weighting materials, and an inhibitor (frequently an oxygen scavenger). Chlorides are also present when drilling through salt formations. Austenitic stainless steels containing nitrogen have found use in this environment as nonmagnetic drill collars, as weight for the drill bit, and as housings for measurement-while-drilling (MWD) instruments. Nonmagnetic materials are required for operation of these instruments, which are used to locate the drill bit in directional-drilling operations. Non-standard stainless steels used as drill collars or MWD components include type 316LN (high nitrogen), Staballoy, XM 19 H, Gammalloy (T286), Super Gammalloy (T287), AM20, Nipponel, 15-15LC, and SCF-19. More information on corrosion during petroleum production is available in the article "Corrosion in Petroleum Production Operations"in this Volume.

In refinery applications, the raw crude contains such impurities as sulfur, water, salts, organic acids, and organic nitrogen compounds. These and other corrosives and their products must be considered in providing stainless steels for the various refinery steps.

Raw crude is separated into materials from petroleum gas to various oils by fractional distillation. These materials are then treated to remove impurities, such as CO_2, NH_3, and H_2S, and to optimize product quality. Refinery applications of stainless steels often involve heat exchangers. Duplex and ferritic grades have been used in this application for their improved SCC resistance. Type 430 and type 444 stainless steel exchanger tubing has been used for resisting hydrogen, chlorides, and sulfur and nitrogen compounds in oil refinery streams. The article "Corrosion in Petroleum Refining and Petrochemical Operations" in this Volume contains detailed information on corrosion of materials in these applications.

Power Industry. Stainless steels are used in the power industry for generator components, feedwater heaters, boiler applications, heat exchangers, condenser tubing, flue gas desulfurization (FGD) systems, and nuclear power applications.

Generator blades and vanes have bee fabricated of modified 12% Cr stainless steel, such as ASTM types 615 (UNS S41800)and 616 (UNS S42200). In some equipment. Custom 450 has replaced AISI type 410 and ASTM type 616 stainless steels.

Heat Exchangers. Stainless steels have been widely used in tubing for surface condensers and feedwater heaters. Both of these are shell and tube heat exchangers that condense steam from the turbine on the shell side. In these heat exchangers, the severity of the corrosion increases with higher temperatures and pressures. Stainless steels resist failure by erosion and do not suffer SCC in NH_3 (from decomposition of boiler feedwater additives), as do some nonferrous materials.

Stainless steel must be chosen to resist chloride pitting. The amount of chloride that can be tolerated is expected to be higher with higher pH and cleaner stainless steel surfaces, that is, the absence of deposits. For example, type 304 stainless steel may resist pitting in chloride levels of 1000 ppm or higher in the absence of fouling, crevices, or stagnant conditions. The presence of one or more of these conditions can allow chlorides to concentrate at the metal surface and initiate pits. Several high-performance stainless steels have been used to resist chloride pitting in brackish water or seawater. High-performance austenitic grades have been useful in feedwater heaters, although duplex stainless steels may also be considered because of their high strength. Ferritic stainless steels have proved to be economically competitive in exchangers and condensers. High-performance austenitic and ferritic grades have been satisfactory for seawater-cooled units. These grades include MONIT, AL-29-4C and Usinor 290 Mo, Sea-Cure, AL-6X, AL-6XN, and 254SMO stainless steels.

Compatibility of materials and good installation practice are required. Tubes of such materials as those listed above have been installed in tubesheets fabricated of alloy 904L, 20Mo-4, and 254SMO stainless steels. Crevice corrosion can occur when some tube materials are rolled into type 316 stainless steel tubesheets (Ref 21). Appropriate levels of cathodic protection have been identified (Ref 22).

Flue Gas Desulfurization. A wide variety of alloys have been used in scrubbers, which are located between the boiler and smokestack of fossil fuel powder plants to treat effluent gases and to remove SO_2 and other pollutants. Typically, fly ash is removed, and the gas travels through an inlet gas duct, followed by the quencher section. Next, SO_2 is removed in the absorber section, most often using either a lime or limestone system. A mist eliminator is employed to remove suspended droplets, and the gas proceeds to the treated-gas duct, reheater section, and the stack.

Two important items for consideration is selecting stainless steels for resistance to pitting in scrubber environments are pH and chloride level. Stainless steels are more resistant to higher pH and lower chloride levels, as shown in Fig. 13 for type 316L stainless steel. Environments that cause pitting or crevice attack of type 316 stainless steel can be handled by using higher-alloy materials, for example, those with increased molybdenum and chromium.

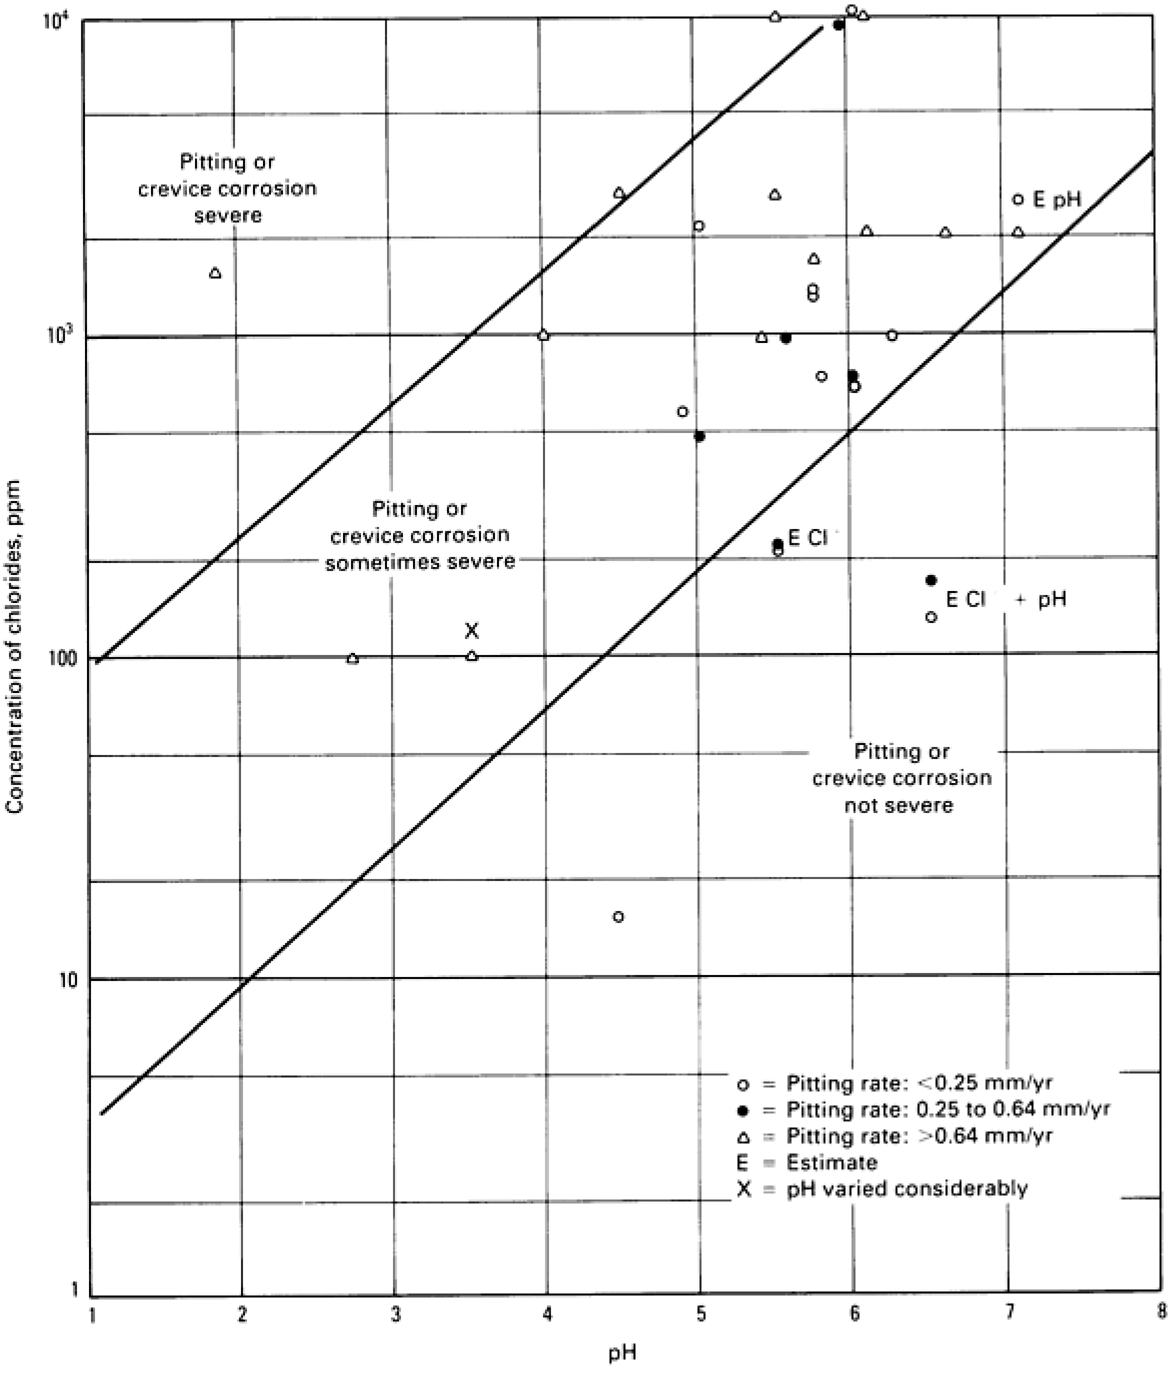

Fig. 13 Pitting of type 316L stainless steel in FGD scrubber environment. Solid lines indicate zones of differing severity of corrosion; because the zones are not clearly defined, the lines cannot be precisely drawn. Source: Ref 23

Some of the materials being considered and specified for varying chloride levels are given in Ref 24. Other materials can also provide good resistance, as evidenced by the results given in Table 10 for samples exposed to several scrubber environments. The maximum depth of localized corrosion and pit density are given for the stainless steels tested. Exposure at the quencher spray header (above slurry) was more severe than expected, probably because of wet-dry concentration effects. Severe attack also occurred in the outlet duct. Samples in this area were exposed to high chlorides, high temperatures, and low pH during the 39 days on bypass operation. More information on corrosion in fossil fuel power generation is available in the article "Corrosion in Fossil Fuel Power Plants" in this Volume; corrosion in FGD systems is also discussed in the article "Corrosion of Emission-Control Equipment" in this Volume.

(a) Slurry contained 7000 ppm dissolved Cl^-. Deposits in the quencher, inlet duct, absorber, and outlet ducting contained 3000-4000 ppm Cl^- and 800-1900 ppm F^-.

(b) Present as halide gases.

(c) Not tested.

(d) During operation.

(e) During bypass. Bypass condition gas stream contained SO_2, SO_3, HCl, HF and condensate.

Nuclear Power Applications. Type 304 stainless steel piping has been used in boiling-water nuclear reactor power plants. The operating temperatures of these reactors are about 290 °C (550 °F), and a wide range of conditions can be present during startup, operation, and shutdown. Because these pipes are joined by welding, there is a possibility of sensitization. This can result in intergranular SCC in chloride-free high-temperature water that contains small amounts of oxygen, for example, 0.2 to 8 ppm. Nondestructive electrochemical tests have been used to evaluate weldments for this service (Ref 26).

Type 304 stainless steel with additions of boron (about 1%) has been used to construct spent-fuel storage units, dry storage casks, and transportation casks. The high boron level provides neutron-absorbing properties. More information on nuclear applications is available in the article "Corrosion in the Nuclear Power Industry" in this Volume.

Pulp and Paper Industry. In the kraft process, paper is produced by digesting wood chips with a mixture of Na_2S and NaOH (white liquor). The products is transferred to the brown stock washers to remove the liquor (black liquor) from the brown pulp. After screening, the pulp may go directly to the paper mill to produce unbleached paper or may be directed first to the bleach plant to produce white paper.

The digester vapors are condensed, and the condensate is pumped to the brown stock washers. The black liquor from these washers is concentrated and burned with sodium sulfate (Na_2SO_4) to recover sodium carbonate (Na_2CO_3) and Na_2S. After dissolution in water, this green liquor is treated with calcium hydroxide ($Ca(OH)_2$) to produce NaOH to replenish the white liquor. Pulp bleaching involves treating with various chemicals, including chlorine, chlorine dioxide (ClO_2), sodium hypochlorite (NaClO), calcium hypochlorite ($Ca(ClO)_2$), peroxide, caustic soda, quicklime, or oxygen.

The sulfite process uses a liquor in the digester that is different from that used in the kraft process. This liquor contains free SO_2 dissolved in water, along with SO_2 as a bisulfite. The compositions of the specific liquors differ, and the pH can range from 1 for an acid process to 10 for alkaline cooking. Sulfur dioxide for the cooking liquor is produced by burning elemental sulfur, cooling rapidly, absorbing the SO_2 in a weak alkaline solution, and fortifying the raw acid.

Various alloys are selected for the wide range of corrosion conditions encountered in pulp and paper mills. Paper mill headboxes are typically fabricated from type 316L stainless steel plate with superior surface finish and are sometimes electropolished to prevent scaling, which may affect pulp flow. The blades used to remove paper from the drums have been fabricated from type 410 and 420 stainless steels and from cold-reduced 22Cr-13Ni-5Mn stainless steel.

Evaporators and reheaters must deal with corrosive liquors and must minimize scaling to provide optimum heat transfer. Type 304 stainless steel ferrite-free welded tubing has been used in kraft black liquor evaporators. Cleaning is often performed with HCl, which attacks ferrite. In the sulfite process, type 316 ($\geq$2.75% Mo) and type 317 stainless steels have been used in black liquor evaporators. Digester liquor heaters in the kraft and sulfite processes have used 7-Mo stainless for resistance to caustic or chloride SCC.

Bleach plants have used type 316 and 317 stainless steels and are upgrading to austenitic grades containing 4.5 and 6% Mo in problem locations. Tightening of environmental regulations has generally increased temperature, chloride level, and acidity in the plant, and this requires grades of stainless steel that are more highly alloyed than those used in the past. Tall oil units have shifted from type 316 and 317 stainless steels to such candidate alloys as 904L or 20Mo-4 stainless steels and most recently to 254SMO and 20Mo-6 stainless steels.

Tests including higher-alloyed materials have been coordinated by the Metals Subcommittee of the TAPPI Corrosion and Materials Engineering Committee. Racks of test samples, which included crevices at polytetrafluoroethylene (PTFE) spacers, were submerged in the vat below the washer in the C (chlorination), D (Chlorine dioxide), and H (hypochlorite) stages of several paper mills. The sum of the maximum attack depth on all samples for each alloy--at crevices and remote from crevices--is shown in Fig. 14(a), 14(b), and 14(c). It should be noted that the vertical axes are different in Fig. 14(a), 14(b), and 14(c). Additional information on corrosion in this industry is available in the article "Corrosion in the Pulp and Paper Industry" in this Volume.

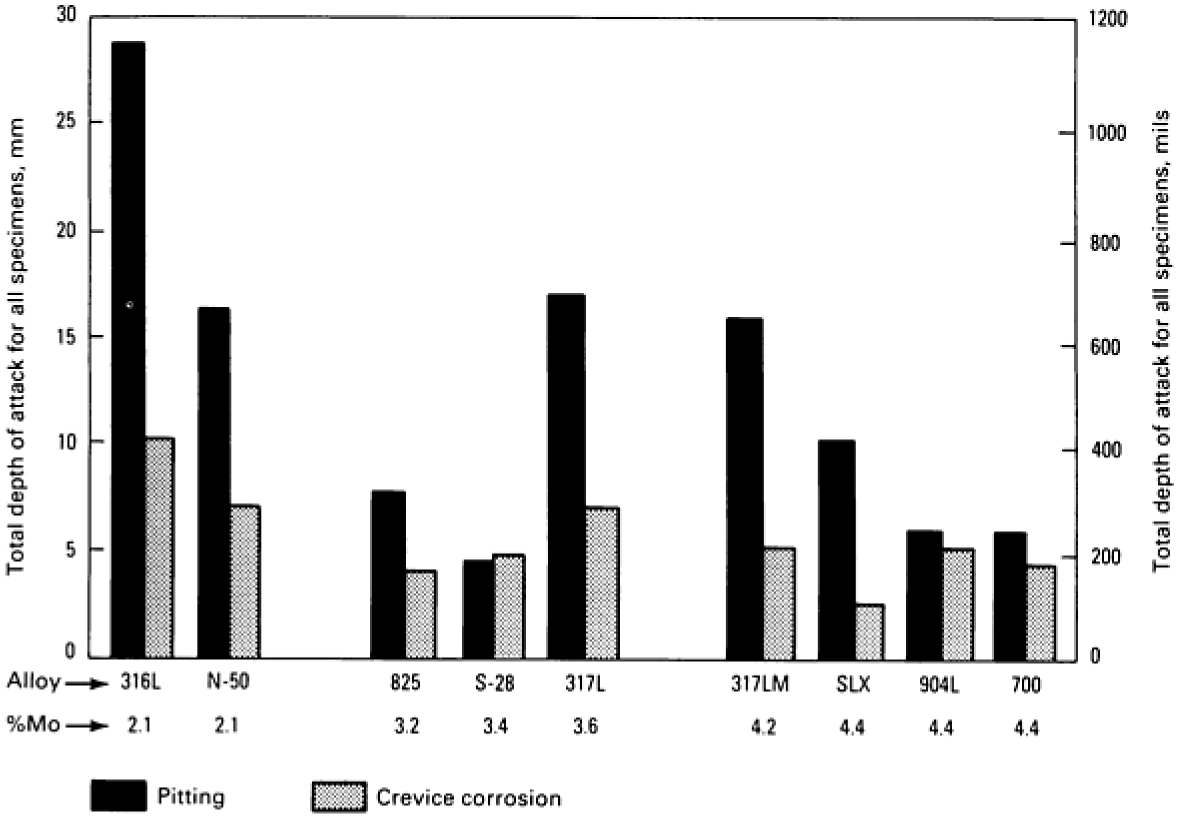

Fig. 14(a) Resistance of austenitic stainless steels containing 2.1 to 4.4% Mo to localized corrosion in paper mill bleach plant environment. Total depth of attack has been divided by 4 because there were four crevice sites per specimen. See also Fig. 14(b) and 14(c). Source: Ref 27

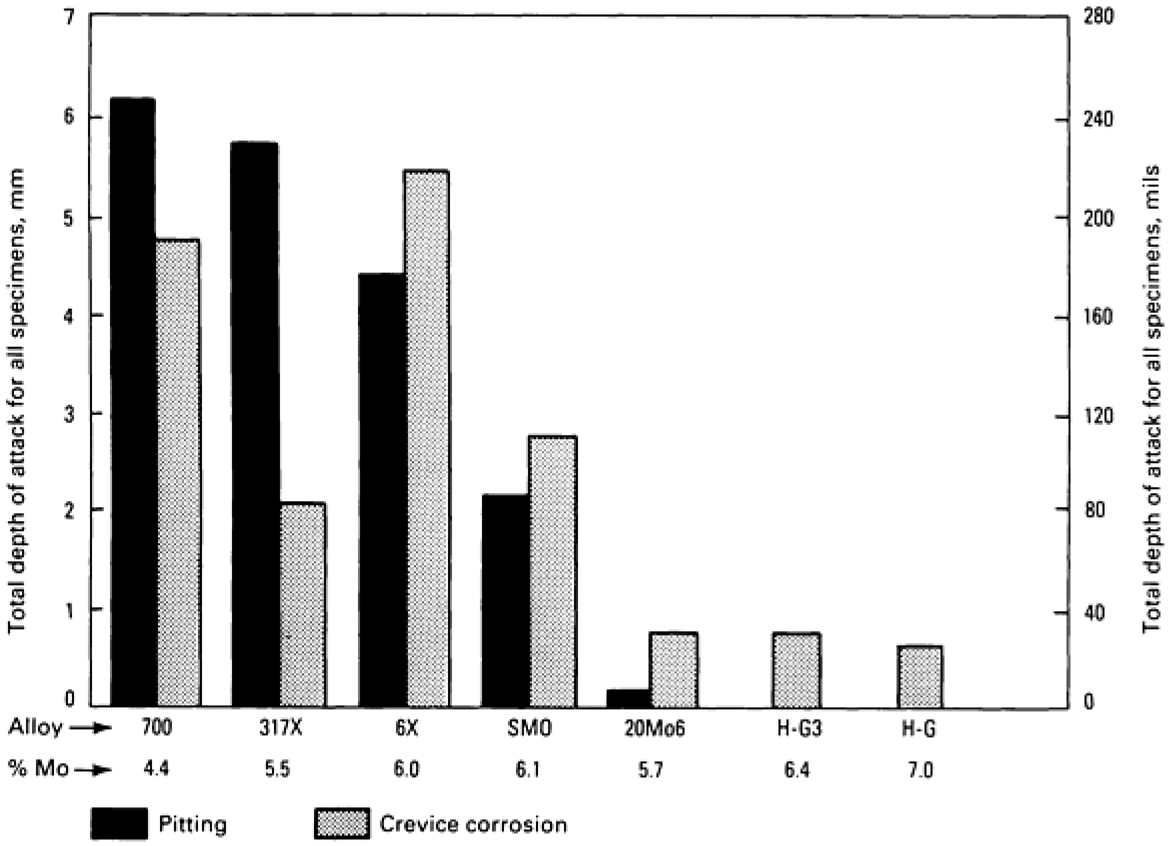

Fig. 14(b) Resistance of austenitic stainless steels containing 4.4 to 7.0% Mo to localized corrosion in paper mill bleach plant environment. Total depth of attack has been divided by 4 because there were four crevice sites per specimen. See also Fig. 14(a) and 14(c). Source: Ref 27

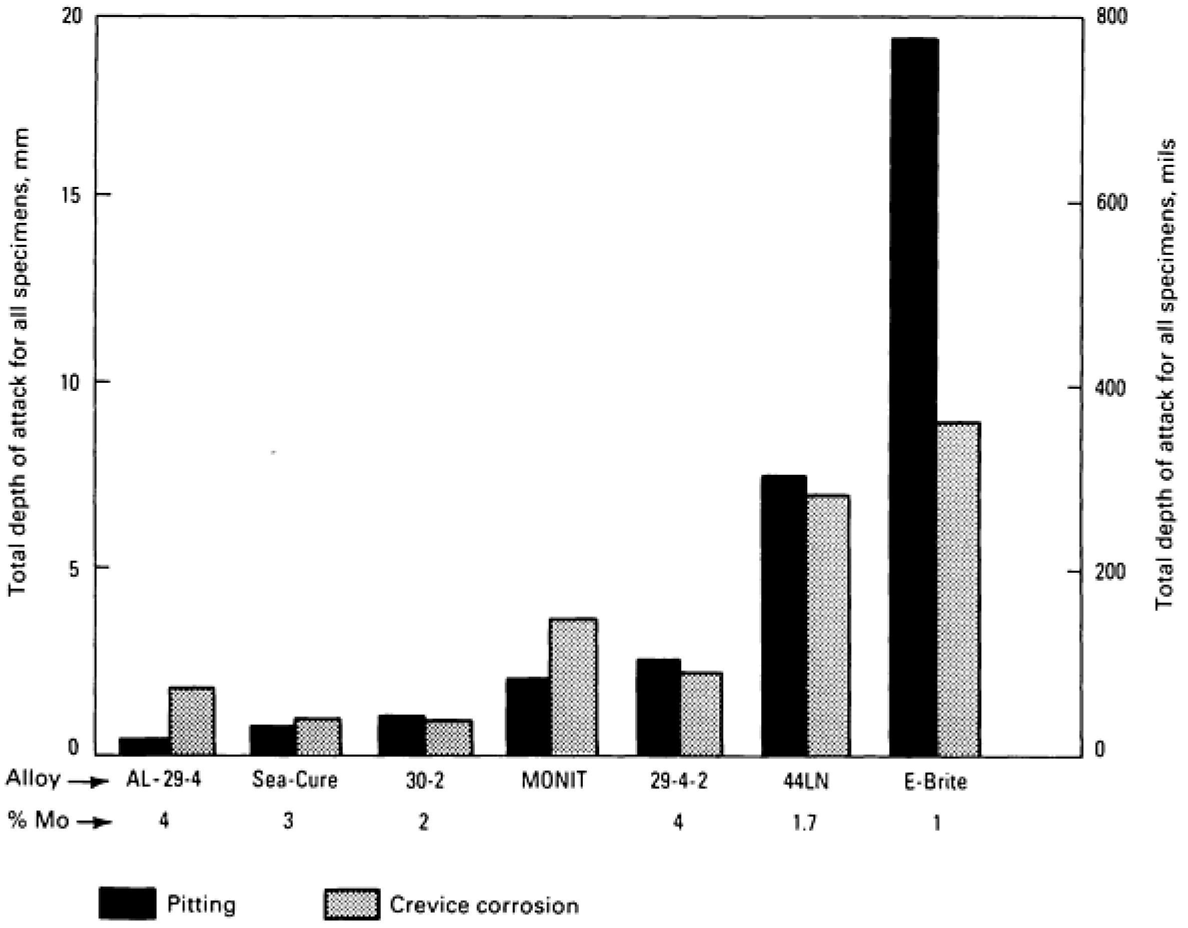

Fig. 14(c) Resistance of ferritic and duplex stainless steels to localized corrosion in paper mill bleach plant environment. Total depth of attack has been divided by 4 because there were four crevice sites per specimen. See also Fig. 14(a) and 14(b). Source: Ref 27

Transportation Industry. Stainless steels are used in a wide range of components in transportation that are both functional and decorative. Bright automobile parts, such as trim, fasteners, wheel covers, mirror mounts, and windshield wiper arms, have generally been fabricated from 17Cr or 18Cr-8Ni stainless steel of similar grades. Example alloys include type 430, 304, 304, and 305 stainless steels. Type 302HQ-FM remains a candidate for such applications as wheel nuts, and Custom 455 stainless has been used as wheel lock nuts. Use of type 301 stainless steel for wheel covers has diminished with the weight reduction programs of the automotive industry.

Stainless steels also serve many nondecorative functions in automotive design. Small-diameter shafts of type 416 and, occasionally, type 303 stainless steels have been used in connection with power equipment, such as windows, door locks, and antennas. Solenoid grades, such as type 430FR stainless steels, have also found application. Type 409 stainless steel has been used for mufflers and catalytic converters for many years, but it is now being employed throughout the exhaust system. The article "Corrosion in the Automotive Industry" in this Volume contains detailed information on corrosion in the automotive environment.

In railroad cars, external and structural stainless steels provide durability, low-cost maintenance, and superior safety through crashworthiness. The fire resistance of stainless steel is a significant safety advantage. Modified type 409 stainless steel is used as structural component in buses. Types 430 and 304 are used for exposed functional parts on buses. Type 304 stainless steel has provided economical performance in truck trailers. For tank trucks, type 304 has been the most frequently used stainless steel, but type 316 and higher-alloyed grades have been used where appropriate to carry more corrosive chemicals safely over the highways.

Stainless steels are used for seagoing chemical tankers, with types 304, 316, 317, and alloy 2205 being selected according to the corrosivity of the cargoes being carried. Conscientious adherence to cleaning procedures between cargo change-overs has allowed these grades to give many years of service with a great variety of corrosive cargoes.

In aerospace, quench-hardenable and precipitation-hardenable stainless steels have been used in varying applications. Heat treatments are chosen to optimize fracture toughness and resistance to SCC. Stainless steel grades 15-5PH and PH13-8Mo have been used in structural parts, and A286 and PH3-8Mo stainless steels have served as fasteners. Parts in cooler sections of the engine have been fabricated from type 410 or A286 stainless steel. Custom 455, 17-4PH, 17-7PH, and 15-5PH stainless steels have been used in the space shuttle program (see the articles "Corrosion in the Aircraft Industry" and "Corrosion in the Aerospace Industry" in this Volume).

Architectural Applications. Typically, type 430 or 304 has been used in architectural applications. In bold exposure these grades are generally satisfactory; however, in marine and industrially contaminated atmospheres, type 316 is often suggested and has performed well (see the article "Corrosion in Structures" in this Volume).

In all applications, but particularly in these cases where appearance is important, it is essential that any chemical cleaning solutions be thoroughly rinsed from the metal.

Corrosion Testing

The physical and financial risks involved in selecting stainless steels for particular applications can be reduced through consideration of corrosion tests. However, care must be taken when selecting a corrosion test. The test must relate to the type of corrosion possible in the application. The steel should be tested in the condition in which it will be applied. The test conditions should be representative of the operating conditions and all reasonably anticipated excursions of operating conditions.

Corrosion tests vary in their degree of simulation of operation in terms of the design of the specimen and the selection of medium and test conditions. Standard test use specimens of defined nature and geometry exposed in precisely defined media and conditions. Standard tests can confirm that a particular lot of steel conforms to the level of performance expected of a standard grade. Standard tests can also rank the performance of standard and proprietary grades. The relevance of test results to performance in particular applications increases as the specimen is made to resemble more closely the final fabricated structure--for example, bent, welded, stressed, or creviced. Relevance also increases as the test medium and conditions more closely approach the most severe operating conditions. However, many types of failures occur only after extended exposures to operating cycles. Therefore, there is often an effort to accelerate testing by increasing the severity of one or more environmental factors, such as temperature, concentration, aeration, and pH. Care must be taken that the altered conditions do not give spurious results. For example, an excessive temperature may either introduce a new failure mode or prevent a failure mode relevant to the actual application. The effects of minor constituents or impurities on corrosion are of special concern in simulated testing.

Pitting and crevice corrosion are readily tested in the laboratory by using small coupons and controlled-temperature conditions. A procedure for such tests using 6% $FeCl_3$ (10% $FeCl_3 \cdot 6H_2O$) is described in ASTM G 48 (Ref 28). This procedure is performed in 3 days. The coupon may be evaluated in terms of weight loss, pit depth, pit density, and appearance. Several suggestions for methods of pitting evaluation are given in ASTM G 46 (Ref 29). Reference 28 also describes the construction of a crevice corrosion coupon (Fig. 15). It is possible to determine a temperature below which crevice corrosion is not initiated for a particular material and test environment. This critical crevice temperature (CCT) provides a useful ranking of stainless steels. For the CCT to be directly applicable in design, it is necessary to determine that the test medium and conditions relate to the most severe conditions to be encountered in service.

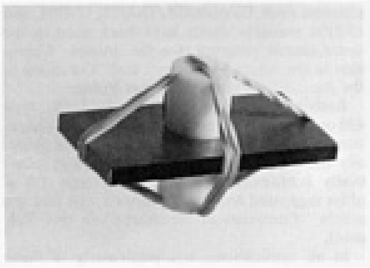

Fig. 15 Assembled crevice corrosion test specimen. Source: Ref 30

Figure 16 shows one of several frequently used specimens with a multiple crevice assembly. The presence of many separate crevices helps to deal with the statistical nature of corrosion initiation. The severity of the crevices can be regulated by means of a standard crevice design and the use of a selected torque in its application.

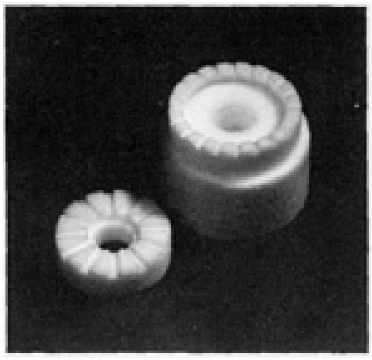

Fig. 16 Multiple-crevice cylinders for use in crevice corrosion testing. Source: Ref 30

Laboratory media do not necessarily have the same response of corrosivity as a function of temperature as do engineering environments. For example, the ASTM G 48 solution is thought to be roughly comparable to seawater at ambient temperatures. However, the corrosivity of $FeCl_3$ increases steadily with temperature. The response of seawater to increasing temperature is quite complex, relating to such factors as concentration of oxygen and biological activity. Also, the various families of stainless steels will be internally consistent, but will differ from one another in response to a particular medium.

Pitting and crevice corrosion may also be evaluated by electrochemical techniques. When immersed in a particular medium a metal coupon will assume a potential that can be measured relative to a standard reference electrode. It is then possible to impress a potential on the coupon and observe the corrosion as measured by the resulting current. Various techniques of scanning the potential range provide extremely useful data on corrosion resistance. Figure 17 demonstrates a simplified view of how these tests may indicate the corrosion resistance for various materials and media.

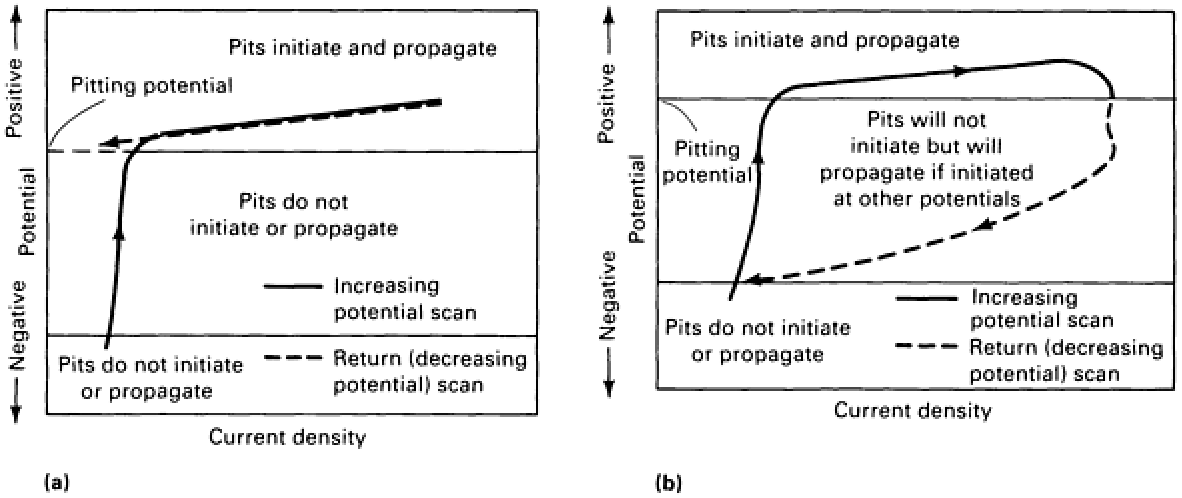

Fig. 17 Schematics showing how electrochemical tests can indicate the susceptibility to pitting of a material in a given environment. (a) Specimen has good resistance to pitting. (b) Specimen has poor resistance to pitting. In both cases, attack occurs at the highest potentials. Source: Ref 30

The nature of intergranular sensitization has been discussed earlier in this article. There are many corrosion tests for detecting susceptibility to preferential attack at the grain boundaries. The appropriate media and test conditions vary widely for the different families of stainless steels. Table 11 summarizes the ASTM tests for intergranular sensitization. Figure 18 shows that electrochemical techniques may also be used, as in the electrochemical potentiostatic reactivation (EPR) test.

Table 11 ASTM standard tests for susceptibility to intergranular corrosion in stainless alloys

ASTM test method	Test medium and duration	Alloys	Phases detected
A 262, practice A	Oxalic acid etch; etch test	AISI types 304, 304L, 316, 316L, 317L, 321, 347 casting alloys	Chromium carbide
A 262, practice B	$Fe_2(SO_4)_3$-H_2SO_4; 120 h	Same as above	Chromium carbide, σ phase[a]
A 262, practice C	HNO_3 (Huey test); 240 h	Same as above	Chromium carbide, σ phase[b]
A 262, practice D	HNO_3-HF; 4 h	AISI types 316, 316L, 317, 317L,	Chromium carbide
A 262, practice E	$CuSO_4$-16%H_2SO_4, with copper contact; 24 h	Austenitic stainless steels	Chromium carbide
A 708 (formerly A 393)	$CuSO_4$-16%H_2SO_4, without copper contact; 72 h	Austenitic stainless steels	Chromium carbide

G 28	$Fe_2(SO_4)_3$-H_2SO_4; 24-120 h	Hastelloy alloys C-276 and G; 20Cb-3; Inconel alloys 600, 625, 800, and 825	Carbide and/or intermetallic phases[(c)]
A 763, practice X	$Fe_2(SO_4)_3$-H_2SO_4; 24-120 h	AISI types 403 and 446; E-Brite, 29-4, 29-4-2	Chromium carbide and nitride intermetallic phases[(d)]
A 763, practice Y	$CuSO_4$-50% H_2SO_4; 96-120 h	AISI types 446, XM27, XM33, 29-4, 29-4-2	Chromium carbide and nitride
A 763, practice Z	$CuSO_4$-16% H_2SO_4; 24 h	AISI types 430, 434, 436, 439, 444	Chromium carbide and nitride

(d) Detects χ and σ phases, which do not cause intergranular attack in unstabilized iron-chromium-molybdenum alloys.

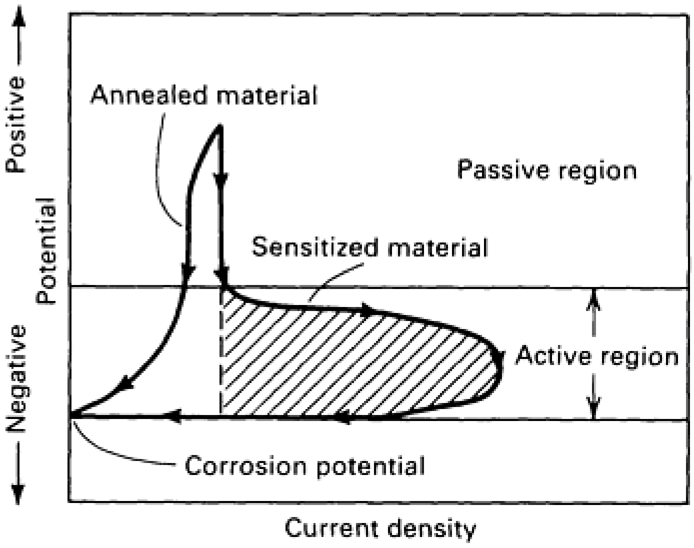

Fig. 18 Schematic showing the use of the EPR test to evaluate sensitization. The specimen is first polarized up to a passive potential at which the metal resists corrosion. Potential is then swept back through the active region, where corrosion may occur. Source: Ref 30

Stress-corrosion cracking covers all types of corrosion involving the combined action of tensile stress and corrodent. Important variables include the level of stress, the presence of oxygen, the concentration of corrodent, temperature, and the conditions of heat transfer. It is important to recognize the type of corrodent likely to produce cracking in a particular family of steel. For example, austenitic stainless steels are susceptible to chloride SCC (Table 12). Martensitic and ferritic grades are susceptible to cracking related to hydrogen embrittlement.

Table 12 Stress-corrosion cracking resistance of stainless steels

Grade	Stress-corrosion cracking test[a]		
	Boiling 42% $MgCl_2$	**Wick test**	**Boiling 25% NaCl**
AISI type 304	F[b]	F	F
AISI type 316	F	F	F
AISI type 317	F	[P[c] or F][d]	(P or F)

(a) U-bend tests, stressed beyond yielding.

(b) Fails, cracking observed.

(c) Passes, no cracking observed.

(d) Susceptibility of grade to SCC determined by variation of composition within specified range.

(e) Susceptibility of grade to SCC determined by variation of thermal history.

It is important to realize that corrosion tests are designed to single out one particular corrosion mechanism. Therefore, determining the suitability of a stainless steel for a particular application will usually require consideration of more than one type of test. No single chemical or electrochemical test has been shown to be an all-purpose measure of corrosion resistance. More information on corrosion testing is available in the Section "Corrosion Testing and Evaluation" in this Volume.

Corrosion of Cast Irons

Donald R. Stickle, The Duriron Company, Inc.

Introduction

CAST IRON is a generic term that identifies a large family of ferrous alloys. Cast irons are primarily alloys of iron that contain more than 2% carbon and 1% or more silicon. Low raw material costs and relative ease of manufacture make cast irons the least expensive of the engineering metals. Cast irons can be cast into intricate shapes because of their excellent fluidity and relatively low melting points and can be alloyed for improvement of corrosion resistance and strength. With proper alloying, the corrosion resistance of cast irons can equal of exceed that of stainless steels and nickel-base alloys.

Because of the excellent properties obtainable with these low-cost engineering materials, cast irons fluid wide application in environments that demand good corrosion resistance. Services in which cast irons are used for their excellent corrosion resistance include water, soils, acids, alkalies, saline solutions, organic compounds, sulfur compounds, and liquid metals. In some services, alloyed cast irons offer the only economical alternative for constructing equipment.

Basic Metallurgy of Cast Irons

The metallurgy of cast irons is similar to that of steels except that sufficient silicon is present to necessitate use of the iron-silicon-carbon ternary phase diagram rather than the simple iron-carbon binary diagram. Figure 1 shows a section of the iron-iron carbide-silicon ternary diagram at 2% Si. The eutectic and eutectoid points in the iron-silicon-carbon diagram are both affected by the introduction of silicon into the system. In the 1 to 3% Si levels normally found in cast irons, eutectic carbon levels are related to silicon levels as follows:

$$\%C + \frac{1}{3}(\%Si) = 4.3 \qquad \textbf{(Eq 1)}$$

where %C is the eutectic carbon level, and %Si is the silicon level in the cast iron. The metallurgy of cast iron can occur in the metastable iron-iron carbide system, the stable iron-graphite system, or both. This causes structures of cast irons to be more complex than those of steel and more susceptible to processing conditions.

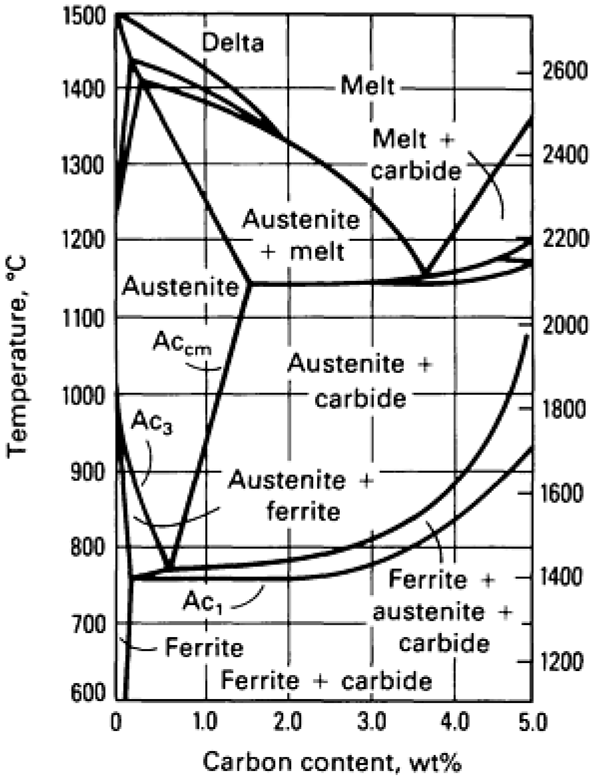

Fig. 1 Section of the iron-iron carbide-silicon ternary phase diagram at 2% Si

An appreciable portion of carbon in cast irons separates during solidification and appears as a separate constituent in the microstructure. The level of silicon in the cast iron has a strong effect on the manner in which carbon segregates in the microstructure. Higher silicon levels favor the formation of graphite, but lower silicon levels favor the formation of iron carbides. The form and shape in which the carbon occurs determine the type of cast iron (Table 1).

Table 1 Summary of cast iron classification based on carbon form and shape

Type of cast iron	Carbon form and shape
White cast iron	Iron carbide compound
Malleable cast iron	Irregularly shaped nodules of graphite
Gray cast iron	Graphite flakes
Ductile cast iron	Spherical graphite nodules
Compacted graphite cast iron	Short, fat interconnected flakes (intermediate between ductile and gray cast iron)

The structure of the metal matrix around the carbon-rich constituent establishes the class of iron within each type of iron. Four basic matrix structures occur in cast iron: ferrite, pearlite, bainite, and martensite.

Ferrite is generally a soft constituent, but it can be solid solution hardened by silicon. When silicon levels are below 3%, the ferrite matrix is readily machined, but exhibits poor wear resistance. Above 14% Si, the ferritic matrix becomes very hard and wear resistant, but is essentially nonmachinable. The low carbon content of the ferrite phase makes hardening difficult. Ferrite can be observed in cast irons upon solidification, but is generally present as the result of special annealing heat treatments. High silicon levels promote the formation of ferritic matrices in the as-cast condition.

Pearlite consists of alternate layers of ferrite and iron carbide (Fe_3C, or cementite). It is very strong and tough. The hardness, strength, machinability, and wear resistance of pearlitic matrices vary with the fineness of its laminations. The carbon content of pearlite is variable and depends on the analysis of the iron and its cooling rate.

Bainite is an acicular structure in cast ions that can be obtained by heat treating, alloying, or combinations of these. Bainitic structures provide very high strength at a machinable hardness.

Martensitic structures also occur in cast irons. These structures can be obtained by alloying, heat treating, or a combination of these practices. Martensitic microstructures are the hardest, most wear-resistant structures obtainable in cast ions. Molybdenum, nickel, manganese, and chromium can be used to produce martensitic or bainitic structures. Silicon has a negative effect on martensite formation, because it promotes the formation of pearlite or ferrite.

Influence of Alloying

Alloying elements can play a dominant role in the susceptibility of cast ions to corrosion attack. The alloying elements generally used to enhance the corrosion resistance of cast ions include silicon, nickel, chromium, copper, and molybdenum. Other alloying elements, such as vanadium and titanium, are sometimes used, but not to the extent of the five elements mentioned.

Silicon is the most important alloying element used to improve the corrosion resistance of cast irons. Silicon is generally not considered an alloying element in cast ions until levels exceed 3%. Silicon levels between 3 and 14% offer some increase in corrosion resistance to the alloy, but above about 14% Si, the corrosion resistance of the cast iron increases dramatically. Silicon levels up to 17% have been used to enhance the corrosion resistance of the alloy further, but silicon levels over 16% make the alloy extremely brittle and difficult to manufacture. Even at 14% Si, the strength and ductility of the material is low, and special design and manufacturing parameters are required to produce and use these alloys.

Alloying with silicon promotes the formation of strongly adherent surface films in cast irons. Considerable time may be required to establish these films fully on the castings. Consequently, in some services, corrosion rates may be relatively high for the first few hours or even days of exposure, then may decline to extremely low steady-state rates for the rest of the time the parts are exposed to the corrosive environment (Fig. 2).

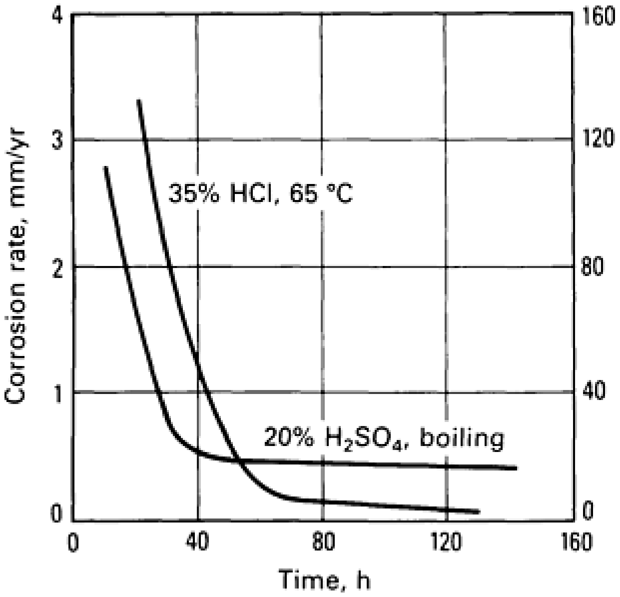

Fig. 2 Corrosion rates of high-silicon cast irons as a function of time and corrosive media

Nickel is used to enhance the corrosion resistance of cast irons in a number of applications. Nickel increases corrosion resistance by the formation of protective oxide films on the surfaces of the castings. Up to 4% Ni is added in combination with chromium to improve both strength and corrosion resistance in cast iron alloys. The enhanced hardness and corrosion resistance obtained is particularly important for improving the erosion-corrosion resistance of the material. Nickel additions enhance the corrosion resistance of cast irons to reducing acids and alkalies. Nickel additions of 12% or greater are necessary to optimize the corrosion resistance of cast irons.

Nickel is not as common an alloying addition as either silicon or chromium for enhancing the corrosion resistance in cast irons. It is much more important as a strengthening and hardening addition.

Chromium is frequently added alone and in combination with nickel and/or silicon to increase the corrosion resistance of cast irons. As with nickel, small additions of chromium are used to refine graphite and matrix microstructures. These refinements enhance the corrosion resistance of cast irons in seawater and weak acids. Chromium additions of 15 to 30% improve the corrosion resistance of cast irons to oxidizing acids, such as nitric acid (HNO_3).

Chromium increases the corrosion resistance of cast iron by the formation of protective oxides on the surfaces of castings. The oxides formed will resist oxidizing acids, but will be of little benefit under reducing conditions. High chromium additions, like higher silicon additions, reduce the ductility of cast irons.

Copper is added to cast irons in special cases. Copper additions of 0.25 to 1% increase the resistance of cast iron to dilute acetic (CH_3COOH), sulfuric (H_2SO_4), and hydrochloric (HCl) acids as well as acid mine water. Small additions of copper are also made to cast irons to enhance atmospheric-corrosion resistance. Additions of up to 10% are made to some high nickel-chromium cast irons to increase corrosion resistance. The exact mechanism by which copper improves the corrosion resistance of cast irons is not known.

Molybdenum. Although an important use of molybdenum in cast irons is to increase strength structural uniformity, it is also used to enhance corrosion resistance, particularly in high-silicon cast irons. Molybdenum is particularly useful in HCl. As little as 1% Mo is helpful in some high-silicon irons, but for optimum resistance, 3 to 4% Mo is added.

Other Alloying Additions. In general, other alloying additions to cast irons have a minimal effect on corrosion resistance. Vanadium and titanium enhance the graphite morphology and matrix structure and impart slightly increased corrosion resistance to cast irons. Few other additions are made to cast irons that have any significant effect on corrosion resistance.

Influence of Microstructure

Although the graphite shape and the amount of massive carbides present are critical to mechanical properties, these structural variables do not have a strong effect on corrosion resistance. Flake graphite structures may trap corrosion products and retard corrosion slightly in some applications. Under unusual circumstances, graphite may act cathodically with regard to the metal matrix and may accelerate attack.

The structure of the matrix has a slight influence on corrosion resistance, but the effect is small compared to that of composition. In gray irons, ferrite structure are generally the least resistant, and graphite flakes exhibit the greatest corrosion resistance. Pearlite and cementite show intermediate corrosion resistance.

Shrinkage or porosity can degrade the corrosion resistance of cast iron parts. The presence of porosity permits the corrosive medium to enter the body of the casting and can provide continuous leakage paths for corrosives in pressure-containing components.

Commercially Available Cast Irons

Based on corrosion resistance, cast irons can be grouped into five basic categories. Each will be discussed.

Unalloyed gray, ductile, malleable, and white cast irons represent the first and largest category. All of these materials contain carbon and silicon of 3% or less and no deliberate additions of nickel, chromium, copper, or molybdenum. As a group, these materials exhibit corrosion resistance that equals or slightly exceeds that of unalloyed steels, but they show the highest rates of attack for cast irons. These materials are available in a wide variety of configurations and alloys. Major ASTM standards that cover these materials are listed in Table 2.

Table 2 ASTM standards that include unalloyed cast irons

Standard	Materials/products covered
A 47	Malleable iron castings
A 48	Gray iron castings
A 74	Cast iron soil pipe and fittings
A 126	Gray iron castings for valves, flanges, and pipe fittings
A 159	Automotive gray iron castings
A 197	Cupola malleable iron
A 220	Pearlitic malleable iron castings
A 278	Gray iron castings for pressure-containing parts for temperatures up to 345 °C (650 °F)
A 319	Gray iron castings for elevated temperatures for nonpressure-containing parts
A 395	Ferritic ductile iron pressure-retaining castings for use at elevated temperatures

A 476	Ductile iron castings for paper mill dryer rolls
A 536	Ductile iron castings
A 602	Automotive melleable iron castings
A 716	Ductile iron culvert pipe
A 746	Ductile iron gravity sewer pipe

Low and moderately alloyed irons constitute the second major class. These irons contain the iron and silicon of unalloyed cast irons plus up to several percent of nickel, copper, chromium, or molybdenum. As a group, these materials exhibit two to three times the service life of unalloyed cast irons. Major ASTM standards that include these materials are listed in Table 3.

Table 3 ASTM standards that include low alloyed cast iron materials

Standard	Materials/products covered
A 159	Automotive gray iron castings
A 319	Gray iron castings for elevated temperatures for nonpressure-containing parts
A 532	Abrasion-resistant cast irons

Note: Because most cast iron standards make chemical composition subordinate to mechanical properties, many of the standards listed in Table 2 may also be used to purchase low alloyed cast iron materials.

High-nickel austenitic cast irons represent a third major class of cast irons for corrosion service. These materials contain large percentages of nickel and copper and are fairly resistant to such acids as concentrated H_2SO_4 and phosphoric (H_3PO_4) acid at slightly elevated temperatures, HCl at room temperature, and such organic acids as CH_3COOH, oleic, and stearic. When nickel levels exceed 18%, austenitic cast irons are nearly immune to alkali or caustics, although stress corrosion can occur. High-nickel cast irons can be nodularized to yield ductile irons. They can be purchased to the ASTM standards listed in Table 4.

Table 4 ASTM standards that include high-nickel austenitic cast iron materials

Standard	Materials/products covered
A 436	Austenitic gray iron castings
A 439	Austenitic ductile iron castings
A 571	Austenitic ductile iron castings for pressure-containing parts suitable for low-temperature service

High-chromium cast irons are the fourth class of corrosion-resistant cast irons. These materials are basically white cast irons alloyed with 12 to 30% Cr. Other alloying elements may also be added to improve resistance to specific environments. When chromium levels exceed 20%, high-chromium cast irons exhibit good resistance to oxidizing acids, particularly HNO_3. High-chromium irons are not resistant to reducing acids. They are used in saline solutions, organic acids, and marine and industrial atmospheres. These materials display excellent resistance to abrasion, and with proper alloying additions, they can also resist combinations of abrasives liquids, including some dilute acid solutions. High-chromium cast irons are covered in ASTM standard A 532. In addition, some proprietary alloys not covered by national standards are produced for special applications.

High-silicon cast irons represent the fifth class of corrosion-resistant cast irons. The principal alloying element is 12 to 18% Si, with more than 14.2% Si needed to develop excellent corrosion resistance. Chromium and molybdenum are also used in combination with silicon to develop corrosion resistance to specific environments. High-silicon cast irons represent the most universally corrosion-resistant alloys available at moderate cost. When silicon levels exceed 14.2% high-silicon cast irons exhibit excellent resistance to H_2SO_4, HNO_3, HCl, CH_3COOH, and most other mineral and organic acids and corrosives. These materials display good resistance in oxidizing and reducing environments and are not appreciably affected by concentration or temperature. Exceptions to universal resistance are hydrofluoric acid (HF), fluoride salts, sulfurous acid (H_2SO_3), sulfite compounds, strong alkalies, and alternating acid-alkali conditions. High-silicon cast irons are defined in ASTM standards A 518 and A 861. In addition, some proprietary compositions not included in these standards, such as alloy SD77 (Fe-4Cr-3Mo-16Si-1Mn-1C), are manufactured for high-temperature HCl service.

Forms of Corrosion

Cast irons exhibit the same general forms of corrosion as other metals and alloys. Examples of the forms of corrosion observed in cast irons include:

- Uniform or general attack
- Galvanic or two-metal corrosion
- Crevice corrosion
- Pitting
- Intergranular corrosion
- Selective leaching
- Erosion-corrosion
- Stress corrosion
- Corrosion fatigue
- Fretting corrosion

Graphite Corrosion. A form of corrosion unique to cast irons is a selective leaching attack commonly referred to as graphitic corrosion. Graphitic corrosion is observed in gray cast irons in relatively mild environments in which selective leaching of iron leaves a graphite network. Selective leaching of the iron takes place because the graphite is cathodic to iron and the gray iron structure establishes an excellent galvanic cell. This form of corrosion generally occurs only when corrosion rates are low. If the metal corrodes more rapidly, the entire surface, including the graphite, is removed, and more or less uniform corrosion occurs. Graphitic corrosion can cause significant problems because, although no dimensional changes occur, the cast iron loses its strength and metallic properties. Thus, without detection, potentially dangerous situations may develop in pressure-containing applications. Graphitic corrosion is observed only in gray cast irons. In both nodular and malleable iron, the lack of graphite flakes provides no network to hold the corrosion products together.

Fretting corrosion is commonly observed when vibration or slight relative motion occurs between parts under load. The relative resistance of cast iron to this form of attack is influenced by such variables as lubrication, hardness variations between materials, the presence of gaskets, and coatings. Table 5 compares the relative fretting resistance of cast iron under different combinations of these variables.

Table 5 Relative fretting resistance of cast iron

Poor	Average	Good
Aluminum on cast iron **Magnesium on cast iron** **Cast iron on chrome plate** **Laminated plastic on cast iron** **Bakelite on cast iron** **Cast iron on tin plate** **Cast iron on cast iron with coating of shellac**	Cast iron on cast iron Copper on cast iron Brass on cast iron Zinc on cast iron Cast iron on silver plate Cast iron on copper plate Cast iron on amalgamated copper plate Cast iron on cast iron with rough surface	Cast iron on cast iron with phosphate coating Cast iron on cast iron with coating or rubber cement Cast iron on cast iron with coating of tungsten sulfide Cast iron on cast iron with rubber gasket Cast iron on cast iron with Molykote lubricant Cast iron on stainless with Molykote lubricant

Source: Ref 1

Pitting and Crevice Corrosion. The presence of chlorides and/or crevices or other shielded areas presents conditions that are favorable to the pitting and/or crevice corrosion of cast iron. Pitting has been reported in such environments as dilute alkylaryl sulfonates, antimony trichloride ($SbCl_3$), and calm seawater. Alloying can influence the resistance of cast irons to pitting and crevice corrosion. For example, in calm seawater, nickel additions reduce the susceptibility of cast irons to pitting attack. High-silicon cast irons with chromium and/or molybdenum offer enhanced resistance to pitting and crevice corrosion. Although microstructural variations probably exert some influence on susceptibility to crevice corrosion and pitting, there are few reports of this relationship.

Intergranular attack is relatively rare in cast irons. In stainless steels, in which this type of attack is most commonly observed, intergranular attack is related to chromium depletion adjacent to grain boundaries. Because only the high-chromium cast irons depend on chromium to form passive films for resistance to corrosion attack, few instances of intergranular attack related to chromium depletion have been reported. The only reference to intergranular attack in cast irons involves ammonium nitrate (NH_4NO_3), in which unalloyed cast irons are reported to be intergranularly attacked. Because this form of selective attack is relatively rare in cast irons, no significant references to the influence of either structure or chemistry on intergranular attack have been reported.

Erosion-Corrosion. Fluid flow by itself or in combination with solid particles can cause erosion-corrosion attack in cast irons. Two methods are known to enhance the erosion-corrosion resistance of cast irons. First, the hardness of the cast irons can be increased through solid-solution hardening or phase transformation induced hardness increases. For example, 14.5% Si additions to cast irons cause substantial solid-solution hardening of the ferritic matrix. In such environments as the sulfate liquors encountered in the pulp and paper industry, this hardness increase enables high-silicon iron equipment to be successfully used, while lower-hardness unalloyed cast irons fail rapidly by severe erosion-corrosion. Use of martensitic or white cast irons can also improve the erosion-corrosion resistance of cast irons as a result of hardness increases.

Second, better inherent corrosion resistance can also be used to increase the erosion-corrosion resistance of cast irons. Austenitic nickel cast irons can have hardnesses similar to unalloyed cast irons, but may exhibit better erosion resistance because of the improved inherent resistance of nickel-alloyed irons compared to unalloyed irons. Microstructure can also affect erosion-corrosion resistance slightly. Gray cast irons generally show better resistance than steels under erosion-corrosion conditions. This improvement is related to the presence of the graphite network in the gray cast iron. Iron is corroded from the gray iron matrix as in steel, but the graphite network that is not corroded traps corrosion products; this layer of corrosion products and graphite offers additional protection against erosion-corrosion attack.

Stress-corrosion cracking (SCC) is observed in cast irons under certain combinations of environment and stress. Because stress is necessary to initiate SCC and because design factors often limit stresses in castings to relatively low levels, SCC is not observed as often in cast irons as in other more highly stressed components. However, under certain conditions, SCC can be a serious problem. Because unalloyed cast irons are generally similar to ordinary steels in resistance to corrosion, the same environments that cause SCC in steels will likely cause problems in cast irons. Environments that may cause SCC in unalloyed cast irons include (Ref 2):

- Sodium hydroxide (NaOH) solutions
- NaOH-Na_2SiO_2 solutions
- Calcium nitrate ($Ca(NO_3)_2$) solutions
- NH_4NO_3 solutions
- Sodium nitrate ($NaNO_3$) solutions
- Mercuric nitrate ($Hg(NO_3)_2$) solutions
- Mixed acids (H_2SO_4-HNO_3)
- Hydrogen cyanide (HCN) solutions
- Seawater
- Acidic hydrogen sulfide (H_2S) solutions
- Molten sodium-lead alloys
- Acid chloride solutions
- Oleum

Graphite morphology can play an important role in SCC resistance in certain environments. In oleum (fuming H_2SO_4), flake graphite structures present special problems. Acid tends to penetrate along graphite flakes and corrodes the iron matrix. The corrosion products formed build up pressure and eventually crack the iron. This problem is found in both gray irons and high-silicon irons, which have flake graphite morphologies, but is not seen in ductile irons that have nodular graphite shapes.

Resistance to Corrosive Environments

No single grade of cast iron will resist all corrosive environments. However, a cast iron can be identified that will resist most of the corrosives commonly used in industrial environments. Cast irons suitable for the more common corrosive environments are discussed below.

Sulfuric Acid. Unalloyed, low-alloyed, and high-nickel austenitic as well as high-silicon cast irons are used in H_2SO_4 applications. Use of unalloyed and low-alloyed cast iron is limited to low-velocity low-temperature concentrated (>70%) H_2SO_4 service. Unalloyed cast iron is rarely used in dilute or intermediate concentrations, because corrosion rates are substantial. In concentrated H_2SO_4 as well as other acids, ductile iron is generally considered superior to gray iron, and ferritic matrix irons are superior to pearlitic matrix irons. In hot, concentrated acids, graphitization of the gray iron can occur. In oleum, unalloyed gray iron will corrode at very low rates. However, acid will penetrate along the graphite flakes, and the corrosion product will form and build up sufficient pressure to split the iron. Interconnecting graphite is believed to be necessary to cause this form of cracking; therefore, ductile and malleable irons are generally acceptable for this service. Some potential galvanic corrosion between cast iron and steel has been reported in 100% H_2SO_4.

High-nickel austenitic cast irons exhibit acceptable corrosion resistance in room temperature and slightly elevated temperature services. As shown in Fig. 3, they are adequate over the entire range of H_2SO_4 concentrations, but are a second choice compared to high-silicon cast irons.

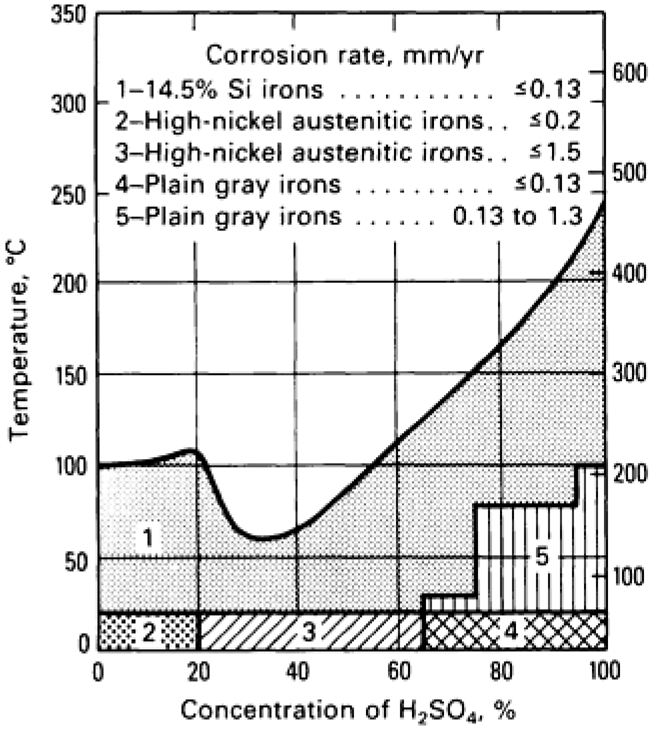

Fig. 3 Corrosion of high-nickel austenitic cast iron in H_2SO_4 as a function of acid concentration and temperature. Source: Ref 2

High-silicon cast irons are the best choice among the cast irons and perhaps among the commonly available engineering material for resistance to H_2SO_4. The material resists the entire H_2SO_4 concentration range at temperatures to boiling (Fig. 4). Rapid attack occurs at concentrations over 100% and in services containing free sulfur trioxide (SO_3). High-silicon cast irons are relatively slow to passivate in H_2SO_4 services. Corrosion rates are relatively high for the first 24 to 48 h of exposure and then decrease to very low steady-state rates (Fig. 2).

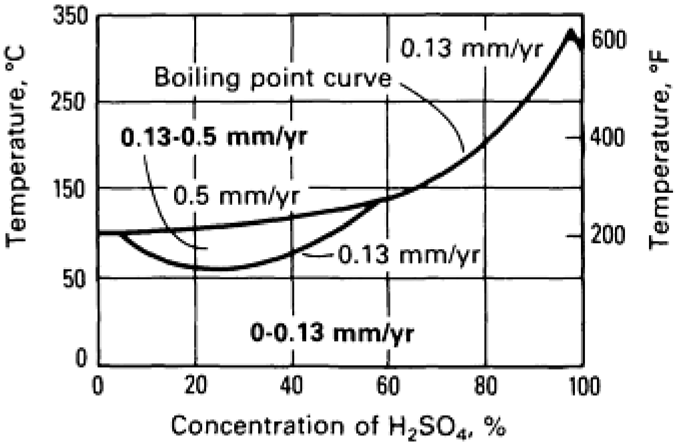

Fig. 4 Corrosion of high-silicon cast iron in H_2SO_4 as a function of acid concentration and temperature

Nitric Acid. All types of cast iron, except high-nickel austenitic iron, find some applications in HNO_3. The use of unalloyed cast iron in HNO_3 is limited to low-temperature low-velocity concentrated acid service. Even in this service, caution must be exercised to avoid dilution of acid because the unalloyed and low-alloyed cast irons both corrode very

rapidly in dilute or intermediate concentrations at any temperature. High-nickel austenitic cast irons exhibit essentially the same resistance as unalloyed cast iron to HNO_3 and cannot be economically justified for this service.

High-chromium cast irons with chromium contents over 20% give excellent resistance to HNO_3, particularly in dilute concentrations (Fig. 5). High-temperature boiling solutions attack these grades of cast iron.

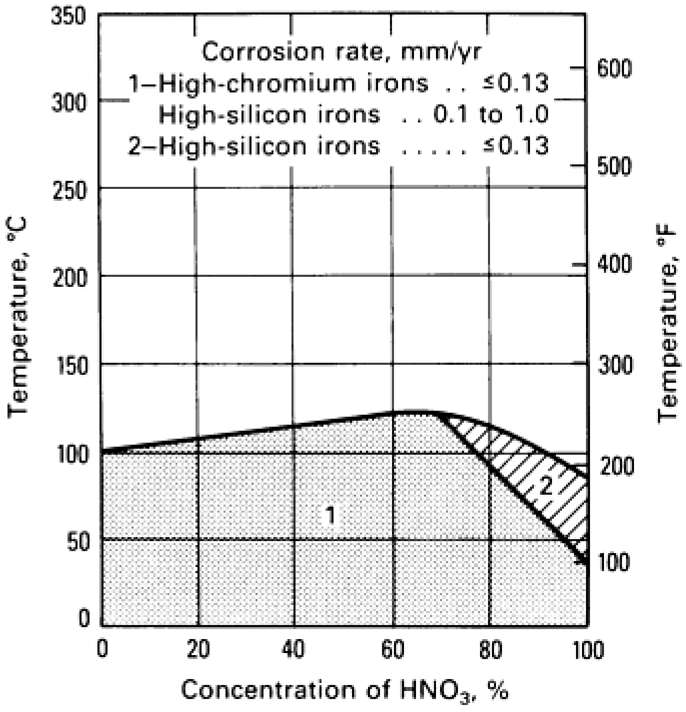

Fig. 5 Corrosion of high-chromium cast iron in HNO_3 as a function of acid concentration and temperature. Source: Ref 2

High-silicon cast irons also offer excellent resistance to HNO_3. Resistance is exhibited over essentially all concentration and temperature ranges with the exception of dilute, hot acids (Fig. 6). High-silicon cast iron equipment has been used for many years in the manufacture and handling of HNO_3 mixed with other chemicals, such as H_2SO_4, sulfates, and nitrates. Contamination of the HNO_3 with HF, such as might be experienced in pickling solutions, may accelerate attack of the high-silicon iron to unacceptable levels.

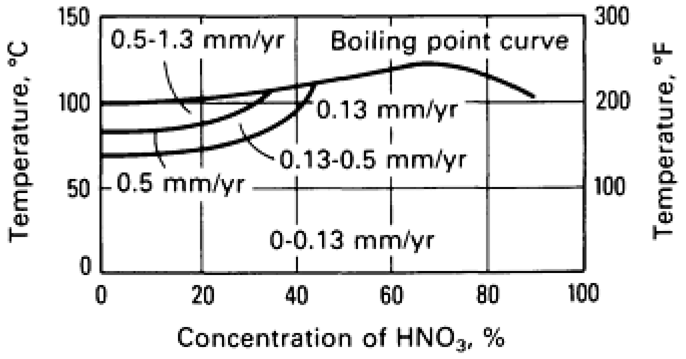

Fig. 6 Corrosion of high-silicon cast iron in HNO_3 as a function of concentration and temperature

Hydrochloric Acid. Use of cast irons is relatively limited in HCl. Unalloyed cast iron is unsuitable for any HCl service. Rapid corrosion occurs at a pH of 5 or lower, particularly if appreciable velocity is involved. Aeration or oxidizing conditions, such as the presence of metallic salts, result in rapid destructive attack of unalloyed cast irons even in very dilute HCl solutions.

High-nickel austenitic cast irons offer some resistance to all HCl concentrations at room temperature or below. High-chromium cast irons are not suitable for HCl services.

High-silicon cast irons offer the best resistance to HCl of any cast iron. When alloyed with 4 to 5% Cr, high-silicon cast iron is suitable for all concentrations of HCl to 28 °C (80 °F). When high-silicon cast iron is alloyed with chromium, molybdenum, and higher silicon levels, the temperature for use can be increased (Fig. 7). In concentrations up to 20%, ferric ions (Fe^{3+}) or other oxidizing agents inhibit corrosion attack on high-silicon iron alloyed with chromium. At over 20% acid concentration, oxidizers accelerate attack on the alloy. As in H_2SO_4, corrosion rates in high-silicon cast iron are initially high in the first 24 to 48 h of exposure then decrease to very low steady-state rates (Fig. 2).

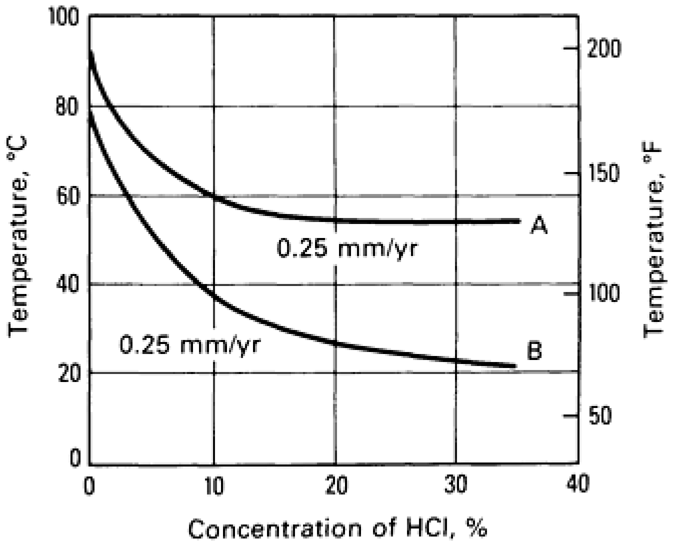

Fig. 7 Isocorrosion diagram for two high-silicon cast irons in HCl. A, Fe-14.3Si-4Cr-0.5Mo; B, Fe-16Si-4Cr-3Mo

Phosphoric Acid. All cast irons find some application in H_3PO_4, but the presence of contaminants must be carefully evaluated before selecting a material for this service. Unalloyed cast iron finds little use in H_3PO_4, with the exception of concentrated acids. Even in concentrated acids, use may be severely limited by the presence of fluorides, chlorides, or H_2SO_4.

High-nickel cast irons find some application in H_3PO_4 at and slightly above room temperature. These cast irons can be used over the entire H_3PO_4 concentration range. Impurities in the acid may greatly restrict the applicability of this grade of cast iron.

High-chromium cast irons exhibit generally low rates of attack in H_3PO_4 up to 60% concentration. High-silicon cast irons show good-to-excellent resistance at all concentrations and temperatures or pure acid. The presence of fluoride ions (F^-) in H_3PO_4 makes the high-silicon irons unacceptable for use.

Organic acids and compounds are generally not as corrosive as mineral acids; consequently, cast irons find many applications in handling these materials. Unalloyed cast iron can be used to handle concentrated CH_3COOH and fatty acids, but will be attacked by more dilute solutions. Unalloyed cast irons are used to handle methyl, ethyl, butyl, and amyl alcohols. If the alcohols are contaminated with water an air, discoloration of the alcohols may occur. Unalloyed cast irons can also be used to handle glycerine, although slight discoloration of the glycerine may result.

Austenitic nickel cast irons exhibit adequate resistance to CH_3COOH, oleic acid, and stearic acid. High-chromium cast irons are adequate for CH_3COOH, but will be more severely corroded by formic acid (HCOOH). High-chromium cast irons are excellent for lactic and citric solutions.

High-silicon cast irons show excellent resistance to most organic acids, including HCOOH and oxalic acid, in all temperature and concentration ranges. High-silicon cast irons also exhibit excellent resistance to alcohols and glycerine.

Alkali solutions require material selections that are distinctly different from those of acid solutions. Alkalies include NaOH, potassium hydroxide (KOH), sodium silicate (Na_2SiO_3), and similar chemicals that contain sodium, potassium, or lithium.

Unalloyed cast irons exhibit generally good resistance to alkalies--approximately equivalent to that of steel. These unalloyed cast irons are not attacked by dilute alkalies at any temperature. Hot Alkalies at concentrations exceeding 30% attack unalloyed iron. Temperatures should not exceed 80 °C (175 °F) for concentrations up to 70% if corrosion rates of less than 0.25 mm/yr (10 mils/yr) are desired. Ductile and gray iron exhibit about equal resistance to alkalies; however, ductile iron is susceptible to cracking in highly alkaline solutions, but gray iron is not. Alloying with 3 to 5% Ni substantially improves the resistance of cast irons to alkalies. High-nickel austenitic cast irons offer even better resistance to alkalies than unalloyed or low-nickel cast irons.

High-silicon cast irons show good resistance to relatively dilute solutions of NaOH at moderate temperatures, but should not be applied for more concentrated conditions at elevated temperatures. High-silicon cast irons are usually economical over unalloyed and nickel cast irons in alkali solutions only when other corrosives are involved for which the lesser alloys are unsuitable. High-chromium cast irons have inferior resistance to alkali solutions and are generally not recommended for alkali services.

Atmospheric corrosion is basically of interest only for unalloyed and low-alloy cast irons. Atmospheric corrosion rates are determined by the relative humidity and the presence of various gases and solid particles in the air. The high humidity, sulfur dioxide (SO_2) or similar compounds found in many industrialized areas, and chlorides found in marine atmospheres increase the rate of attack on cast irons.

Cast irons typically exhibit very low corrosion rates in industrial environments--generally under 0.13 mm/yr (5 mils/yr)--and the cast irons are usually found to corrode at lower rates than steel structures in the same environment. White cast irons show the lowest rate of corrosion of the unalloyed materials. Pearlitic irons are generally more resistant that ferritic irons to atmospheric corrosion.

In marine atmospheres, unalloyed cast irons also exhibit relatively low rates of corrosion. Low alloy additions are sometimes made to improve corrosion resistance further. Higher alloy additions are even more beneficial, but are rarely warranted. Gray iron offers some added resistance over ductile iron in marine atmospheres.

Corrosion in Soils. Cast iron use in soils, as in atmospheric corrosion, is basically limited to unalloyed and low-alloyed cast irons. Corrosion in soils is a function of soil porosity, drainage, and dissolved constituents in the soil. Irregular soil contact can cause pitting, and poor drainage increases corrosion rates substantially above the rates in well-drained soils.

Neither metal structure nor graphite morphology has an important influence on the corrosion of cast irons in soils. Some alloying additions are made to improve the resistance of cast irons to attack in soils. For example, 3% Ni additions to cast iron are made to reduce initial attack in cast irons in poorly drained soils. Alloyed cast irons would exhibit better resistance than unalloyed or low-alloyed cast irons, but are rarely needed for soil applications, because unalloyed cast irons generally have long service lives.

Anodes placed in soils are frequently constructed from high-silicon cast iron. The high-silicon cast iron is not needed to resist the basic soil environment but rather to extend service life when subjected to the high electrical current discharge rates commonly used in protective anodes.

Corrosion in Water. Unalloyed and low-alloyed cast irons are the primary cast irons used in water. The corrosion resistance of unalloyed cast iron in water is determined by its ability to form protective scales. In hard water, corrosion rates are generally low because of the formation of calcium carbonate ($CaCO_3$) scales on the surface of the iron. In softened or deionized water, the protective scales cannot be fully developed, and some corrosion will occur.

In industrial waste waters, corrosion rates are primarily a function of the contaminants present. Acid pH waters increase corrosion, but alkaline pH waters lower rates. Chlorides increase the corrosion rates of unalloyed cast irons, although the influence of chlorides is small at a neutral pH.

Seawater presents some special problems for cast irons. Gray iron may experience graphitic corrosion in calm seawater. It will also be galvanically active in contact with most stainless steels, copper-nickel alloys, titanium, and Hastelloy C. Because these materials are frequently used in seawater structures, this potential for galvanic corrosion must be considered. In calm seawater, the corrosion resistance of cast iron is not greatly affected by the presence of crevices. However, intermittent exposure to seawater is very corrosive to unalloyed cast irons.

Use of high-alloy cast irons in water is relatively limited. High-nickel austenitic cast irons are used to increase the resistance of cast iron components to pitting in calm seawater. High-silicon cast iron is used to produce anodes for the anodic protection systems used in seawater and brackish water.

Corrosion in Saline Solutions. The presence of salts in water can have dramatic effects on the selection of suitable grades of cast iron. Unalloyed cast irons exhibit very low corrosion in such salts as cyanides, silicates, carbonates, and sulfides, which hydrolyze to form alkaline solutions. However, in salts such as ferric chloride ($FeCl_3$), cupric chloride ($CuCl_2$), stannic salts, and mercuric salts, which hydrolyze to form acid solutions, unalloyed cast irons experience much higher rates. In salts that form dilute acid solutions, high-nickel cast irons are acceptable. More acidic and oxidizing salts, such as $FeCl_3$, usually necessitate the use of high-silicon cast irons.

Chlorides and sulfates of alkali metals yield neutral solutions, and unalloyed cast iron experiences very low corrosion rates in these solutions. More highly alloyed cast irons also exhibit low rates, but cannot be economically justified for this application.

Unalloyed cast irons are suitable for oxidizing salts, such as chromates, nitrates, nitrites, and permanganates, when the pH is neutral or alkaline. However, if the pH is less than 7, corrosion rates can increase substantially. At the lower pH with oxidizing salts, high-silicon cast iron is an excellent material selection.

Ammonium salts are generally corrosive to unalloyed iron. High-nickel, high-chromium, and high-silicon cast irons provide good resistance to these salts.

Other Environments. Unalloyed cast iron is used as a melting crucible for such low-melting metals as lead, zinc, cadmium, magnesium, and aluminum. Resistance to molten metals is summarized in Table 6. Ceramic coatings and washes are sometimes used to inhibit metal attack on cast irons.

Table 6 Resistance of gray cast iron to liquid metals at 300 and 600 °C (570 and 1110 °F)

Liquid metal	Liquid metal melting point, °C	Resistance of gray cast iron[a]	
		300 °C (570 °F)	**600 °C (1110 °F)**
Mercury	-38.8	Unknown	Unknown
Sodium, potassium, and mixtures	-12.3 to 97.9	Limited	Poor
Gallium	29.8	Unknown	Unknown
Bismuth-lead-tin	97	Good	Unknown
Bismuth-lead	125	Unknown	Unknown
Tin	321.9	Limited	Poor
Bismuth	271.3	Unknown	Unknown
Lead	327	Good at 327 °C (621 °F)	Unknown
Indium	156.4	Unknown	Unknown
Lithium	186	Unknown	Unknown
Thallium	303	Unknown	Unknown
Cadmium	321	Good at 321 °C (610 °F)	Good
Zinc	419.5	. . .	Poor
Antimony	630.5	. . .	Poor at 630.5 °C (1167 °F)
Magnesium	651	. . .	Good at 651 °C (1204 °F)
Aluminum	660	. . .	Poor at 660 °C (1220 °F)

Source: Ref 3

(a) Good, considered for long-time use, <0.025 mm/yr (<1.0 mil/yr); Limited, short-time use only, 0.025-0.25 mm/yr (1.0-10 mils/yr); Poor, no structural possibilities, >0.25 mm/yr (>10 mils/yr); Unknown, no data for these temperatures.

Cast iron can also be used in hydrogen chloride and chloride gases. In dry hydrogen chloride, unalloyed cast iron is suitable to 205 °C (400 °F), while in dry chlorine, unalloyed cast iron is suitable to 175 °C (350 °F). If moisture is present, unalloyed cast iron is unacceptable at any temperature.

Coatings

Four general categories of coatings are used on cast irons to enhance corrosion resistance: metallic, organic, conversion, and enamel coatings. Coatings on cast irons are generally used to enhance the corrosion resistance of unalloyed and low-alloy cast irons. High-alloy cast irons are rarely coated.

Metallic coatings are used to enhance the corrosion resistance of cast irons. These coatings may either be sacrificial metal coatings, such as zinc, or barrier metal coatings, such as nickel-phosphorus. From a corrosion standpoint, these two classes of coatings have important differences. Sacrificial coatings are anodic when compared to iron, and the coatings corrode preferentially and protect the cast iron substrate. Small cracks and porosity in the coatings have a minimal overall effect on the performance of the coatings. Barrier coatings are cathodic compared to iron, and the coatings can protect the cast iron substrate only when porosity or cracks are not present. If there are defects in the coatings, the service environment will attack the cast iron substrate at these imperfections, and the galvanic couple set up between the relatively inert coating and the casting may accelerate attack on the cast iron.

Several methods are used to apply metallic coatings to cast iron. Cast irons may be electroplated, hot dipped, flame sprayed, diffusion coated, or hard faced. Table 7 lists the metals that can be applied by these various techniques.

Table 7 Summary of metallic coating techniques to enhance corrosion resistance of cast irons

Coating technique	Metals/alloys applied
Electroplating	Cadmium, chromium, copper, lead, nickel, zinc, tin, tin-nickel, brass, bronze
Hot dipped	Zinc, tin, lead, lead-tin, aluminum
Hard facing	Cobalt-base alloys, nickel-base alloys, metal carbides, high-chromium ferrous alloys, high-manganese ferrous alloys, high chromium and nickel ferrous alloys
Flame spraying	Zinc, aluminum, lead, iron, bronze, copper, nickel, ceramics, cermets
Diffusion coating	Aluminum, chromium, nickel-phosphorus, zinc, nitrogen, carbon

Zinc is one of the most widely used coatings on cast irons. Although zinc is anodic to iron, its corrosion rate is very low, and it provides relatively long-term protection for the cast iron substrate. A small amount of zinc will protect a large area of cast iron. Zinc coatings provide optimum protection in rural or arid areas.

Other metal coatings are also commonly used on cast irons. Cadmium provides atmospheric protection similar to that of zinc. Tin coatings are frequently used to improve the corrosion resistance of equipment intended for food handling, and aluminum coatings protect against corrosive environments containing sulfur fumes, organic acids, salts, and compounds of nitrate-phosphate chemicals. Lead and lead-tin coating are primarily applied to enhance the corrosion resistance of iron castings to H_2SO_3 and H_2SO_4. Nickel-phosphorus diffusion coatings offer corrosion resistance approaching that obtainable with stainless steel.

Organic coatings can be applied to cast irons to provide short-term or long-term corrosion resistance. Short-term rust preventatives include oil, solvent-petroleum-base inhibitors and film formers dissolved in petroleum solvents, emulsified-petroleum-base coatings modified to form a stable emulsion in water, and wax.

For longer-term protection and resistance to more corrosive environments, rubber-base coatings, bituminous paints, asphaltic compounds, or thermoset and thermoplastic coatings can be applied. Rubber-case coatings include chlorinated rubber neoprene, and Hypalon. These coatings are noted for their mechanical properties and corrosion resistance but not for their decorative appearance. Bituminous paints have very low water permeability and provide high resistance in cast iron castings exposed to water. Use of bituminous paints is limited to applications that require good resistance to water, weak acids, alkalies, and salts. Asphaltic compounds are used to increase the resistance to cast irons to alkalies, sewage, acids, and continued exposure to tap water. Their application range is similar to that of bituminous paints. Cast irons are also lined with thermoset and thermoplastics, such as epoxy and polyethylene, to resist attack by fluids.

Fluorocarbon coatings offer superior corrosion resistance except in abrasion services. Fluorocarbon coatings applied to cast irons include such materials as polytetrafluoroethylene (PTFE), perfluoroalkoxy resins (PFA), and fluorinated ethylene polypropylene (FEP). Fluorocarbon coatings resist most common industrial services and can be used to 205 °C (400 °F). Cast iron lined with fluorocarbons is very competitive with stainless, nickel-base, and even titanium and zirconium materials in terms of range of services covered and product cost.

Conversion coatings are produced when the metal on the surface of the cast iron reacts with another element or compound to produce an iron-containing compound. Common conversion coatings include phosphate coatings, oxide coatings, and chromate coatings. Phosphate coatings enhance the resistance of cast iron to corrosion in sheltered atmospheric exposure. If the surface of the casting is oxidized and black iron oxide or magnetic is formed, the corrosion resistance of the iron can be enhanced, particularly if the oxide layer is impregnated with oil or wax. Chromate coatings are formed by immersing the iron castings in an aqueous solution of chromic acid (H_2CrO_4) or chromium salts. Chromate coatings are sometimes used as a supplement to cadmium plating in order to prevent the formation of powdery corrosion products. The overall benefits of conversion coatings are small with regard to atmospheric corrosion.

Enamel Coatings. In the enamel coating of cast irons, glass frits are melted on the surface and form a hard, tenacious bond to the cast iron substrate. Good resistance to all acids except HF can be obtained with the proper selection and application of the enamel coating. Alkaline-resistant coatings can also be applied, but they do not exhibit the same general resistance to alkalies as acids do.

Proper design and application are essential for developing enhanced corrosion resistance on cast irons with enamel coatings. Any cracks, spalling, or other coating imperfections may permit rapid attack of the underlying cast iron.

Selection of Cast Irons

Cast irons can provide excellent resistance to a wide range of corrosion environments when properly matched with the service environment for which they are intended. The basic parameters to consider before selecting cast irons for corrosion services include:

- Concentration of solution components in weight percent
- Contaminants, even at parts per million levels
- pH of solution
- Temperatures and its potential range and rate of change
- Degree of aeration
- Percent and type of solids
- Continuous or intermittent operation
- Upset potential: maximum temperature and concentration
- Unusual conditions, such as high velocity and vacuum
- Materials currently used in the system and potential for galvanic corrosion

Although it is advisable to consider each of the parameters before ultimate selection of a cast iron, the information needed to assess all variables of importance properly is often lacking. In such cases, introduction of test coupons of the candidate materials into the process stream should be considered before extensive purchases of equipment are made. If neither test coupons nor complete service data are viable alternatives, consultation with a reputable manufacturer of the equipment or the cast iron with a history of applications in the area of interest should be considered.

Corrosion of Cast Steels

Raymond W. Monroe, Maynard Steel Casting Company; Steven J. Pawel, University of Tennessee

Introduction

STEEL CASTING COMPOSITIONS are generally divided into the categories of carbon, low-alloy, corrosion-resistant, or heat-resistant, depending on alloy content and intended service. Castings are classified as corrosion resistant if they are capable of sustained operation when exposed to attack by corrosive agents at service temperatures normally below 315 °C (600 °F).

The high-alloy ferrous-base compositions are usually given the name stainless steel, although this name has been questioned. Actually, they are widely referred to as cast stainless steels. Some of the high alloys, such as 12% Cr steel, exhibit many of the familiar physical characteristics of carbon and low-alloy steels, and some of their mechanical properties, such as hardness and tensile strength, can be altered by suitable heat treatment. The alloys of higher chromium content (20 to 30%)--chromium-nickel and nickel-chromium--do not show the changes in phase observed in ordinary steel when heated or cooled in the range from room temperature to the melting point. Consequently, these materials are nonhardenable, and their mechanical properties depend on their composition rather than heat treatment.

The high-alloy steels differ from carbon and low-alloy steels in other respects, such as their production and properties. Special consideration must be given to each grade with regard to casting design and foundry practice. For example, such elements as chromium, nickel, carbon, nitrogen, silicon, molybdenum, and niobium may exert a profound influence on the ultimate structure of these complex alloys; therefore, balancing of the alloy compositions is frequently required to obtain a satisfactory product. The chemical ranges used in the manufacture of wrought stainless alloys are not used to produce castings, because a different balance of alloying elements may be required to provide castability, desired mechanical properties, and optimum corrosion resistance.

Corrosion resistance is a relative term that depends on the particular environment to which a specific alloy is exposed. Carbon and low-alloy steels are considered resistant only to very mild corrosives, but the various high-alloy grades are applicable for varying situations from mild to severe services, depending on the particular conditions involved.

It is often misleading to list the comparative corrosion rates of different alloys exposed to the same corroding medium. In this article, no attempt will be made to recommend alloys for specific applications, and the data supplied should be used only as a general guideline. Alloy casting users will find it helpful to consult materials and corrosion specialists when selecting alloys for a particular application. The factors that must be considered in material selection include:

- The principal corrosive agents and their concentrations
- Known or suspected impurities, including abrasive materials and their concentration
- Average operating temperature, including variations even if encountered only for short periods
- Presence (or absence) of oxygen or other gases in solution
- Continuous or intermittent operation
- Fluid velocity

Each of these can have a vital effect on the service life of both cast and wrought equipment, and such detailed information usually must be provided. Many rapid failures are traceable to these details being overlooked--often when the information was available.

Selection of the most economical alloy is often made by the judicious use of corrosion data. However, discretion is suggested in evaluating the relative corrosion rates of various steels because of the uncertainties of the actual test or service conditions. Corrosion rates determined in controlled laboratory tests should be applied cautiously when considering actual service. The best information is obtained from equipment used under similar operating conditions. However, exposing samples to service conditions will also provide valuable information.

Corrosion of Carbon and Low-Alloy Cast Steels

Unless shielded by a protective coating, iron and steel will corrode in the presence of water and oxygen; therefore, steel will corrode when it is exposed to moist air. The rate at which corrosion proceeds in the atmosphere depends on the corroding medium, the conditions of the particular location in which the material is in use, and the steps that have been taken to prevent corrosion. The rate of corrosion also depends on the character of the steel as determined by its chemical composition and heat treatment. The probable rate of corrosion of a material in an environment can generally be estimated only from long-term tests.

Cast steel and wrought steel of similar analysis and heat treatment exhibit about the same corrosion resistance in the same environments. Plain carbon steel and some of the low-alloy steels do not ordinarily resist drastic corrosive conditions, although there are some exceptions, such as strong sulfuric acid (H_2SO_4). To increase the corrosion resistance of steel significantly, it is necessary to resort to extensive alloying. Small amounts of copper and nickel slightly improve the resistance of steel to atmospheric attack, but appreciably larger amounts of other elements, such as chromium or nickel, improve resistance significantly.

Atmospheric Corrosion. A 15-year research program compared the corrosion resistance of nine cast steels in marine and industrial atmospheres. Table 1 shows the compositions of the cast steels tested. The cast steel specimens exposed were 13-mm ($\frac{1}{2}$-in.) thick, 100- × 150-mm (4- × 6-in.) panels with beveled edges. The surfaces of half the specimens were machined. Specimens of each composition and surface condition were divided into three groups. One group was exposed to an industrial atmosphere at East Chicago, IN, and the other two groups were exposed to marine atmospheres 24 and 240 m (80 and 800 ft) from the ocean at Kure Beach, NC. The weight losses of the specimens during exposure were converted to corrosion rates in terms of millimeters (mils) per year. The results of this research are shown in Fig. 1, 2, 3, and 4.

Table 1 Compositions of cast steels tested in atmospheric corrosion

Figure 5 shows the results of another portion of this project. Corrosion rates for a 3-year exposure of various cast steels, wrought steels, and malleable iron in both atmospheres are compared. The following conclusions can be drawn from these tests:

- The condition of the specimen surface has no significant effect on the corrosion resistance of cast steels. Unmachined surfaces with the casting skin intact have corrosion rates similar to those of machined surfaces regardless of the atmospheric environment
- The highest corrosion rate occurs in the marine atmosphere 24 m (80 ft) from the ocean, with lower but similar corrosion rates occurring in the industrial atmosphere and the marine atmosphere 240 m (800 ft) from the ocean
- The corrosion rate of cast steel decreases as a function of time, because corrosion products (scale and rust coating) build up and act as a protective coating on the cast steel surface. However, the corrosion rate of the most resistant cast steel (2% Ni) is always less than that of lesser corrosion-resistant cast steels
- Cast steels containing small percentages of nickel, copper, or chromium as alloying elements have corrosion resistance superior to that of cast carbon steels and those containing manganese when exposed to atmospheric environments
- Increasing the nickel and the chromium contents of cast steel increases the corrosion resistance in all three of the atmospheric environments
- All cast steels have greater corrosion resistance than malleable iron in industrial atmospheres and are superior or equivalent to the wrought steels in this environment. The corrosion rate in the marine atmosphere depends primarily on the alloy content. The cast carbon steel is much superior to the AISI 1020 wrought steel, but is slightly inferior to malleable iron (Ref 1)

Other Environments. Several low- and high-alloy cast steels have been studied regarding their corrosion resistance to high-temperature steam. Test specimens 150 mm (6 in.) in length and 13 mm ($\frac{1}{2}$-in.) in diameter were machined from

test coupons and then exposed to steam at 650 °C (1200 °F) for 570 h. The steel compositions and test results are given in Table 2. Table 3 shows the resistance of cast steels to petroleum corrosion, and Tables 4 and 5 supply similar data relating to water and acid attack. These data show the value of higher chromium content for improved corrosion resistance.

Corrosion of Cast Stainless Steels

Cast stainless steels are usually specified on the basis of composition by using the alloy designation system established by the Alloy Casting Institute (ACI). The ACI designations, such as CF-8M, have been adopted by the American Society for Testing and Materials (ASTM) and are preferred for cast alloys over the designations used by the American Iron and Steel Institute (AISI) for similar wrought steels.

The first letter of the ACI designation indicates whether the alloy is intended primarily for liquid corrosion service (C) or heat-resistant service (H). The second letter denotes the nominal chromium-nickel type, as shown in Fig. 6. As the nickel content increases, the second letter in the ACI designation increases from A to Z. The numerals following the two letters refer to the maximum carbon content (percent × 100) of the alloy. If additional alloying elements are included, they can be denoted by the addition of one or more letters after the maximum carbon content. Thus, the designation CF-8M refers to an alloy for corrosion-resistant service (C) of the 19Cr-9Ni (F) type, with a maximum carbon content of 0.08% and containing molybdenum (M).

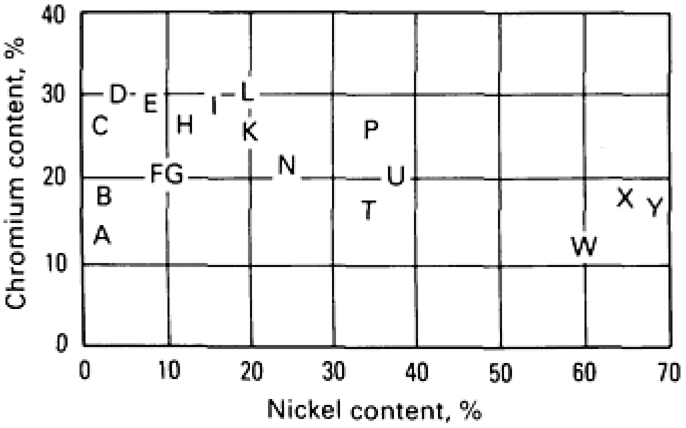

Fig. 6 Chromium and nickel contents in ACI standard grades of heat- and corrosion-resistant castings. See text for details. Source: Ref 2

Corrosion-resistant cast steels are also often classified on the basis of microstructure. The classifications are not completely independent, and a classification by composition often involves microstructural distinctions. Cast corrosion-resistant alloy compositions are listed in Table 6.

(a) Cast alloy chemical composition ranges are not the same as the wrought composition ranges; buyers should use cast alloy designations for proper identification of castings.

(b) Maximum, unless range is given.

(c) Molybdenum not intentionally added.

Composition and Microstructure

The principal alloying element in the high-alloy family is usually chromium, which, through the formation of protective oxide films, is the first step for these alloys in achieving stainless quality. For all practical purposes, stainless behavior requires at least 12% Cr. As will be discussed later, corrosion resistance further improves with additions of chromium to at least the 30% level. As shown in Table 5, nickel and lesser amounts of molybdenum and other elements are often added to the iron-chromium matrix.

Although chromium is the ferrite and martensite promoter, nickel is an austenite promoter. By varying the amounts and ratios of these two elements (or their equivalents), almost any desired combination of microstructure, strength, or other property can be achieved. Equally important is heat treatment. Temperature, time at temperature, and cooling rate must be controlled to obtain the desired results.

It is useful to think of the compositions of high-alloy steels in terms of the balance between austenite promoters and ferrite promoters. This is done on the widely used Schaeffler-type diagrams (Fig. 7). The phases shown are those that persist after cooling to room temperature at rates normally used in fabrication (Ref 2, 3).

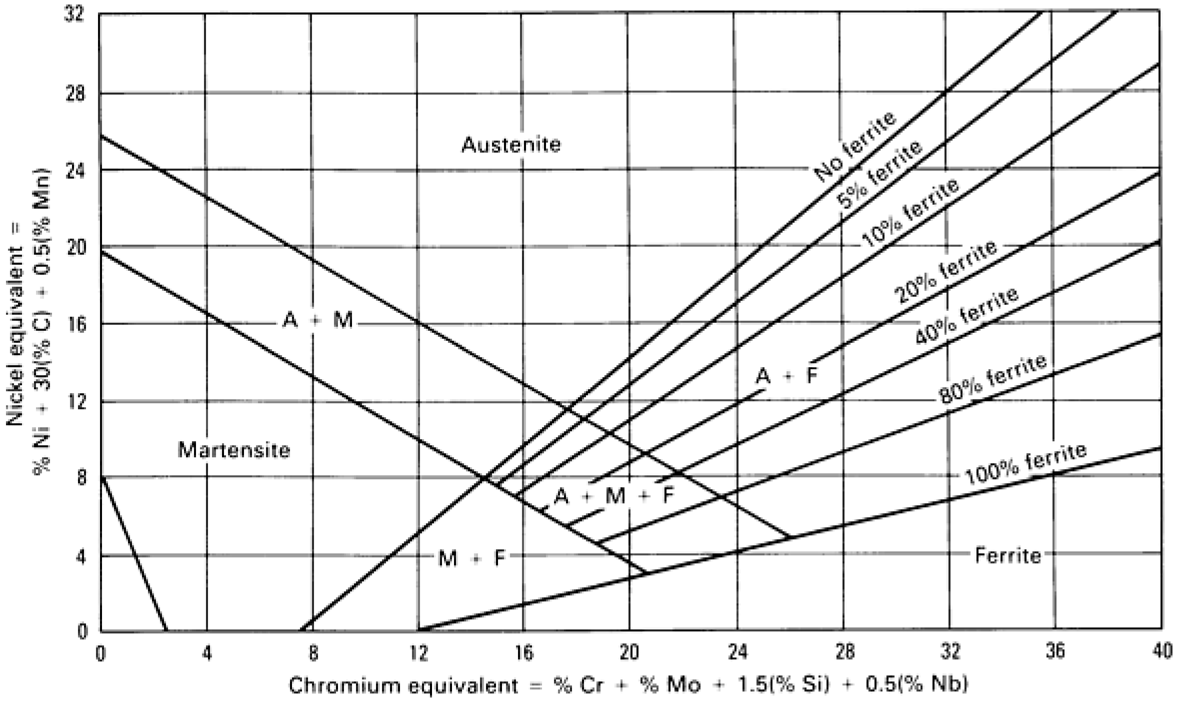

Fig. 7 Schaeffler diagram showing the amount of ferrite and austenite present in weldments as a function of chromium and nickel equivalents. Source: Ref 2

The empirical correlations shown in Fig. 7 can be understood from the following. The field designated as martensite encompasses such alloys as CA-15, CA-6NM, and even CB-7Cu. These alloys contain 12 to 17% Cr, with adequate nickel, molybdenum, and carbon to promote high hardenability, that is, the ability to transform completely to martensite when cooled at even the moderate rates associated with the air cooling of heavy sections. High alloys have low thermal conductivities and cool slowly. To obtain the desired properties, a full heat treatment is required after casting; that is, the casting is austenitized by heating to 870 to 980 °C (1600 to 1800 °F), cooled to room temperature to produce the hard martensite, and then tempered at 595 to 760 °C (1100 to 1400 °F) until the desired combination of strength, toughness, ductility, and resistance to corrosion or stress corrosion is obtained (Ref 2, 3).

Increasing the nickel equivalent (moving vertically in Fig. 7) eventually results in an alloy that is fully austenitic, such a CC-20, CH-20, CK-20, or CN-7M. These alloys are extremely ductile, tough, and corrosion resistant. On the other hand, the yield and tensile strength may be relatively low for the fully austenitic alloys. Because these high-nickel alloys are fully austenitic, they are nonmagnetic. Heat treatment consists of a single step: water quenching from a relatively high temperature at which carbides have been taken into solution. Solution treatment may also homogenize the structure, but because no transformation occurs, there can be no grain refinement. The solutionizing step and rapid cooling ensure maximum resistance to corrosion. Temperatures between 1040 and 1205 °C (1900 and 2200 °F) are usually required (Ref 2, 3).

Adding chromium to the lean alloys (proceeding horizontally in Fig. 7) stabilizes the δ-ferrite that forms when the casting solidifies. Examples are CB-30 and CC-50. With high chromium content, these alloys have relatively good resistance to corrosion, particularly in sulfur-bearing atmospheres. However, being single-phase, they are nonhardenable, have

moderate-to-low strength, and are often used as-cast or after only a simple solutioning treatment. Ferritic alloys also have poor toughness (Ref 2, 3).

Between the fields designated M, A, and F in Fig. 7 are regions indicating the possibility of two or more phases in the alloys. Commercially, the most important of these alloys are the ones in which austenite and ferrite coexist, such as CF-3, CF-8, CF-3M, CF-8M, CG-8M, and CE-30. These alloys usually contain 3 to 30% ferrite in a matrix of austenite. Predicting and controlling ferrite content is vital to the successful application of these materials. Duplex alloys offer superior strength, weldability, and corrosion resistance. Strength, for example, increases directly with ferrite content. Achieving specified minimums may necessitate controlling the ferrite within narrow bands. Figure 8 and Schoefer's equations are used for this purpose. These duplex alloys should be solution treated and rapidly cooled before use to ensure maximum resistance to corrosion (Ref 2, 3).

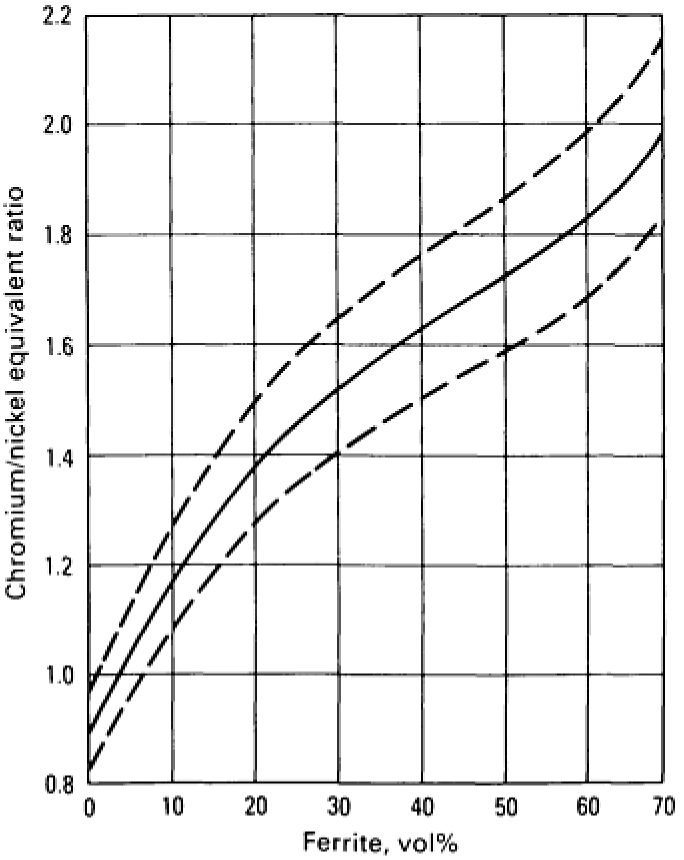

Fig. 8 Schoefer diagram for estimating the average ferrite content in austenitic iron-chromium-nickel alloy castings. Source: Ref 2

The presence of ferrite is not entirely beneficial. Ferrite tends to reduce toughness, although this is not of great concern given the extremely high toughness of the austenite matrix. However, in applications that require exposure to elevated temperatures, usually 315 °C (600 °F) and higher, the metallurgical changes associated with the ferrite can be severe and detrimental. In the low end of this temperature range, the reductions in toughness observed have been attributed to carbide precipitation or reactions associated with 475-°C embrittlement. The 475-°C embrittlement is caused by precipitation of an intermetallic phase with a composition of approximately 80Cr-20Fe. The name derives from the fact that this embrittlement is most severe and rapid when it occurs at approximately 475 °C (885 °F). At 540 °C (1000 °F) and above, the ferrite phase may transform to a complex iron-chromium-nickel-molybdenum intermetallic compound known as σ phase, which reduces toughness, corrosion resistance, and creep ductility. The extent of the reduction increases with time and temperature to about 815 °C (1500 °F) and may persist to 925 °C (1700 °F). In extreme cases, Charpy V-notch energy at room temperature may be reduced 95% from its initial value (Ref 2, 3). More information on the metallography and microstructures of these alloys is available in the article "Stainless Steel Casting Alloys" in *Metallography and Microstructures,* Volume 9 of *ASM Handbook,* formerly 9th Edition *Metals Handbook.*

Corrosion Behavior of H-Type Alloys

The ACI heat-resistant (H-type) alloys must be able to withstand temperatures exceeding 1095 °C (2000 °F) in the most severe high-temperature service. An important factor pertaining to the corrosion behavior of these alloys is chromium content. Chromium imparts resistance to oxidation and sulfidation at high temperatures by forming a passive oxide film. Heat-resistant casting alloys must also have good resistance to carburization. More information on the corrosion of metals and alloys in high-temperature gases is available in the article "Fundamentals of Corrosion in Gases" in this Volume.

Oxidation. Resistance to oxidation increases directly with chromium content (Fig. 9). For the most severe service at temperatures above 1095 °C (2000 °F), 25% or more chromium is required. Additions of nickel, silicon, manganese, and aluminum promote the formation of relatively impermeable oxide films that retard further scaling. Thermal cycling is extremely damaging to oxidation resistance because it leads to breaking, cracking, or spalling of the protective oxide film. The best performance is obtained with austenitic alloys containing 40 to 50% combined nickel and chromium. Figure 10 shows the behavior of the H-type grades.

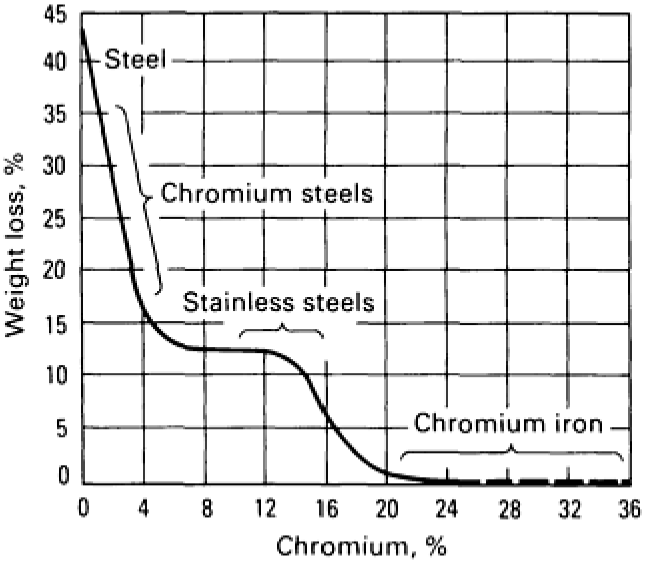

Fig. 9 Effect of chromium on oxidation resistance of cast steels. Specimens (13-mm, or 0.5-in., cubes) were exposed for 48 h at 1000 °C (1830 °F). Source: Ref 3

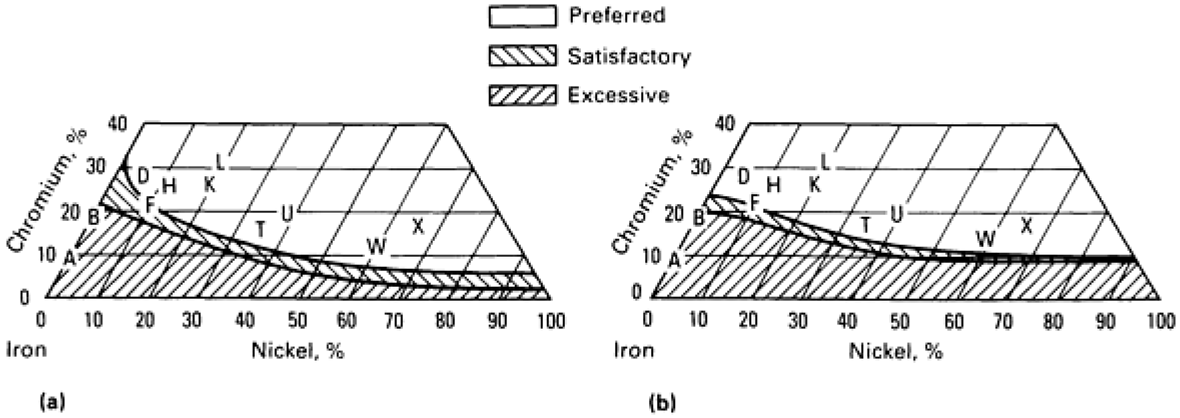

Fig. 10 Corrosion behavior of ACI H-type (heat-resistant) alloy castings in air (a) and in oxidizing flue gases containing 5 grains of sulfur per 2.8 m^3 (100 ft^3) of gas (b). Source: Ref 3

Sulfidation environments are becoming increasingly important. Petroleum processing, coal conversion, utility and chemical applications, and waste incineration have heightened the need for alloys resistant to sulfidation attack in relatively weak oxidizing or reducing environments. Fortunately, high chromium and silicon contents increase resistance to sulfur-bearing environments. On the other hand, nickel has been found to be detrimental to the most aggressive gases. The problem is attributable to the formation of low-melting nickel-sulfur eutectics. These produce highly destructive liquid phases at temperatures even below 815 °C (1500 °F). Once formed, the liquid may run onto adjacent surfaces and rapidly corrode other metals. The behavior of H-type grades in sulfidizing environments is represented in Fig. 11.

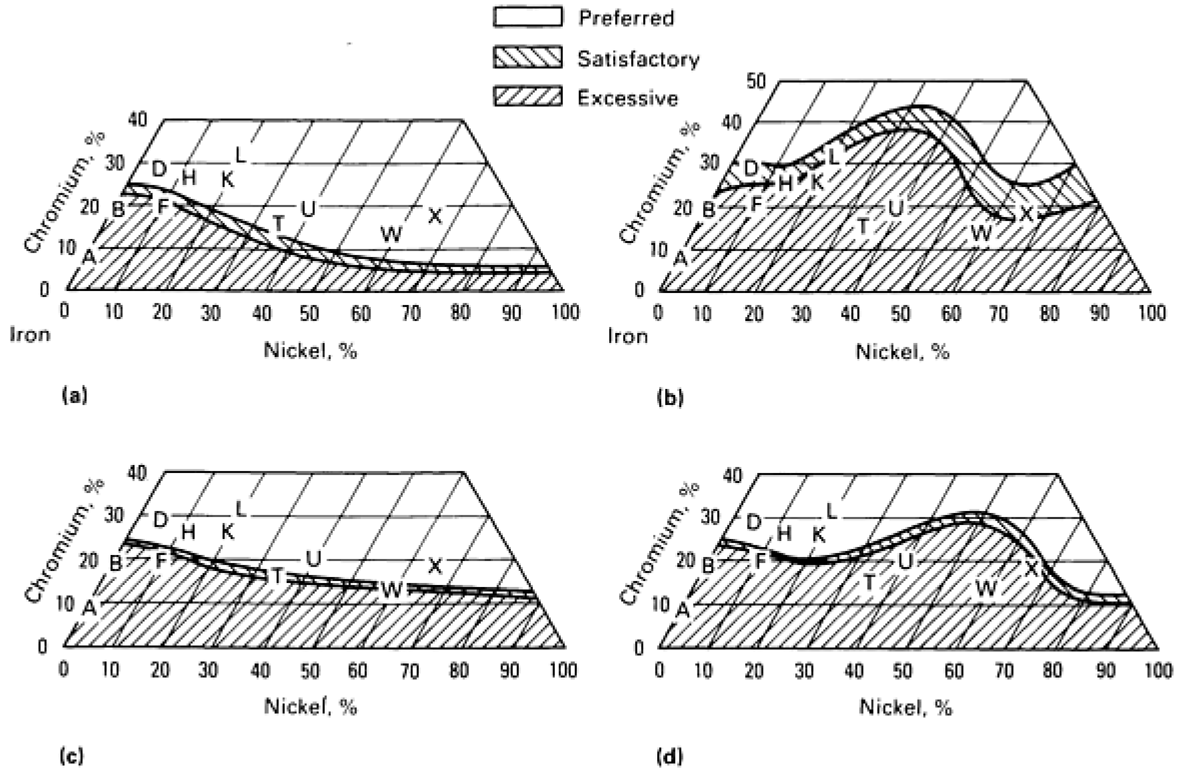

Fig. 11 Corrosion behavior of ACI H-type alloys in 100-h tests at 980 °C (1800 °F) in reducing sulfur-bearing gases. (a) Gas contained 5 grains of sulfur per 2.8 m^3 (100 ft^3) of gas. (b) Gas contained 300 grains of sulfur per 2.8 m^3 (100 ft^3) of gas. (c) Gas contained 100 grains of sulfur per 2.8 m^3 (100 ft^3) of gas; test at constant temperature. (d) Some sulfur content as gas in (c), but cooled to 150 °C (300 °F) each 12 h

Carburization. High alloys are often used in nonoxidizing atmospheres in which carbon diffusion into metal surfaces is possible. Depending on chromium content, temperature, and carburizing potential, the surface may become extremely rich in chromium carbides, rendering it hard and possibly susceptible to cracking. Silicon and nickel are thought to be beneficial and enhance resistance to carburization.

Corrosion Behavior of C-Type Alloys

The ACI C-type (for liquid corrosion service) stainless steels must resist corrosion in the various environments in which they regularly serve. In this section, the general principles and important highlights of corrosion behavior will be discussed as influenced by the metallurgy of these materials. Topics include general corrosion, intergranular corrosion, localized corrosion, corrosion fatigue, and stress corrosion.

General Corrosion of Martensitic Alloys. The martensitic grades include CA-15, CA-15M, CA-6NM, CA-6NM-B, CA-40, CB-7Cu-1 and CB-7Cu-2. These alloys are generally used in applications requiring high strength and some corrosion resistance.

Alloy CA-15 typically exhibits a microstructure of martensite and ferrite. This alloy contains the minimum amount of chromium to be considered a stainless steel (11 to 14% Cr) and as such may not be used in aggressive environments. It

does, however, exhibit good atmospheric-corrosion resistance, and it resists staining by many organic environments. Alloy CA-15M may contain slightly more molybdenum than CA-15 (up to 1% Mo) and therefore may have improved general corrosion resistance in relatively mild environments. Alloy CA-6NM is similar to CA-15M except that it contains more nickel and molybdenum, which improves its general corrosion resistance. Alloy CA-6NM-B is a lower-carbon version of this alloy. The lower strength level promotes resistance to sulfide stress cracking. Alloy CA-40 is a higher-strength version of CA-15, and it also exhibits excellent atmospheric-corrosion resistance after a normalize and temper heat treatment. Microstructurally, the CB-7Cu alloys usually consist of mixed martensite and ferrite, and because of the increased chromium and nickel levels compared to the other martensitic alloys, they offer improved corrosion resistance to seawater and some mild acids. These alloys also have good atmospheric-corrosion resistance. The CB-7Cu alloys are hardenable and offer the possibility of increased strength and improved corrosion resistance among the martensitic alloys.

General Corrosion of Ferritic Alloys. Alloys CB-30 and CC-50 are higher-carbon and higher-chromium alloys than the CA alloys previously mentioned. Each alloy is predominantly ferritic, although a small amount of martensite may be found in CB-30. Alloy CB-30 contains 18 to 21% Cr and is used in chemical-processing and oil-refining applications. The chromium content is sufficient to have good corrosion resistance to many acids, including nitric acid (HNO_3). Figure 12 shows an isocorrosion diagram for CB-30 in HNO_3. Alloy CC-50 contains substantially more chromium (26 to 30%) and offers relatively high resistance to localized corrosion and high resistance to many acids, including dilute H_2SO_4 and such oxidizing acids as HNO_3.

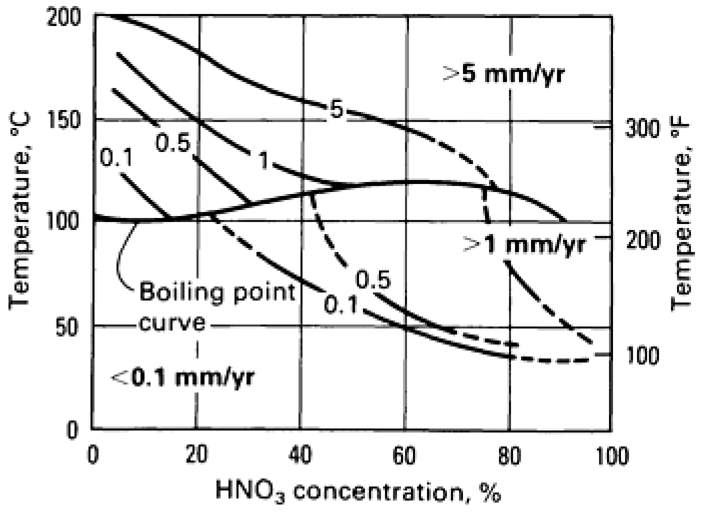

Fig. 12 Isocorrosion diagram for ACI CB-30 in HNO_3. Castings were annealed at 790 °C (1450 °F), furnace cooled to 540 °C (1000 °F), and then air cooled to room temperature.

General Corrosion of Austenitic and Duplex Alloys. Alloy CF-8 typically contains approximately 19% Cr and 9% Ni and is essentially the cast equivalent of AISI 304-type wrought alloys. Alloy CF-8 may be fully austenitic, but it more commonly contains some residual ferrite (3 to 30%) in an austenite matrix. In the solution-treated condition, this alloy has excellent resistance to a wide variety of acids. It is particularly resistant to highly oxidizing acids, such as boiling HNO_3. Figure 13 shows isocorrosion diagrams for CF-8 in HNO_3, phosphoric acid (H_3PO_4), and sodium hydroxide (NaOH). The duplex nature of the microstructure of this alloy imparts additional resistance to stress-corrosion cracking (SCC) compared to its wholly austenitic counterparts. Alloy CF-3 is a reduced-carbon version of CF-8 with essentially identical corrosion resistance except that CF-3 is much less susceptible to sensitization (Fig. 14). For applications in which the corrosion resistance of the weld heat-affected zone (HAZ) may be critical, CF-3 is a common material selection.

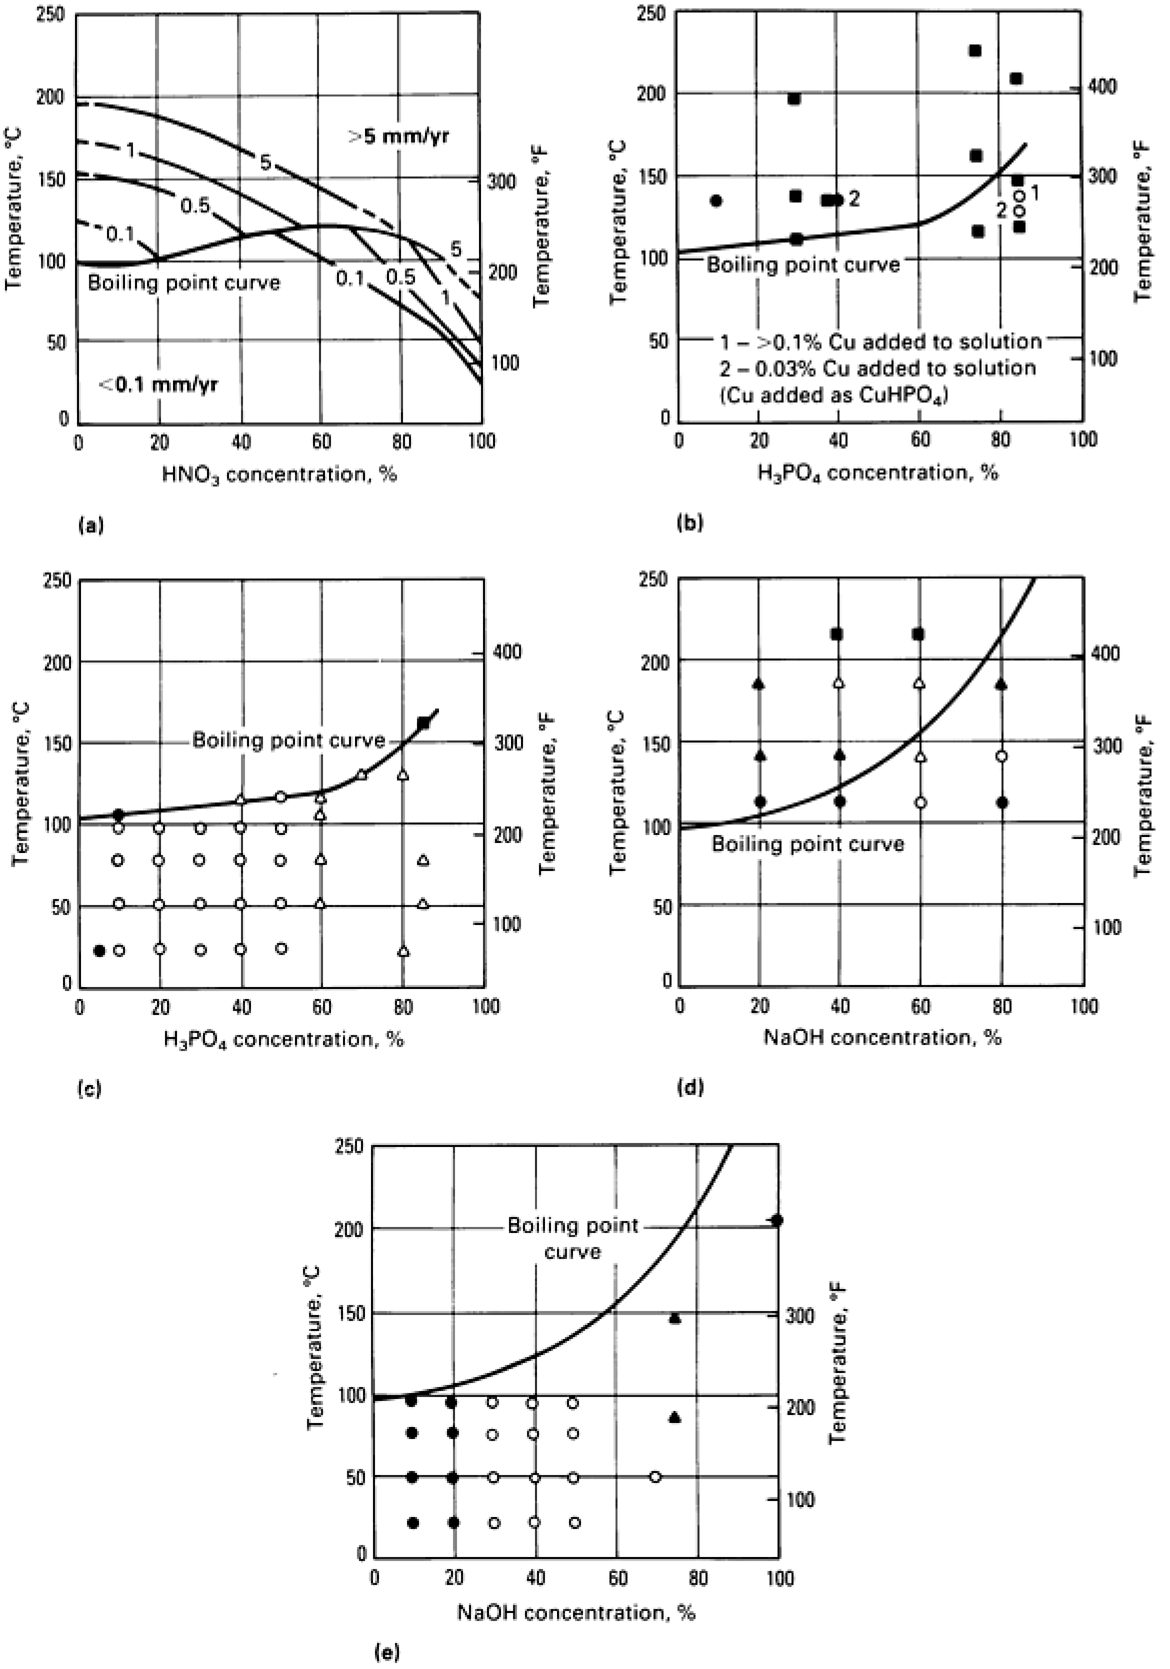

Fig. 13 Isocorrosion diagrams for ACI CF-8 in HNO_3 (a), H_3PO_4 (b and c), and NaOH solutions (d and e). (b) and (d) Tests performed in a closed container at equilibrium pressure. (c) and (e) Tested at atmospheric pressure

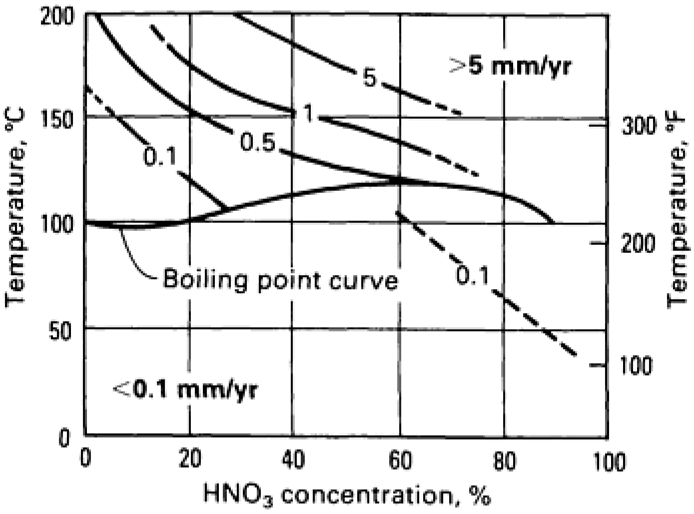

Fig. 14 Isocorrosion diagram for solution-treated quenched and sensitized ACI CF-3 in HNO_3

Alloys CF-8A and CF-3A contain more ferrite than their CF-8 and CF-3 counterparts. Because the higher ferrite content is achieved by increasing the chromium/nickel equivalent ratio, the CF-8A and CF-3A alloys may have slightly higher chromium or slightly lower nickel contents than the low-ferrite equivalents. In general, the corrosion resistance is very similar, but the strength increases with ferrite content. Because of the high ferrite content, service should be restricted to temperature below 400 °C (750 °F) due to the possibility of severe embrittlement. Alloy CF-8C is the niobium-stabilized grade of the CF-8 alloy class. This alloy contains small amounts of niobium, which tend to form carbides preferentially over chromium carbides and improve intergranular corrosion resistance in applications involving relatively high service temperatures.

Alloys CF-8M, CF-3M, CF-8MA, and CF-3MA are molybdenum-bearing (2 to 3%) versions of the CF-8 and CF-3 alloys. The addition of 2 to 3% Mo increases resistance to corrosion by seawater and improves resistance to many chloride-bearing environments. The presence of 2 to 3% Mo also improves crevice corrosion and pitting resistance compared to the CF-8 and CF-3 alloys. Molybdenum-bearing alloys are generally not as resistant to highly oxidizing environments (this is particularly true for boiling HNO_3), but for weakly oxidizing environments and reducing environments, Mo-bearing alloys are generally superior.

Alloy CF-16F is a selenium-bearing free-machining grade of cast stainless steel. Because CF-16F nominally contains 19% Cr and 10% Ni, it has adequate corrosion resistance to a wide range of corrodents, but the large number of selenide inclusions makes surface deterioration and pitting definite possibilities.

Alloy CF-20 is a fully austenitic, relatively high-strength corrosion-resistant alloy. The 19% Cr content provides resistance to many types of oxidizing acids, but the high carbon content makes it imperative that this alloy be utilized in the solution-treated condition for environments known to cause intergranular corrosion.

Alloy CE-30 is a nominally 27Cr-9Ni alloy that normally contains 10 to 20% ferrite in an austenite matrix. The high carbon and ferrite contents provide relatively high strength. The high chromium content and duplex structure act to minimize corrosion because of the formation of chromium carbides in the microstructure. This particular alloy is known for good resistance to sulfurous acid and sulfuric acid, and it is extensively used in the pulp and paper industry (see the article "Corrosion in the Pulp and Paper Industry" in this Volume).

Alloy CG-8M is slightly more highly alloyed than the CF-8M alloys, with the primary addition being increased molybdenum (3 to 4%). The increased amount of molybdenum provides superior corrosion resistance to halide-bearing media and reducing acids, particularly H_2SO_3 and H_2SO_4 solutions. The high molybdenum content, however, renders CG-8M generally unsuitable in highly oxidizing environments.

Alloy CD-4MCu is the most highly alloyed material in this group of alloys; it has a nominal composition of Fe-26Cr-5Ni-2Mo-3Cu. The chromium/nickel equivalent ratio for this alloy is quite high, and a microstructure containing

approximately equal amounts of ferrite and austenite is common. The low carbon content and high chromium content render the alloy relatively immune to intergranular corrosion. High chromium and molybdenum provide a high degree of localized corrosion resistance (crevices and pitting), and the duplex microstructure provides SCC resistance in many environments. This alloy can be precipitation hardened to provide strength and is also relatively resistant to abrasion and erosion-corrosion. Figures 15 and 16 show isocorrosion diagrams for CD-4MCu in HNO_3 and H_2SO_4, respectively.

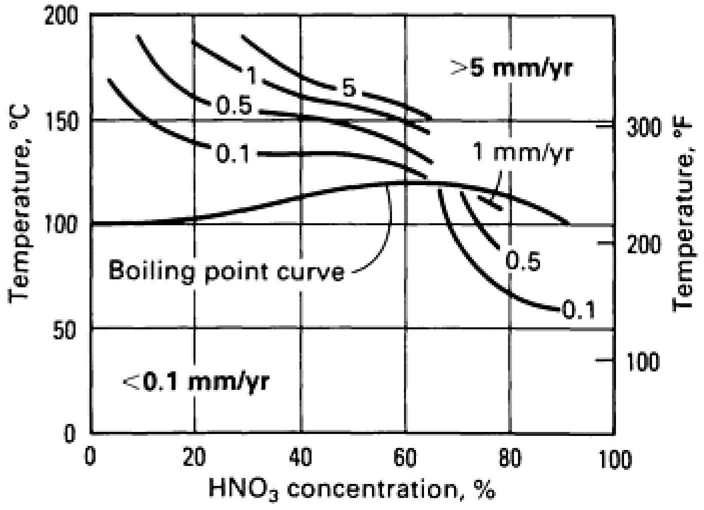

Fig. 15 Isocorrosion diagram for ACI CD-4MCu in HNO_3. The material was solution treated at 1120 °C (2050 °F) and water quenched.

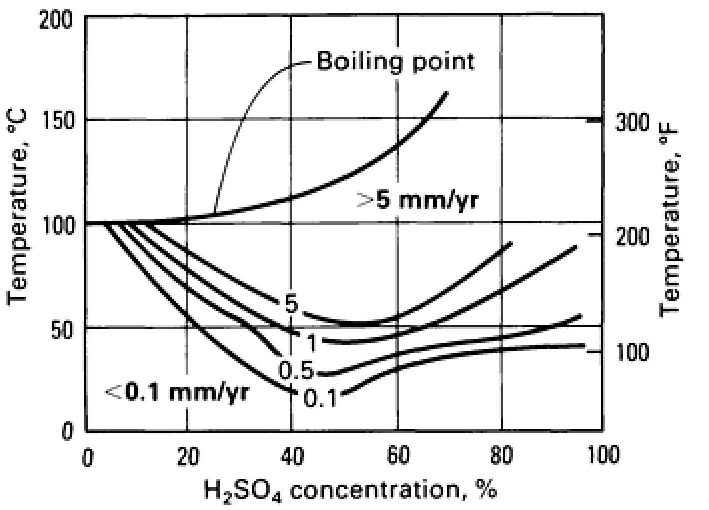

Fig. 16 Isocorrosion diagram for ACI CD-4MCu in H_2SO_4. The material was solution annealed at 1120 °C (2050 °F) and water quenched.

Fully Austenitic Alloys. Alloys CH-10 and CH-20 are fully austenitic and contain 22 to 26% Cr and 12 to 15% Ni. The high chromium content minimizes the tendency toward the formation of chromium-depleted zones due to sensitization. These alloys are used for handling paper pulp solutions and are known for good resistance to dilute H_2SO_4 and HNO_3.

Alloy CK-20 contains 23 to 27% Cr and 19 to 22% Ni and is less susceptible than CH-20 to intergranular corrosion attack in many acids after brief exposures to the chromium carbide formation temperature range. Maximum corrosion resistance is achieved by solution treatment. Alloy CK-20 possesses good corrosion resistance to many acids and, because of its fully austenitic structure, can be used at relatively high temperature.

Alloy CN-7M, with a nominal composition of Fe-29Ni-20Cr-2.5Mo-3.5Cu, exhibits excellent corrosion resistance in a wide variety of environments and is often used for H_2SO_4 service. Figure 17 shows isocorrosion diagrams for CN-7M in H_2SO_4, HNO_3, H_3PO_4, and NaOH. Relatively high resistance to intergranular corrosion and SCC make this alloy attractive for very many applications. Although relatively highly alloyed, the fully austenitic structure of CN-7M may lead to SCC susceptibility for some environments and stress states.

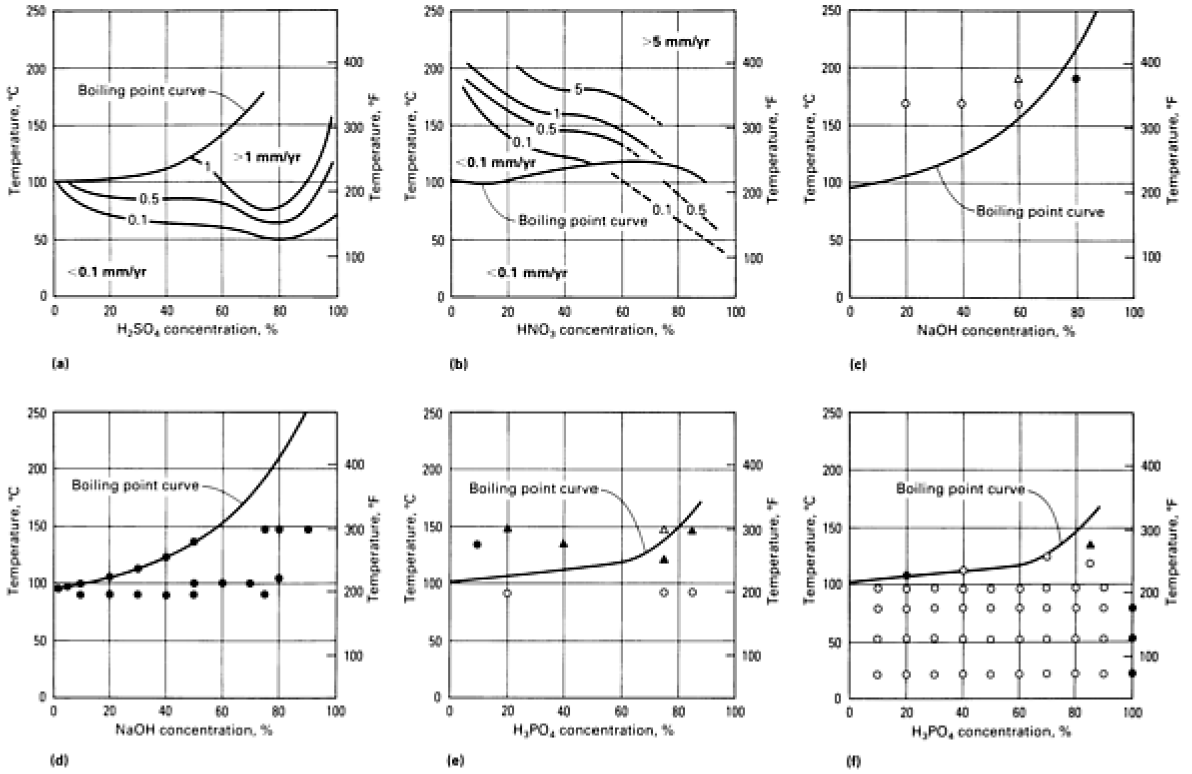

Fig. 17 Isocorrosion diagrams for solution-annealed and quenched ACI CN-7M in H_2SO_4, HNO_3, NaOH, and H_3PO_4. (a), (b), (d), and (f) Tested at atmospheric pressure. (c) and (e) Tested at equilibrium pressure in a closed container. See Fig. 13 for legend.

Intergranular Corrosion of Austenitic and Duplex Alloys. The optimum corrosion resistance for these alloys is developed by solution treatment. Depending on the specific alloy in question, temperatures between 1040 and 1205 °C (1900 and 2200 °F) are required to ensure complete solution of all carbides and phases, such as σ and χ, the sometimes form in highly alloyed stainless steels. Alloys containing relatively high total alloy content, particularly high molybdenum content, often require the higher solution treatment temperature. Water quenching from the temperature range of 1040 to 1205 °C (1900 to 2200 °F) normally completes the solution treatment.

Failure to solution treat a particular alloy or an improper solution treatment may seriously compromise the observed corrosion resistance in service. Inadvertent or unavoidable heat treatment in the temperature range of 480 to 820 °C (900 to 1500 °F)--for example, welding--may destroy the intergranular corrosion resistance of the alloy. When austenitic or duplex (ferrite in austenite matrix) stainless steels are heated in or cooled slowly through this temperature range, chromium-rich carbides form at grain boundaries is austenitic alloys and at ferrite/austenite interfaces in duplex alloys. These carbides deplete the surrounding matrix of chromium, thus diminishing the corrosion resistance of the alloy. An alloy in this condition of reduced corrosion resistance due to the formation of chromium carbides is said to be sensitized. In small amounts, these carbides may lead to localized pitting in the alloy, but if the chromium-depleted zones are extensive throughout the alloy or HAZ of a weld, the alloy may disintegrate intergranularly in some environments.

If solution treatment of the alloy after casting and/or welding is impractical or impossible, the metallurgist has several tools from which to choose to minimize potential intergranular corrosion problems. The low carbon grades CF-3 and CF-3M are commonly used as a solution to the sensitization incurred during welding. The low carbon content (0.03% C maximum) of these alloys precludes the formation of an extensive number of chromium carbides. In addition, these alloys

normally contain 3 to 30% ferrite in an austenitic matrix. By virtue of rapid carbide precipitation kinetics at ferrite/austenite interfaces compared to austenite/austenite interfaces, carbide precipitation is confined to ferrite/austenite boundaries in alloys containing a minimum of about 3 to 5% ferrite (Ref 4, 5). If the ferrite network is discontinuous in the austenite matrix (depending on the amount, size, and distribution of ferrite pools), then extensive intergranular corrosion will not be a problem in most of the environments to which these alloys would be subjected.

An example of attack at the ferrite/austenite boundaries is shown in Fig. 18. These low-carbon alloys need not sacrifice significant strength compared to their high-carbon counterparts, because nitrogen may be added to increase strength. However, a large amount of nitrogen will begin to reduce the ferrite content, which will cancel some of the strength gained by interstitial hardening. Appropriate adjustment of the chromium/nickel equivalent ratio is beneficial in such cases. Fortunately, nitrogen is also beneficial to the corrosion resistance of austenitic and duplex stainless steels (Ref 6). Nitrogen seems to retard sensitization and improve the resistance to pitting and crevice corrosion of many stainless steels.

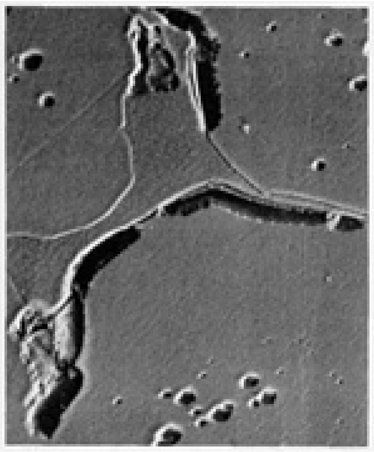

Fig. 18 Ferrite/austenite grain-boundary ditching in as-cast ACI CF-8. The specimen, which contained 3% ferrite, was EPR tested. SEM micrograph. 4550×. Source: Ref 5

The standard practices of ASTM A 262 (Ref 7) are commonly implemented to predict and measure the susceptibility of austenitic and duplex stainless steels to intergranular corrosion. Table 7 indicates some representative results for CF-type alloys as tested according to practices A, B, and C of Ref 7 as well as two electrochemical tests described in Ref 10 and 11. Table 8 lists the compositions of the alloys investigated. The data indicate the superior resistance of the low-carbon alloys to intergranular corrosion. Table 7 also indicates that for highly oxidizing environments (represented here by A 262C-boiling HNO_3) the CF-3 and CF-3M alloys are equivalent in the solution-treated condition but that subsequent heat treatment causes the corrosion resistance of the CF-3M alloys to deteriorate rapidly for service in oxidizing environments (Ref 9). In addition, the degree of chromium depletion necessary to cause susceptibility to intergranular corrosion appears to increase in the presence of molybdenum (Ref 5). The passive film stability imparted by molybdenum may offset the loss of solid-solution chromium for mild degrees of sensitization.

(a) This value is the percentage of ferrite.

Intergranular Corrosion of Ferritic and Martensitic Alloys. Ferritic alloys may also be sensitized by the formation of extensive chromium carbide networks, but because of the high bulk chromium content and rapid diffusion rates of chromium in ferrite, the formation of carbides can be tolerated if the alloy has been slowly cooled from a solutionizing temperature of 780 to 900 °C (1435 to 1650 °F). The slow cooling allows replenishment of the chromium adjacent to carbides. Martensitic alloys normally do not contain sufficient bulk chromium to be used in applications in which intergranular corrosion is likely to be of concern. Typical chromium contents for martensitic alloys may be as low as 11 to 12%.

Localized Corrosion. Austenitic and martensitic alloys display a tendency toward localized corrosion. The conditions conducive to this behavior may be any situation in areas where flow is restricted and an oxygen concentration cell may be established. Duplex alloys have been found to be less susceptible. Localized corrosion is particularly acute in environments containing chloride ion (Cl^-) and in acidic solutions.

Increasing the alloy content improves resistance to localized corrosion. Molybdenum has long been recognized as effective in reducing localized corrosion, although it is not a total solution. Excellent results have been obtained with CG-8M, but the CF-3M or CN-7M alloys are readily attacked. Nitrogen is also effective at retarding localized corrosion.

It has been suggested that resistance to pitting is good when a crevice factor (%Cr + 3(%Mo) + 15(%N)) exceeds 35 (Fig. 19). Another technique for comparing alloy composition resistance to localized corrosion is to ascertain the critical crevice temperature (CCT). This involves determining the maximum temperature at which nocrevice attack occurs during a 24-h testing period. These tests have been conducted on a number of cast stainless alloys; the results are given in Table 9. Although the CCT has been shown to correlate well with tests in aerated seawater (Ref 16), it must not be used as the maximum operating temperature in seawater or other chloride-containing media. The ferric chloride ($FeCl_3$) test environment is a very severe, highly oxidizing environment containing about 39,000 ppm Cl^- at a pH of about 1.4. Therefore, the $FeCl_3$ CCT is lower than that normally found in aerated seawater (Ref 16), which contains about 20,000 ppm Cl^- with a pH of about 7.5 to 8.0.

Table 9 CCTs for several common cast and wrought alloys

Alloy	Structure	CCT		Ref
		°C	°F	
Wrought AISI type 317L	Austenitic	2	35	13
Cast CF-3M	90% austenite, 10% ferrite	2	35	12
Cast CN-7M	Austenitic	-1.1	30	12
Cast CF-8M	90% austenite, 10% ferrite	-2.5	28	15
Wrought AISI type 316L	Austenitic	-2.5	28	14
Wrought AISI type 316	Austenitic	-3	27	13

Note: See text and Ref 12 for information on CCTs.

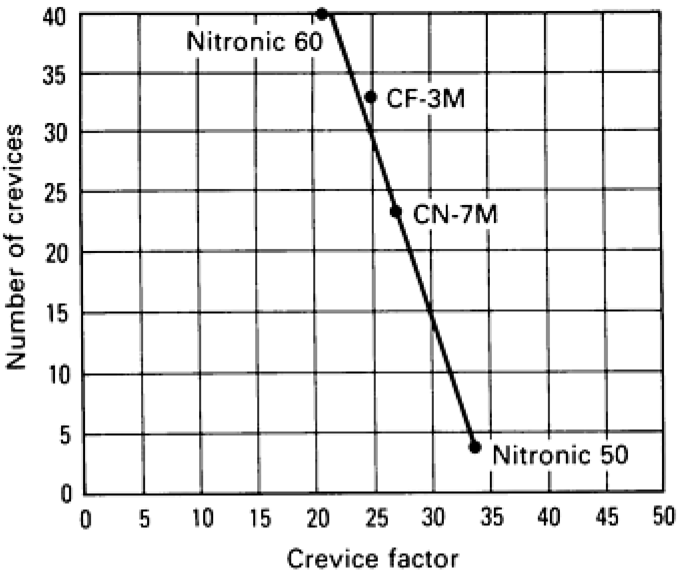

Fig. 19 Crevice corrosion resistance of various alloys in 5-day test in $FeCl_3$ at room temperature. See text and Ref 12 for explanation of crevice factor. Source: Ref 12

Corrosion fatigue is one of the most destructive and unpredictable corrosion-related failure mechanisms. Behavior is highly specific to the environment and alloy. The martensitic materials are degraded the most in both absolute and relative terms. If left to corrode freely in seawater, they have very little resistance to corrosion fatigue. This is a remarkable in view of their very high strength and fatigue resistance in air.

Properties can be protected if suitable cathodic protection is applied. However, because these materials are susceptible to hydrogen embrittlement, cathodic protection must be carefully applied. Too large a protective potential will lead to catastrophic hydrogen-stress cracking.

Austenitic materials are also severely degraded in corrosion fatigue strength under conditions conducive to pitting, such as in seawater. However, they are easily cathodically protected without fear of hydrogen embrittlement and perform well in fresh waters. The corrosion fatigue behavior of duplex alloys has not been widely studied.

Stress-Corrosion Cracking. The SCC of cast stainless steels has been investigated for only a limited number of environments, heat treatments, and test conditions. From the limited information available, the following generalizations apply.

First, SCC resistance seems to improve as the composition is adjusted to provide increasingly greater amounts of ferrite in an austenitic matrix. This trend continues to a certain level, apparently near 50% ferrite (Fig. 20 and 21). Second, lower nickel contents tend to improved SCC resistance in cast duplex alloys, possibly because of its effect on ferrite content (Ref 17). Third, ferrite appears to be involved in a keying action in discouraging SCC. At low and medium stress levels, the ferrite tends to block the propagation of stress-corrosion cracks. This may be due to a change in composition and/or crystal structure across the austenite/ferrite boundary (Fig. 21). As the stress level increases, crack propagation may change from austenite/ferrite boundaries to transgranular propagation (Ref 17, 18). Finally, reducing the carbon content of cast stainless alloys--thus reducing the susceptibility to sensitization--improves SCC resistance. This is also true for wrought alloys (Ref 17, 19, 20, 21).

Corrosion of Aluminum and Aluminum Alloys

E.H. Hollingsworth (retired) and H.Y. Hunsicker (retired), Aluminum Company of America*[*]

Introduction

ALUMINUM, as indicated by its position in the electromotive force (emf) series, is a thermodynamically reactive metal; among structural metals, only beryllium and magnesium are more reactive. Aluminum owes its excellent corrosion resistance and its usage as one of the primary metals of commerce to the barrier oxide film that is bonded strongly to its surface and that, if damaged, re-forms immediately in most environments. On a surface freshly abraded and then exposed to air, the barrier oxide film is only 1 nm (10 Å) thick but is highly effective in protecting the aluminum from corrosion.

The oxide film that develops in normal atmospheres grows to thicknesses much greater than 1 nm (10 Å) and is composed of two layers (Ref 1). The inner oxide next to the metal is a compact amorphous barrier layer whose thickness is determined solely by the temperature of the environment. At any given temperature, the limiting barrier thickness is the same in oxygen, dry air, or moist air. Covering the barrier layer is a thicker, more permeable outer layer of hydrated oxide. Most of the interpretation of aluminum corrosion processes has been developed in terms of the chemical properties of these oxide layers.

The natural film can be visualized as the result of a dynamic equilibrium between opposing forces--those tending to form the compact barrier layer and those tending to break it down. If the destructive forces are absent, as in dry air, the natural film will consist only of the barrier layer and will form rapidly to the limiting thickness. If the destructive forces are too strong, the oxide will be hydrated faster than it is formed, and little barrier will remain. Between these extremes, where the opposing forces reach a reasonable balance, relatively thick (20 to 200 nm, or 200 to 2000 Å) natural films are formed (Ref 2).

The conditions for thermodynamic stability of the oxide film are expressed by the Pourbaix (potential versus pH) diagram shown in Fig. 1. As shown by this diagram, aluminum is passive (is protected by its oxide film) in the pH range of about 4 to 8.5. The limits of this range, however, vary somewhat with temperature, with the specific form of oxide film present, and with the presence of substances that can form soluble complexes or insoluble salts with aluminum. The relative inertness in the passive range is further illustrated in Fig. 2, which gives results of weight loss measurements for alloy 3004-H14 specimens exposed in water and in salt solutions at various pH values.

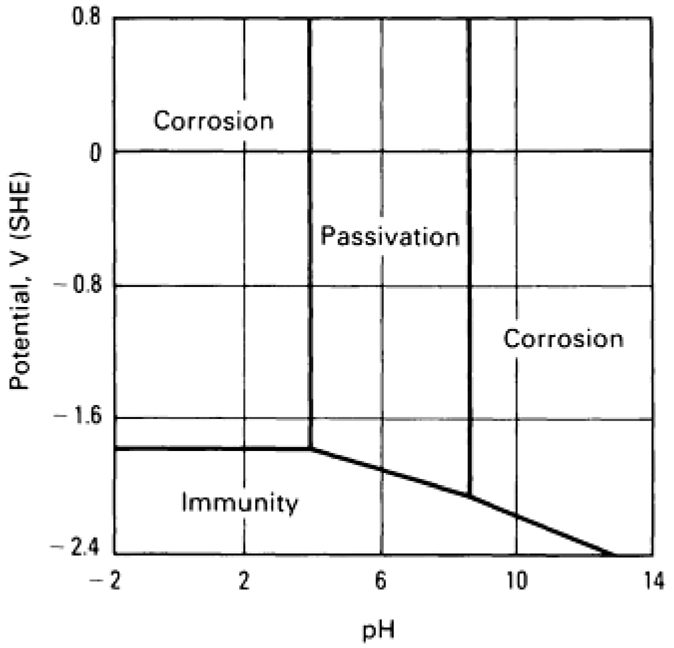

Fig. 1 Pourbaix diagram for aluminum with an $Al_2O_3 \cdot 3H_2O$ film at 25 °C (75 °F). Potential values are for the standard hydrogen electrode (SHE) scale. Source: Ref 3

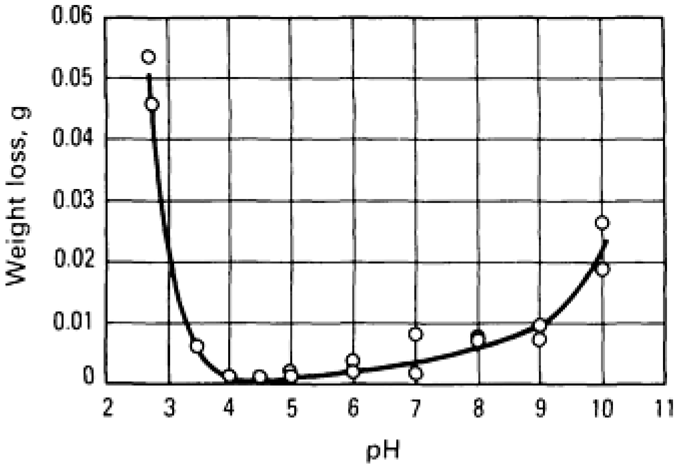

Fig. 2 Weight loss of alloy 3004-H14 exposed 1 week in distilled water and in solutions of various pH values. Specimens were 1.6 × 13 × 75 mm (0.06 × 0.5 × 3 in.). The pH values of solutions were adjusted with HCl and NaOH. Test temperature was 60 °C (140 °F).

Beyond the limits of it passive range, aluminum corrodes in aqueous solutions because its oxides are soluble in many acids and bases, yielding Al^{3+} ions in the former and AlO_2^- (aluminate) ions in the latter. There are, however, instances when corrosion does not occur outside the passive range, for example, when the oxide film is not soluble or when the film is maintained by the oxidizing nature of the solution (Ref 4).

Pitting Corrosion

Corrosion of aluminum in the passive range is localized, usually manifested by random formation of pits. The pitting-potential principle establishes the conditions under which metals in the passive state are subject to corrosion by pitting (Ref 5, 6, 7). Simply stated, pitting potential E_p is that potential in a particular solution above which pits will initiate and below which they will not.

Four laboratory procedures have been developed to measure E_p--one based on fixed current and the other three on controlled potential (Ref 8). The most widely used is controlled potential, in which the potential of a specimen, usually immersed in a deaerated electrolyte of interest, is made more positive and the resulting current density from the specimen measured. The potential at which the current density increases sharply and remains high is called the oxide breakdown potential, E_{br}. With polished specimens in many electrolytes, E_{br} is a close approximation of E_p, and the two are used interchangeably.

An example is shown in Fig. 3. A specimen of aluminum alloy 1100 was immersed in a neutral deaerated sodium chloride (NaCl) solution, and the relationship between anode potential and current density was plotted (solid line, Fig. 3). At potentials more active than E_p, where the oxide layer can maintain its integrity, anodic polarization is easy, and corrosion is slow and uniform. Above E_p, anodic polarization is difficult, and the current density sharply increases. The oxide ruptures at random weak points in the barrier layer and cannot repair itself, and localized corrosion develops at these points.

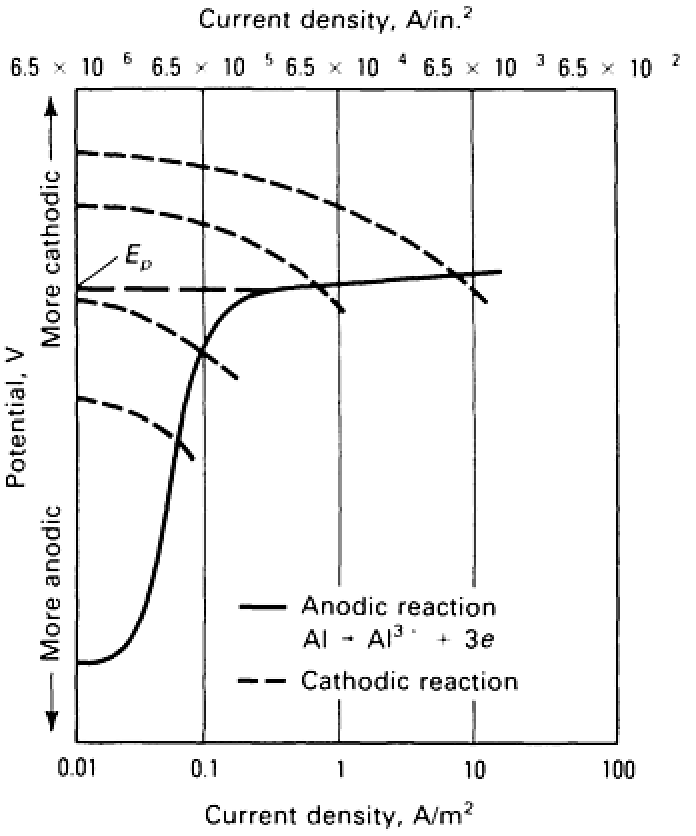

Fig. 3 Anodic-polarization curve for aluminum alloy 1100. Specimens were immersed in neutral deaerated NaCl solution free of cathodic reactant. Pitting develops only at potentials more cathodic than the pitting potential E_p. The intersection of the anodic curve for aluminum (solid line) with a curve for the applicable cathodic reaction (one of the representative dashed lines) determines the potential to which the aluminum is polarized, either by cathodic reaction on the aluminum itself or on another metal electrically connected to it. The potential to which the aluminum is polarized by a specific cathode reaction determines corrosion current density and corrosion

rate.

Potential-current relationship for various cathodic reactions are indicated by the dashed lines in Fig. 3. Only when the cathodic reaction is sufficient to polarize the metal to its pitting potential will significant current flow and pitting corrosion start.

For aluminum, pitting corrosion is most commonly produced by halide ions, of which chloride (Cl^-) is the most frequently encountered in service. The effect of chloride ion concentration on the pitting potential of aluminum 1199 (99.99 + % Al) is shown in Fig. 4. Pitting of aluminum in halide solutions open to the air occurs because, in the presence of oxygen, the metal is readily polarized to its pitting potential. In the absence of dissolved oxygen or other cathodic reactant, aluminum will not corrode by pitting because it is not polarized to its pitting potential. Generally, aluminum does not develop pitting in aerated solutions of most nonhalide salts because its pitting potential in these solutions is considerably more noble (cathodic) than in halide solutions, and it is not polarized to these potentials in normal service (Ref 7).

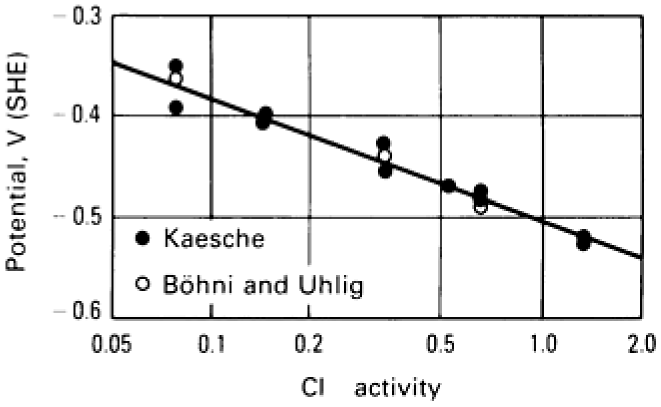

Fig. 4 Effect of chloride-ion activity on pitting potential of aluminum 1199 in NaCl solutions. Source: Ref 5 and 6.

Pitting potentials for selected aluminum alloys in several electrolytes are reported in Ref. 8. Examples of application of pitting-potential analysis to particular corrosion problems are given in Ref 9 and 10.

Solution Potentials

Because of the electrochemical nature of most corrosion processes, relationships among solution potentials of different aluminum alloys, as well as between potentials of aluminum alloys and those of other metals, are of considerable importance. Furthermore, the solution-potential relationships among the microstructural constituents of a particular alloy significantly affect its corrosion behavior. Compositions of solid solutions and additional phases, as well as amounts and spatial distributions of the additional phases, may affect both the type and extent of corrosion.

The solution potential of an aluminum alloy is primarily determined by the composition of the aluminum-rich solid solution, which constitutes the predominant volume fraction and area fraction of the alloy microstructure (Ref 11). Solution potential is not affected significantly by second-phase particles of microscopic size, but because these particles frequently have solution potentials differing from that of the solid-solution matrix in which they occur, localized galvanic cells may be formed between them and the matrix.

The effects of principal, alloying elements on solution potential of high-purity aluminum are shown in Fig. 5. For each element, the significant changes that occur do so within the range in which the element is completely in solid solution. Further addition of the same element, which forms a second phase, causes little additional change in solution potential.

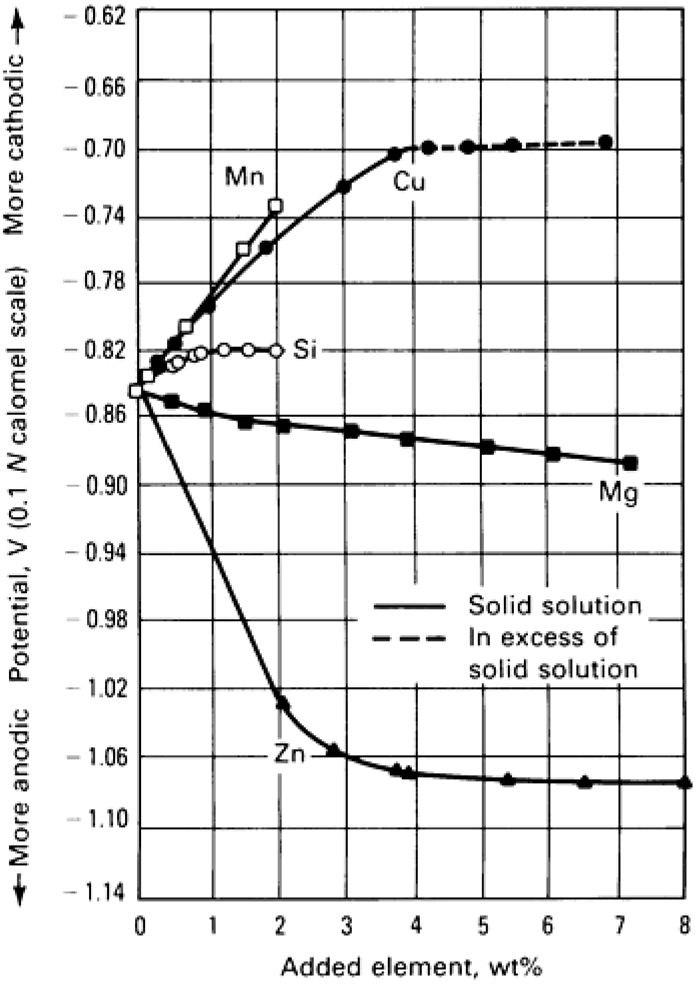

Fig. 5 Effects of principal alloying elements on the electrolytic-solution potential of aluminum. Potentials are for solution-treated and quenched high-purity binary alloys in a solution of 53 g/L NaCl plus 3 g/L H_2O_2 at 25 °C (75 °F).

Most commercial aluminum alloys contain additions of more than one of these elements; effects of multiple elements in solid solution on solution potential are approximately additive. The amounts retained in solid solution, particularly for more highly alloyed compositions, depend highly on fabrication and thermal processing so that heat treatment and other processing variables influence the final electrode potential of the product. Tables 1(a), 1(b), 1(c), and 1(d) present representative solution potentials of commercial aluminum alloys and of several other metals and alloys.

The amounts of second phases present in aluminum and aluminum alloy products vary from nearly zero in those of aluminum 1199 and some others that also are nearly pure solid solutions to over 20% in hypereutectic aluminum-silicon casting alloys, such as 392.0 and 393.0. These phases are generally intermetallic compounds of binary, ternary, or higher-order compositions, although some elements in excess of their solid solubility are present as elemental phases. Electrode potentials of some of the simpler second-phase constituents have been measured and are presented in Table 2. Measurement of the solution potentials of aluminum alloys has been standardized in ASTM G 69 (Ref 12).

Table 2 Solution potentials of some second-phase constituents in aluminum alloys

(a) Potential versus standard calomel electrode

Solution-potential measurements are useful for the investigation of heat-treating, quenching, and aging practices, and they are applied principally to alloys containing copper, magnesium, or zinc. In aluminum-copper and aluminum-copper-magnesium (2*xxx*) alloys, potential measurements can determine the effectiveness of solution heat treatment by measuring the amount of copper in solid solution. Also, by measuring the potentials of grain boundaries and grain bodies separately,

the difference in potential responsible for intergranular corrosion, exfoliation, and stress-corrosion cracking (SCC) can be quantified. Solution-potential measurements of alloys containing copper also show the progress of artificial aging as increased amounts of precipitates are formed and the matrix is depleted of copper.

Potential measurements are valuable with zinc-containing (7*xxx*) alloys for evaluating the effectiveness of the solution heat treatment, for following the aging process, and for differentiating among the various artificially aged tempers. These factors can affect corrosion behavior. In the magnesium-containing (5*xxx*) alloys, potential measurements can detect low-temperature precipitation and are useful in qualitatively evaluating stress-corrosion behavior. Potential measurements can also be used to follow the diffusion of zinc or copper in alclad products, thus determining whether the sacrificial cladding can continue to protect the core alloy (Ref 13).

Effects of Composition and Microstructure on Corrosion

1*xxx* Wrought Alloys. Wrought aluminums of the 1*xxx* series conform to composition specifications that set maximum individual, combined, and total contents for several elements present as natural impurities in the smelter-grade or refined aluminum used to produce these products. Aluminums 1100 and 1135 differ somewhat from the others in this series in having minimum and maximum specified copper contents. Corrosion resistance of all 1*xxx* compositions is very high, but under many conditions, it decreases slightly with increasing alloy content. Iron, silicon, and copper are the elements present in the largest percentages. The copper and part of the silicon are in solid solution. The second-phase particles present contain either iron or iron and silicon--Al_6Fe, Al_3Fe, and $Al_{12}Fe_3Si_2$ (Ref 14). The specific phase present or the relative amounts when more than one are present depend on the ratio of iron to silicon and on thermal history. The microstructural particles of these phases are cathodic to the aluminum solid solution, and exposed surfaces of these particles are covered by an oxide film thinner than that covering exposed areas of the solid solution (Ref 15). Corrosion may be initiated earlier and progress more rapidly in the aluminum solid solution immediately surrounding the particles. The number and/or size of such corrosion sites is proportional to the area fraction of the second-phase particles.

Not all impurity elements are detrimental to corrosion resistance of 1*xxx* series aluminum alloys, and detrimental elements may reduce the resistance of some types of alloys but have no ill effects in others. Therefore, specification limitations established for impurity elements are often based on maintaining consistent and predictable levels of corrosion resistance in various applications rather than on their effects in any specific application.

2*xxx* wrought alloys and 2*xx.x* casting alloys, in which copper is the major alloying element, are less resistant to corrosion than alloys of other series, which contain much lower amounts of copper. Alloys of this type were the first heat-treatable high-strength aluminum-base materials and have been used for more than 75 years in structural applications, particularly in aircraft and aerospace applications (Ref 16). Much of the thin sheet made of these alloys is produced as an alclad composite, but thicker sheet and other products in many applications require no protective cladding.

Electrochemical effects on corrosion can be stronger in these alloys than in alloys of many other types because of two factors: greater change in electrode potential with variations in amount of copper in solid solution (Fig. 5) and, under some conditions, the presence of nonuniformities in solid-solution concentration. However, that general resistance to corrosion decreases with increasing copper content is not primarily attributable to these solid-solution or second-phase solution-potential relationships, but to galvanic cells created by formation of minute copper particles or films deposited on the alloy surface as a result of corrosion. As corrosion progresses, copper ions, which initially go into solution, replate onto the alloy to form metallic copper cathodes. Reduction of copper ions and increased efficiency of O_2 and H^+ reduction reactions in the presence of copper increase the corrosion rate.

These alloys are invariably solution heat treated and are used in either the naturally aged or the precipitation heat-treated temper. Development of these tempers using good heat-treating practice can minimize electrochemical effects on corrosion resistance. The rate of quenching and the temperature and time of artificial aging can both affect the corrosion resistance of the final product.

2*xxx* Wrought Alloys Containing Lithium. Lithium additions decrease the density and increase the elastic modulus of aluminum alloys, making aluminum-lithium alloys good candidates for replacing the existing high-strength alloys, primarily in aerospace applications.

One of the earliest aluminum alloys containing lithium was 2020. This alloy in the T6 temper was commercially introduced in 1957 as a structural alloy with good strength properties up to 175 °C (350 °F). It has a modulus 8% higher

and a density 3% lower than alloy 7075-T6, but was rarely used in aircraft because of its relatively low fracture toughness. It was used in the thrust structure of the Saturn S-II, the second stage of the Saturn V launch vehicle (Ref 17).

Two recently registered lithium-bearing alloys are 2090 and 8090. Alloy 2090, in T8-type tempers, has a higher resistance to exfoliation than that of 7075-T6, and the resistance to SCC is comparable (Ref 18). Alloy 8090 is being designed by various producers to meet other combinations of mechanical-property goals (Ref 19).

Although lithium is highly reactive, addition of up to 3% Li to aluminum shifts the pitting potential of the solid solution only slightly in the anodic direction in 3.5% NaCl solution (Ref 20). In an extensive corrosion investigation of several binary and ternary aluminum-lithium alloys, modifications to the microstructure that promote formation of the δ phase (AlLi) were found to reduce the corrosion resistance of the alloy in 3.5% NaCl solution (Ref 21). It was concluded that an understanding of the nucleation and growth of the δ phase is central to an understanding of the corrosion behavior of these alloys.

3*xxx* Wrought Alloys. Wrought alloys of the 3*xxx* series (aluminum-manganese and aluminum-manganese-magnesium) have very high resistance to corrosion. The manganese is present in the aluminum solid solution, in submicroscopic particles of precipitate, and in larger particles of $Al_6(Mn,Fe)$ or $Al_{12}(Mn,Fe)_3Si$ phases, both of which have solution potentials almost the same as that of the solid-solution matrix (Ref 22). Such alloys are widely used for cooking and food-processing equipment, chemical equipment, and various architectural products requiring high resistance to corrosion.

4*xxx* Wrought Alloys and 3*xx.x* and 4*xx.x* Casting Alloys. Elemental silicon is present as second-phase constituent particles in wrought alloys of the 4*xxx* series, in brazing and welding alloys, and in casting alloys of the 3*xx.x* and 4*xx.x* series. Silicon is cathodic to the aluminum solid-solution matrix by several hundred millivolts and accounts for a considerable volume fraction of most of the silicon-containing alloys. However, the effects of silicon on the corrosion resistance of these alloys are minimal because of low corrosion current density resulting from the fact that the silicon particles are highly polarized.

Corrosion resistance of 3*xx.x* casting alloys is strongly affected by copper content, which can be as high as 5% in some compositions, and by impurity levels. Modifications of certain basic alloys have more restrictive limits on impurities, which benefit corrosion resistance and mechanical properties.

5*xxx* Wrought Alloys and 5*xx.x* Casting Alloys. Wrought alloys of the 5*xxx* series (aluminum-magnesium-manganese, aluminum-magnesium-chromium, and aluminum-magnesium-manganese-chromium) and casting alloys of the 5*xx.x* series (aluminum-magnesium) have high resistance to corrosion, and this accounts in part for their use in a wide variety of building products and chemical-processing and food-handling equipment, as well as applications involving exposure to seawater (Ref 23).

Alloys in which the magnesium is present in amounts that remain in solid solution, or is partially precipitated as Al_8Mg_5 particles dispersed uniformly throughout the matrix, are generally as resistant to corrosion as commercially pure aluminum and are more resistant to salt water and some alkaline solutions, such as those of sodium carbonate and amines. The wrought alloys containing about 3% or more magnesium under conditions that lead to an almost continuous intergranular Al_8Mg_5 precipitate, with very little precipitate within the grains, may be susceptible to exfoliation or SCC (Ref 24). Tempers have been developed for these higher-magnesium wrought alloys to produce microstructures having extensive Al_8Mg_5 precipitate within the grains, thus eliminating such susceptibility.

In the 5*xxx* alloys that contain chromium, this element is present as a submicroscopic precipitate, $Al_{12}Mg_2Cr$. Manganese in these alloys is in the form of $Al_6(Mn,Fe)$, both submicroscopic and larger particles. Such precipitates and particles do not adversely affect corrosion resistance of these alloys.

6*xxx* Wrought Alloys. Moderately high strength and very good resistance to corrosion make the heat-treatable wrought alloys of the 6*xxx* series (aluminum-magnesium-silicon) highly suitable in various structural, building, marine, machinery, and process-equipment applications. The Mg_2Si phase, which is the basis for precipitation hardening, is unique in that it is an ionic compound and is not only anodic to aluminum but also reactive in acidic solutions. However, either in solid solution or as submicroscopic precipitate, Mg_2Si has a negligible effect on electrode potential. Because these alloys are normally used in the heat-treated condition, no detrimental effects result from the major alloying elements or from the supplementary chromium, manganese, or zirconium, which are added to control grain structure. Copper

additions, which augment strength in many of these alloys, are limited to small amounts to minimize effects on corrosion resistance. In general, the level of resistance decreases somewhat with increasing copper content.

When the magnesium and silicon contents in a 6*xxx* alloy are balanced (in proportion to form only Mg_2Si), corrosion by intergranular penetration is slight in most commercial environments (Ref 25). If the alloy contains silicon beyond that needed to form Mg_2Si or contains a high level of cathodic impurities, susceptibility to intergranular corrosion increases (Ref 26).

7*xxx* wrought alloys and 7*xx.x* casting alloys contain major additions of zinc, along with magnesium or magnesium plus copper in combinations that develop various levels of strength. Those containing copper have the highest strengths and have been used as constructional materials, primarily in aircraft applications, for more than 40 years. The copper-free alloys of the series have many desirable characteristics: moderate-to-high strength; excellent toughness; and good workability, formability, and weldability. Use of these copper-free alloys has increased in recent years and now includes automotive applications (such as bumpers), structural members and armor plate for military vehicles, and components of other transportation equipment.

The 7*xxx* wrought and 7*xx.x* casting alloys, because of their zinc contents, are anodic to 1*xxx* wrought aluminums and to other aluminum alloys. They are among the aluminum alloys most susceptible to SCC. However, SCC can be avoided by proper alloy and temper selection and by observing appropriate design, assembly, and application precautions (Ref 27). Stress-corrosion cracking of aluminum alloys is discussed in greater detail in a subsequent section in this article.

Resistance to general corrosion of the copper-free wrought 7*xxx* alloys is good, approaching that of the wrought 3*xxx*, 5*xxx*, and 6*xxx* alloys (Ref 28). The copper-containing alloys of the 7*xxx* series, such as 7049, 7050, 7075, and 7178 have lower resistance to general corrosion than those of the same series that do not contain copper. All 7*xxx* alloys are more resistant to general corrosion than 2*xxx* alloys, but less resistant than wrought alloys of other groups.

Although the copper in both wrought and cast alloys of the aluminum-zinc-magnesium-copper type reduces resistance to general corrosion, it is beneficial from the standpoint of resistance to SCC. Copper allows these alloys to be precipitated at higher temperatures without excessive loss in strength and thus makes possible the development of T73 tempers, which couple high strength with excellent resistance to SCC (Ref 29).

Composites. Aluminum alloys reinforced with silicon carbide (Ref 30), graphite (Ref 31), or boron (Ref 32) show promise as metal matrix composites for lightweight structural applications with increased modulus and strength and are potentially well suited to aerospace and military needs. The corrosion behavior of composites is governed by galvanic action between the aluminum matrix and the reinforcing material. When both are exposed to an aggressive environment, corrosion of the aluminum is accelerated. Silicon carbide, graphite, and boron are cathodic to aluminum and do not polarize easily.

For a useful service life, some form of corrosion protection is needed. Aluminum thermal spraying has been reported as a successful protection method for discontinuous silicon carbide/aluminum composites; for continuous graphite/aluminum or silicon carbide/aluminum, sulfuric acid (H_2SO_4) anodizing has provided protection, as have organic coatings or ion vapor deposited aluminum (Ref 33).

Effects of Additional Alloying Elements. In addition to the major elements that define the various alloy systems discussed above, commercial aluminum alloys may contain other elements that provide special characteristics. Lead and bismuth are added to alloys 2011 and 6262 to improve chip breakage and other machining characteristics. Nickel is added to wrought alloys 2018, 2218, and 2618, which were developed for elevated-temperature service, and to certain 3*xx.x* cast alloys used for pistons, cylinder blocks, and other engine parts subjected to high temperatures. Cast aluminum bearing alloys of the 850.0 group contain tin. In all cases, these alloying additions introduce constituent phases that are cathodic to the matrix and decrease resistance to corrosion in aqueous saline media. However, these alloys are often used in environments in which they are not subject to corrosion.

Corrosion Ratings of Alloys and Tempers

Simplified ratings of resistance to general corrosion and to SCC for wrought and cast aluminum alloys are presented in Tables 3 and 4(a) and 4(b). These ratings may be useful in evaluating and comparing alloy/temper combinations for

corrosion service (more detailed ratings of resistance to SCC for high-strength wrought aluminum alloys are given in Table 6 and in Ref 34).

(a) Ratings are relative and in decreasing order of merit, based on exposure to NaCl solution by intermittent spraying or immersion. Alloys with A and B ratings can be used in industrial and seacoast atmospheres without protection. Alloys with C, D, and E ratings generally should be protected, at least on faying surfaces.

(b) SCC ratings are based on service experience and on laboratory tests of specimens exposed to alternate immersion in 3.5% NaCl solution. A, no known instance of failure in service or in laboratory tests; B, no known instance of failure in service; limited failures in laboratory tests of short transverse specimens; C, service failures when sustained tension stress acts in short-transverse direction relative to grain structure; limited failures in laboratory tests of long transverse specimens; D, limited service failures when sustained stress acts in longitudinal or long-transverse direction relative to grain structure.

(c) In relatively thick sections, the rating would be E.

(d) This rating may be different for material held at elevated temperatures for long periods.

(c) For electric motor rotors

Galvanic Corrosion and Protection

The solution-potential values in Tables 1(b), 1(a), 1(c), and 1(d) as measured against a standard calomel electrode (SCE), form a galvanic series for aluminum alloys and other metals. The galvanic relationships indicated by these values have wide applicability because of the similarity of the electrochemical behavior of these metals in the NaCl solution to that in marine and other saline environments. This galvanic series, however, is not necessarily valid in nonsaline solutions. For example, aluminum is anodic to zinc in an aqueous 1 *M* sodium chromate (Na_2CrO_4) solution and cathodic to iron in an aqueous 1 *M* sodium sulfate (Na_2SO_4) solution.

Under most environmental conditions frequently encountered in service, aluminum and its alloys are the anodes in galvanic cells with most other metals, protecting them by corroding sacrificially. Only magnesium and zinc are more anodic. Sacrificial corrosion of aluminum or cadmium is slight when these two metals are coupled in a galvanic cell, because of the small difference in electrode potential between them.

Contact of aluminum with more cathodic metals should be avoided in any environment in which aluminum by itself is subject to pitting corrosion. Where such contact is necessary, protective measures should be implemented to minimize sacrificial corrosion of the aluminum. In such an environment, aluminum is already polarized to its pitting potential, and the additional potential imposed by contact with the more cathodic metal greatly increases the corrosion current. In many environments, aluminum can be used in contact with chromium or stainless steels with only slight acceleration of

corrosion; chromium and stainless steels are easily polarized cathodically in mild environments, so that the corrosion current is small despite the large differences in the open-circuit potentials between these metals and aluminum.

To minimize corrosion of aluminum wherever contact with more cathodic metals cannot be avoided, the ratio of the exposed surface area of the aluminum to that of the more cathodic metal should be as high as possible to minimize the current density at the aluminum and therefore the rate of corrosion. The area ratio may be increased by painting the cathodic metal or both metals, but painting only the aluminum is not effective and may even accelerate corrosion.

Corrosion of aluminum in contact with more cathodic metals is much less severe in solutions of most nonhalide salts, in which aluminum alone normally is not polarized to its pitting potential, than in solutions of halide salts, in which it is. As shown in Fig. 3, increases in potential, as long as the value does not reach the pitting potential, have small effects on current density.

Galvanic current between aluminum and another metal also can be reduced by removing oxidizing agents from the electrolyte. Thus, the corrosion rate of aluminum coupled to copper in seawater is greatly reduced wherever the seawater is deaerated. In closed multimetallic systems, the corrosion rate of aluminum, although initially high, decreases to a low value whenever the cathodic reactant is depleted. Galvanic current is also low in solutions having high electrical resistivity, such as high-purity water, but some semi-conductors, such as graphite and magnetite, are cathodic to aluminum, and when in contact with them, aluminum corrodes sacrificially.

In alclad products, the difference in solution potential between the core alloy and the cladding alloy is used to provide cathodic protection to the core (Ref 35). These products, primarily sheet and tube, consist of a core clad on one or both surfaces with a metallurgically bonded layer of an alloy that is anodic to the core alloy. The thickness of the cladding layer is usually less than 10% of the overall thickness of the product.

Cladding alloys are generally of the nonheat-treatable type, although heat-treatable alloys are sometimes used for higher strength. For mechanical-design calculations, such sacrificial claddings are treated as corrosion allowances and are not normally included in the determination of the strength of an alclad product.

Composition relationships of core and cladding alloys are generally designed so that the cladding is 80 to 100 mV anodic to the core. Table 5 lists several core alloy/cladding alloy combinations for common alclad products. Because of the cathodic protection provided by the cladding, corrosion progresses only to the core/cladding interface, then spreads laterally. This is highly effective in eliminating perforation of thin-wall products.

Table 5 Combinations of aluminum alloys used in some alclad products

Core alloy	Cladding alloy
2014	6003 or 6053
2024	1230

7178	7072

Surface Treatments. A process that produces an effect similar to that of conventional sacrificial cladding is called diffusion cladding. Aluminum products can be clad using this process, regardless of their shape (Ref 36). The process involves two steps: first, a thin film of zinc is deposited on the aluminum surface by chemical displacement from an alkaline zincate solution, then the zinc is diffused into the aluminum to produce a zone of zinc-enriched alloy that is anodic to the underlying aluminum. It was found that 3003 aluminum with a correctly balanced zinc diffusion treatment exhibited uniform corrosion and that the depth of corrosion was restricted to about one-half the thickness of the diffusion zone (Ref 37). These results suggest that a zinc diffusion treatment may be as effective as conventional alcladding for the prevention of localized pitting.

Another way to simulate alcladding is to apply a coating of an anodic alloy to an aluminum surface by thermal-spray techniques, such as flame or plasma spray. These coatings act in the same way as the cladding layer on an alclad product and corrode sacrificially to protect the core alloy (Ref 38, 39).

Cathodic Protection. In some applications, aluminum alloy parts, assemblies, structures, and pipelines are cathodically protected by anodes either made of more anodic metals or made anodic by using impressed potentials. In either case, because the usual cathodic reaction produces hydroxyl ions, the current on these alloys should not be high enough to make the solution sufficiently alkaline to cause significant corrosion (Ref 40).

The criterion for cathodic protection of aluminum in soils and waters has been published by the National Association of Corrosion Engineers (Ref 41). The suggested practice is to shift the potential at least -0.15 V but not beyond the value of -1.20 V as measured against a saturated copper sulfate ($Cu/CuSO_4$) reference electrode. In some soils, potentials as low as -1.4 V have been encountered without appreciable cathodic corrosion (Ref 42). Essentially the same criterion is followed in Eastern Europe (Ref 43).

Several examples of cathodic protection of aluminum equipment in chemical plants, as well as a preference for sacrificial anodes of zinc or aluminum-zinc alloy, are discussed in Ref 44. Such protection is most successful in electrolytes in the pH range of 4 to 8.5--the so-called neutral range. The cathodic protection of aluminum structures is reviewed in Ref 45, which supports general experience that cathodic protection is effective in preventing or greatly reducing several types of corrosion attack.

Buried aluminum pipelines are usually protected by sacrificial anodes--zinc for coated lines and magnesium for uncoated lines. It is generally accepted that such coatings as extruded polyethylene or a tape wrap should be applied to aluminum pipes for underground service. Because of the effectiveness and longevity of sacrificial anode systems and the need to avoid overprotection, impressed current (rectifier) systems generally are not used to protect aluminum pipelines.

The cathodic protection of aluminum alloys in seawater has been extensively studied (Ref 46, 47). Sacrificial anodes were found to be effective in reducing surface pitting and crevice corrosion without causing cathodic attack.

Deposition Corrosion

In designing aluminum and aluminum alloys for satisfactory corrosion resistance, it is important to keep in mind that ions of several metals have reduction potentials that are more cathodic than the solution potential of aluminum and therefore can be reduced to metallic form by aluminum. For each chemical equivalent of so-called heavy-metal ions reduced, a chemical equivalent of aluminum is oxidized. Reduction of only a small amount of these ions can lead to severe localized corrosion of aluminum, because the metal reduced from them plates onto the aluminum and set up galvanic cells. The more important heavy metals are copper, lead, mercury, nickel, and tin. The effects of these metals on aluminum are of greatest concern in acidic solutions; in alkaline solutions, they have much lower solubilities and therefore much less severe effects.

Copper is the heavy metal most commonly encountered in applications of aluminum. A copper-ion concentration of 0.02 to 0.05 ppm in neutral or acidic solutions is generally considered to be the threshold value for initiation of pitting on aluminum. A specific value for the copper-ion threshold is normally not proposed because the pitting tendency also depends on the aluminum alloy; the pH of the water; concentrations of other ions in the water, particularly bicarbonate

(HCO_3^-), chloride (Cl^-), and calcium (Ca^{2+}); and on whether the pits that develop are open or occluded (Ref 48). Copper contamination of solutions in contact with aluminum should be minimized or avoided. As discussed previously, the relatively low corrosion resistance of aluminum-copper alloys results from reduction of copper ions present in the corrosion product of the alloy.

Ferric (Fe^{3+}) ion can be reduced by aluminum, but does not form a metallic deposit. This ion is rarely encountered in service because it reacts preferentially with oxygen and water to form insoluble oxides and hydroxides, except in acidic solutions outside the passive range of aluminum. On the other hand, at room temperature, the most anodic aluminum alloys (those with a corrosion potential approaching -1.0 V versus the SCE) can reduce ferrous (Fe^{2+}) ions to metallic iron and produce a metallic deposit on the surface of the aluminum. The presence of (Fe^{2+}) ion also tends to be rare in service; it exists only in deaerated solutions or in other solutions free of oxidizing agents (Ref 49).

Mercury amalgamates with aluminum with difficulty because the natural oxide film on aluminum prevents metal-to-metal contact. However, after the two metals have been brought together, if the oxide film is broken by mechanical or chemical action, amalgamation occurs immediately, and in the presence of moisture, corrosion of the aluminum proceeds rapidly (Ref 50). Aluminum in contact with a solution of a mercury salt forms metallic mercury, which then readily amalgamates the aluminum. Of all the heavy metals, mercury can cause the most corrosion damage to aluminum (Ref 51). The effect can be severe when stress is present. For example, attack by mercury and zinc amalgam combined with residual stresses from welding caused cracking of the weldment (Fig. 6). The corrosive action of mercury can be serious with or without stress because amalgamation, once initiated, continues to propagate unless the mercury can be removed. If an aluminum surface has become contaminated with mercury, the mercury can be removed by treatment with 70% nitric acid (HNO_3) or by evaporation in steam or hot air (Ref 52). It is difficult to determine the safe level of mercury that can be tolerated on aluminum. In solutions, concentrations exceeding a few parts per billion should be viewed with suspicion; in atmospheres, any amount exceeding that allowed by Environmental Protection Agency regulations is suspect.

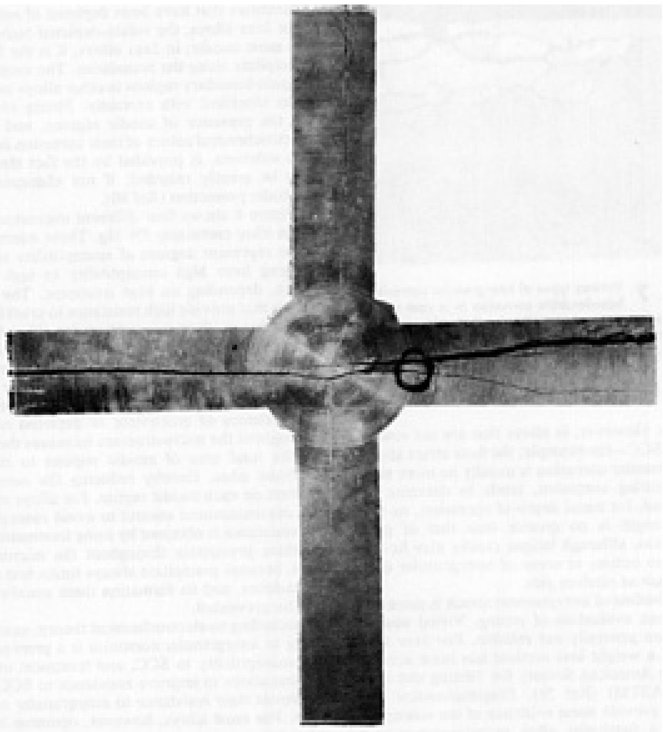

Fig. 6 Section through cruciform weldment of alloy 5083-H131 plate cracked by mercury. Attack was initiated by applying a few drops of mercury chloride ($HgCl_2$) solution and zinc amalgam to the sectioned surface at the circled area (right of center). 0.33×

Intergranular Corrosion

Intergranular (intercrystalline) corrosion is selective attack of grain boundaries or closely adjacent regions without appreciable attack of the grains themselves. Intergranular corrosion is a generic term that includes several variations associated with different metallic structures and thermomechanical treatments (Fig. 7).

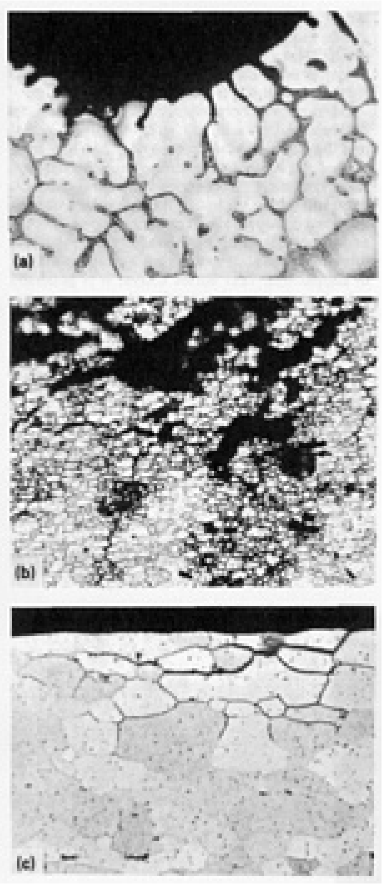

Fig. 7 Various types of intergranular corrosion. (a) Interdendritic corrosion in a cast structure. (b) Interfragmentary corrosion in a wrought, unrecrystallized structure. (c) Intergranular corrosion in a recrystallized wrought structure. All etched with Keller's reagent. 500×

Intergranular corrosion is caused by potential differences between the grain-boundary region and the adjacent grain bodies (Ref 53). The location of the anodic path varies with the different alloy systems. In 2*xxx* series alloys, it is a narrow band on either side of the boundary that is depleted in copper; in 5*xxx* series alloys, it is the anodic constituent Mg_2Al_3 when that constituent forms a continuous path along a grain boundary; in copper-free 7*xxx* series alloys, it is generally considered to be the anodic zinc- and magnesium-bearing constituents on the grain boundary; and in the copper-bearing 7*xxx* series alloys, it appears to be the copper-depleted bands along the grain boundaries (Ref 54, 55). The 6*xxx* series alloys generally resist this type of corrosion, although slight intergranular attack has been observed in aggressive environments. The electrochemical mechanism for intergranular corrosion proposed by E.H. Dix has been verified (Ref 56) and related to the pitting potentials of aluminum (Ref 57).

Because intergranular corrosion is involved in SCC of aluminum alloys, it is often presumed to be more deleterious than pitting or general corrosion. However, in alloys that are not susceptible to SCC--for example, the 6*xxx* series alloys--intergranular corrosion is usually no more severe than pitting corrosion, tends to decrease with time and, for equal depth of corrosion, its effect on strength is no greater than that of pitting corrosion, although fatigue cracks may be more likely to initiate at areas of intergranular corrosion than at random pits.

Evaluation of intergranular attack is more complex than evaluation of pitting. Visual observations are generally not reliable. For 5*xxx* series alloys, a weight loss method has been accepted by The American Society for Testing and

Materials (ASTM) (Ref 58). Electrochemical techniques provide some evidence of the susceptibility of a particular alloy or microstructure to intergranular corrosion, but such techniques should be accompanied by a metallographic examination of carefully prepared sections.

Stress-Corrosion Cracking

Only aluminum alloys that contain appreciable amounts of soluble alloying elements, primarily copper, magnesium, silicon, and zinc, are susceptible to SCC. For most commercial alloys, tempers have been developed that provide a high degree of immunity to SCC in most environments.

The electrochemical theory of stress corrosion, which was developed in about 1940, describes certain conditions required for SCC of aluminum alloys (Ref 53, 59, 60). Further research showed inadequacies in this theory, and the complex interactions among factors that lead to SCC of aluminum alloys are not yet fully understood (Ref 61). However, there is general agreement that for aluminum the electrochemical factor predominates and the electrochemical theory continues to be the basis for developing aluminum alloys and tempers resistant to SCC (Ref 62).

Stress-corrosion cracking in aluminum alloys is characteristically intergranular. According to the electrochemical theory, this requires a condition along grain boundaries that makes them anodic to the rest of the microstructure so that corrosion propagates selectively along them. Such a condition is produced by localized decomposition of solid solution, with a high degree of continuity of decomposition products, along the grain boundaries. The most anodic regions may be either the boundaries themselves (most commonly, the precipitate formed in them) or regions adjoining the boundaries that have been depleted of solute.

In 2*xxx* alloys, the solute-depleted regions are the most anodic; in 5*xxx* alloys, it is the Mg_2Al_3 precipitate along the boundaries. The most anodic grain-boundary regions in other alloys have not been identified with certainty. Strong evidence for the presence of anodic regions, and of the electrochemical nature of their corrosion in aqueous solutions, is provided by the fact that SCC can be greatly retarded, if not eliminated, by cathodic protection (Ref 60).

Figure 8 shows four different microstructures in an alloy containing 5% Mg. These microstructures represent degrees of susceptibility to SCC ranging from high susceptibility to high resistance, depending on heat treatment. The treatments that provide high resistance to cracking are those that produce microstructures either free of precipitate along grain boundaries (Fig. 8a) or with precipitate distributed as uniformly as possible within grains (Fig. 8d). In the latter case, corrosion along boundaries is minimized because the presence of precipitate or depleted regions throughout the microstructure increases the ratio of the total area of anodic regions to that of cathodic ones, thereby reducing the corrosion current on each anodic region. For alloys requiring microstructural control to avoid susceptibility, resistance is obtained by using treatments that produce precipitate throughout the microstructure, because precipitate always forms first along boundaries, and its formation there usually cannot be prevented.

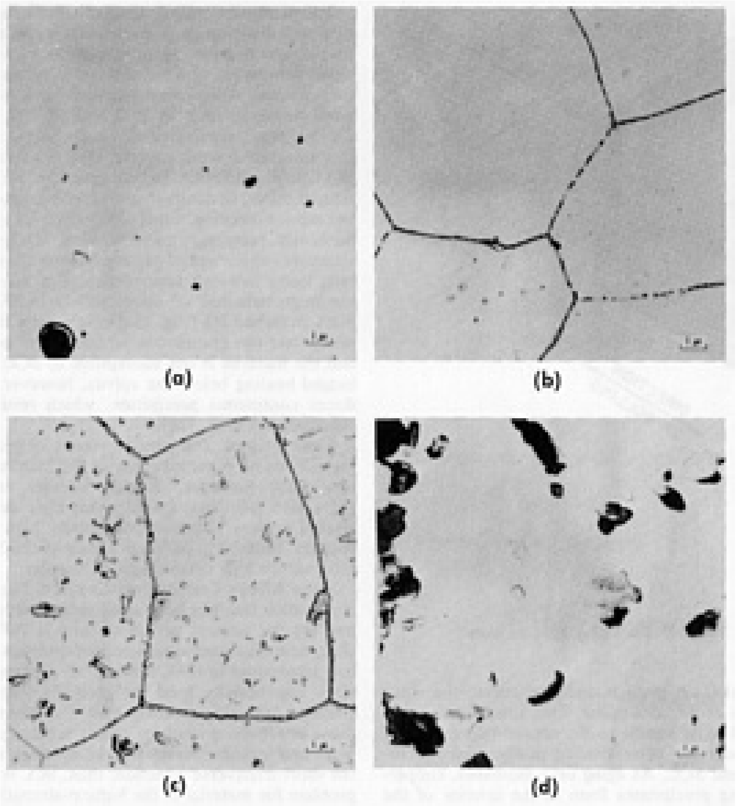

Fig. 8 Microstructures of alloy 5356-H12 after treatment to produce varying degrees of susceptibility to SCC. (a) Cold rolled 20%; highly resistant. (b) Cold rolled 20%, then heated 1 year at 100 °C (212 °F); highly susceptible. (c) Cold rolled 20%, then heated 1 year at 150 °C (300 °F); slightly susceptible. (d) Cold rolled 20%, then heated 1 year at 205 °C (400 °F); highly resistant

According to electrochemical theory, susceptibility to intergranular corrosion is a prerequisite for susceptibility to SCC, and treatment of aluminum alloys to improve resistance to SCC also improves their resistance to intergranular corrosion. For most alloys, however, optimum levels of resistance to these two types of failure require different treatments, and resistance to intergranular corrosion is not a reliable indication of resistance to SCC.

In many cases, susceptibility to SCC of an aluminum alloy cannot be predicted reliably by examining its microstructure. Many observations have been made of the progressive changes in dislocation network, precipitation pattern, and other microstructural features that occur as an alloy is treated to improve its resistance to SCC, but these changes have not been correlated quantitatively with susceptibility.

Effect of Stress. Whether or not SCC develops in a susceptible aluminum alloy product depends on both magnitude and duration of tensile strength acting at the surface. The effects of the factors have been established most commonly by means of accelerated laboratory tests; results of one set of such tests are reflected in the shaded bands in Fig. 9. Despite introduction of fracture mechanics techniques capable of determining crack growth rates, such tests continue to be the basic tools used in evaluating resistance of aluminum alloys to SCC. These tests suggest a minimum (threshold) stress that is required for cracking to develop.

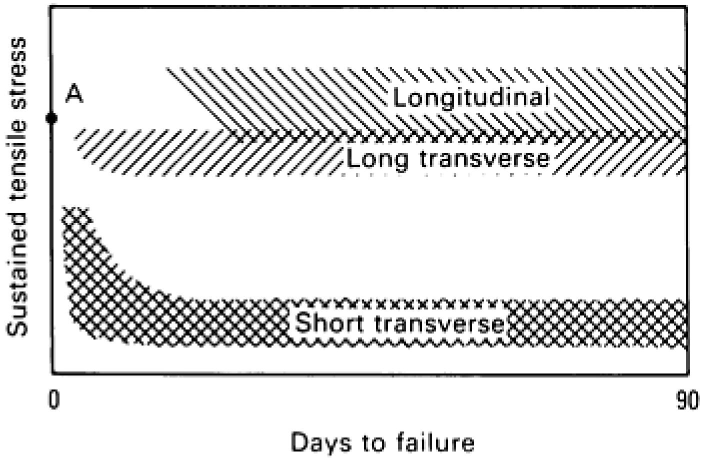

Fig. 9 SCC of alloy 7075-T651 plate. Shaded bands indicate combinations of stress and time known to produce SCC in specimens intermittently immersed in 3.5% NaCl solution. Point A is minimum yield strength in the long-transverse direction for a 75-mm (3-in.) thick plate.

Although empirical in nature, the threshold value provides a valid measure of the relative susceptibilities of aluminum alloys to SCC under the specific conditions of a particular test or environment. Also, for some alloy/temper combinations, results of accelerated laboratory tests reliably predict stress-corrosion performance in service; for example, results of an 84-day alternate immersion test of alloy 7075 and alloy 7178 products correlated well with performance of these products in a seacoast environment.

Stress Relieving. Residual stresses are induced in aluminum alloy products when they are solution heat treated and quenched. Figure 10(a) shows the typical distribution and magnitude of residual stresses in thick high-strength material of constant cross section. Quenching places the surfaces in compression and the center in tension. If the compressive surface stresses are not disturbed by subsequent fabrication practices, the surface has an enhanced resistance to SCC because a sustained tensile stress is necessary to initiate and propagate this type of corrosion.

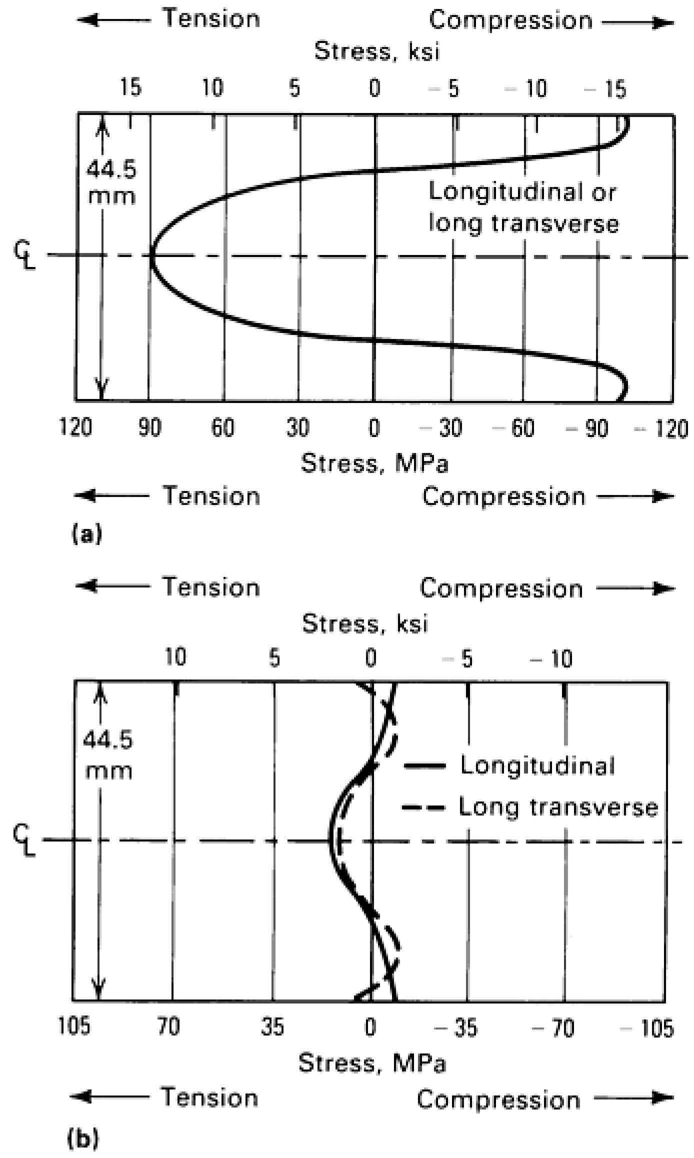

Fig. 10 Comparison of residual stresses in a thick, constant cross-section 7075-T6 aluminum alloy plate before and after stress relief. (a) High residual stresses in the solution-treated and quenched alloy. (b) Reduction in stresses after stretching 2%. Source: Ref 63

On the other hand, one of the most common practices associated with SCC problems is machining into the residual high tensile stress areas of material that has not been stress relieved. If the exposed tensile stresses are in a transverse direction or have a transverse component and if a susceptible alloy or temper is involved, the probability of SCC is present (Ref 63).

Aluminum products of constant cross section are stress relieved effectively and economically by mechanical stretching. The stretching operation must be done after quenching and, for most alloys, before artificial aging. Note the low magnitude of residual stresses after stretching (Fig. 10b) as compared to the as-quenched material in Fig. 10(a). Federal specifications for rolled and extruded products provide for stress relieving by stretching on the order of 1 to 3%.

Thus, the use of the stress-relieved temper for heat-treated mill products will minimize SCC problems related to quenching stresses. The stress-relieved temper for most alloys is identified by the designation T*x*5*x* or T*x*5*xx* after the alloy number, for example, 2024-T351 or 7075-T6511 (Ref 64).

Effects of Grain Structure and Stress Direction. Many wrought aluminum alloy products have highly directional grain structures (Fig. 11). Such products are highly anisotropic with respect to resistance to SCC (Fig. 9). Resistance,

which is measured by magnitude of tensile stress required to cause cracking, is highest when the stress is applied in the longitudinal direction, lowest in the short-transverse direction, and intermediate in other directions. These differences are most noticeable in the more susceptible tempers, but are usually much lower in tempers produced by extended precipitation treatments, such as T6 and T8 tempers for 2*xxx* alloys and T73, T736, and T76 tempers for 7*xxx* alloys.

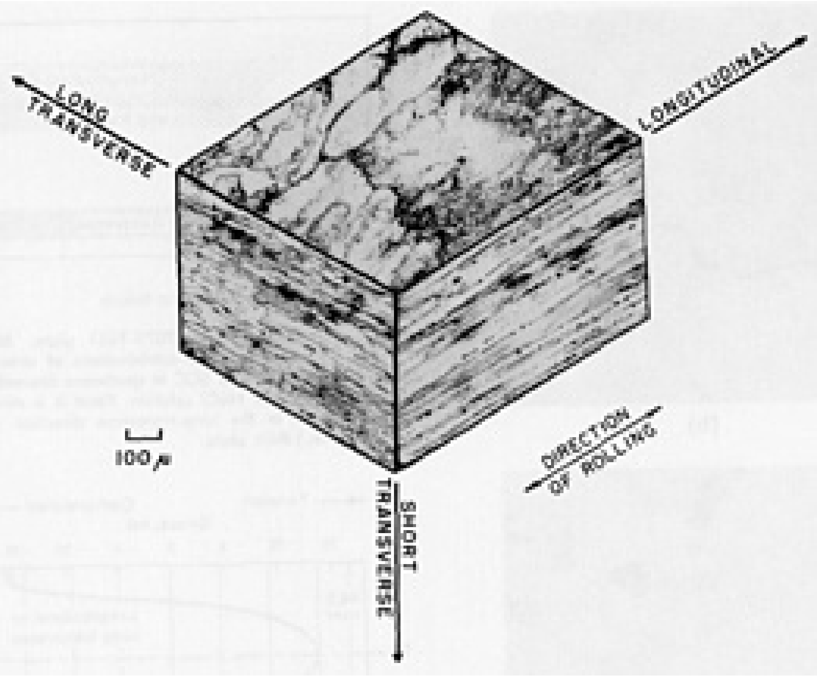

Fig. 11 Composite micrograph showing grain structure of a 38-mm (1.5-in.) alloy 7075-T6 plate

Thus, direction and magnitude of stresses anticipated under conditions of assembly and service may govern alloy and temper selection. For products of thin section, applied in ways that induce little or no tensile stress in the short-transverse direction, resistance of 2*xxx* alloys in T3 or T4 tempers or of 7*xxx* alloys in T6 tempers may suffice. Resistance in the short-transverse direction usually controls application of products that are of thick section or are machined or applied in ways that result in sustained tensile stresses in the short-transverse direction. More resistant tempers are preferred in these cases.

Effects of Environment. Research indicates that water or water vapor is the key environmental factor required to produce SCC in aluminum alloys. Halide ions have the greatest effects in accelerating attack. Chloride is the most important halide ion because it is a natural constituent of marine environments and is present in other environments as a contaminant. Because it accelerates SCC, Cl^- is the principal component of environments used in laboratory tests to determine susceptibility of aluminum alloys to this type of attack. In general, susceptibility is greater in neutral solutions than in alkaline solutions and is greater still in acidic solutions.

Stress-Corrosion Ratings. A system of ratings of resistance to SCC for high-strength aluminum alloy products has been developed by a joint task group of ASTM and the Aluminum Association to assist alloy and temper selection, and has been incorporated into Ref 34. Definitions of these ratings, which range from A (highest resistance) to D (lowest resistance), are as follows:

- **A: Very high.** No record of service problems; SCC not anticipated in general applications
- **B: High.** No record of service problems; SCC not anticipated at stresses of the magnitude caused by solution heat treatment. Precautions must be taken to avoid high sustained tensile stresses (exceeding 50% of the minimum specified yield strength) produced by any combination of sources including heat treatment, straightening, forming, fit-up, and sustained service loading
- **C: Intermediate.** Stress-corrosion cracking not anticipated if total sustained tensile stress is maintained below 25% of minimum specified yield strength. This rating is designated for the short-transverse

direction in products used primarily for high resistance to exfoliation corrosion in relatively thin structures, where appreciable stresses in the short-transverse direction are unlikely

- **D: Low.** Failure due to SCC is anticipated in any application involving sustained tensile stress in the designated test direction. This rating is currently designated only for the short-transverse direction in certain products

These stress levels are not to be interpreted as threshold stresses and are not recommended for design. Documents such as MIL-HANDBOOK-5, MIL-STD-1568, NASC SD-24, and MSFC-SPEC-522A should be consulted for design recommendations.

The relative ratings of resistance to SCC for high-strength wrought aluminum alloys are presented in Table 6. These ratings, assigned primarily by alloy and temper, also distinguish among test directions and product types.

2*xxx* Alloys. Thick-section products of 2*xxx* alloys in the naturally aged T3 and T4 tempers have low ratings of resistance to SCC in the short-transverse direction. Ratings of such products in other directions are higher, as are ratings of thin-section products in all directions. These differences are related to the effects of quenching rate (largely determined by section thickness) on the amount of precipitation that occurs during quenching. If 2*xxx* alloys in T3 and T4 tempers are heated for short periods in the temperature range used for artificial aging, selective precipitation along grain or subgrain boundaries may further impair their resistance.

Longer heating, as specified for T6 and T8 tempers, produces more general precipitation and significant improvements in resistance to SCC. Precipitates are formed within grains at a greater number of nucleation sites during treatment to T8 tempers. These tempers require stretching, or cold working by other means, after quenching from the solution heat treatment temperature and before artificial aging. These tempers provide the highest resistance to SCC and the highest strength in the 2*xxx* alloy.

Some studies on aluminum-copper-lithium alloys indicate that these alloys have their highest resistance to SCC at or near peak-aged tempers (Ref 65, 66, 67). Underaging of these alloys (for example, 2090) is detrimental; overaging decreases resistance only slightly. The susceptibility of the underaged microstructure has been attributed to the precipitation of an intermetallic constituent, Al_2CuLi, on grain boundaries during the early stages of artificial aging. This constituent is believed to be anodic to the copper-rich matrix of an underaged alloy, causing preferential dissolution and SCC. As aging time increases, copper-bearing precipitates form in the interior of the grains, thus increasing the anode-cathode area ratio in the microstructure to a more favorable value that avoids selective grain-boundary attack. Similar studies of stress-corrosion behavior are being conducted on aluminum-lithium-copper-magnesium alloys (for example, 8090) (Ref 68).

5*xxx* alloys are not considered heat treatable and do not develop their strength through heat treatment. However, these alloys are processed to H3 tempers, which require a final thermal stabilizing treatment to eliminate age softening, or to H2 tempers, which require a final partial annealing. The H116 or H117 tempers are also used for high-magnesium 5*xxx* alloys and involve special temperature control during fabrication to achieve a microstructural pattern of precipitate that increases the resistance of the alloy to intergranular corrosion and SCC. The alloys of the 5*xxx* series span a wide range of magnesium contents, and the tempers that are standard for each alloy are primarily established by the magnesium content and the desirability of micro-structures highly resistant to SCC and other forms of corrosion.

Although 5*xxx* alloys are not heat treatable, they develop good strength through solution hardening by the magnesium retained in solid solution, dispersion hardening by precipitates, and strain-hardening effects. Because the solid solutions in the higher-magnesium alloys are more highly supersaturated, the excess magnesium tends to precipitate out as Mg_2Al_3, which is anodic to the matrix. Precipitation of this phase with high selectivity along grain boundaries, accompanied by little or no precipitation within grains, may result in susceptibility to SCC.

The probability that a susceptible microstructure will develop in a 5*xxx* alloy depends on magnesium content, grain structure, amount of strain hardening, and subsequent time/temperature history. Alloys with relatively low magnesium contents, such as 5052 and 5454 (2.5 and 2.75% Mg, respectively), are only mildly supersaturated; consequently, their resistance to SCC is not affected by exposure to elevated temperatures. In contrast, alloys with magnesium contents exceeding about 3%, when in strain-hardened tempers, may develop susceptible structures as a result of heating or even after very long times at room temperature. For example, the microstructure of alloy 5083-O (4.5% Mg) plate stretched 1% (Fig. 12a) is relatively free of precipitate (no continuous second-phase paths), and the material is not susceptible to SCC. Prolonged heating below the solvus, however, produces continuous precipitate, which results in susceptibility (Fig. 12b).

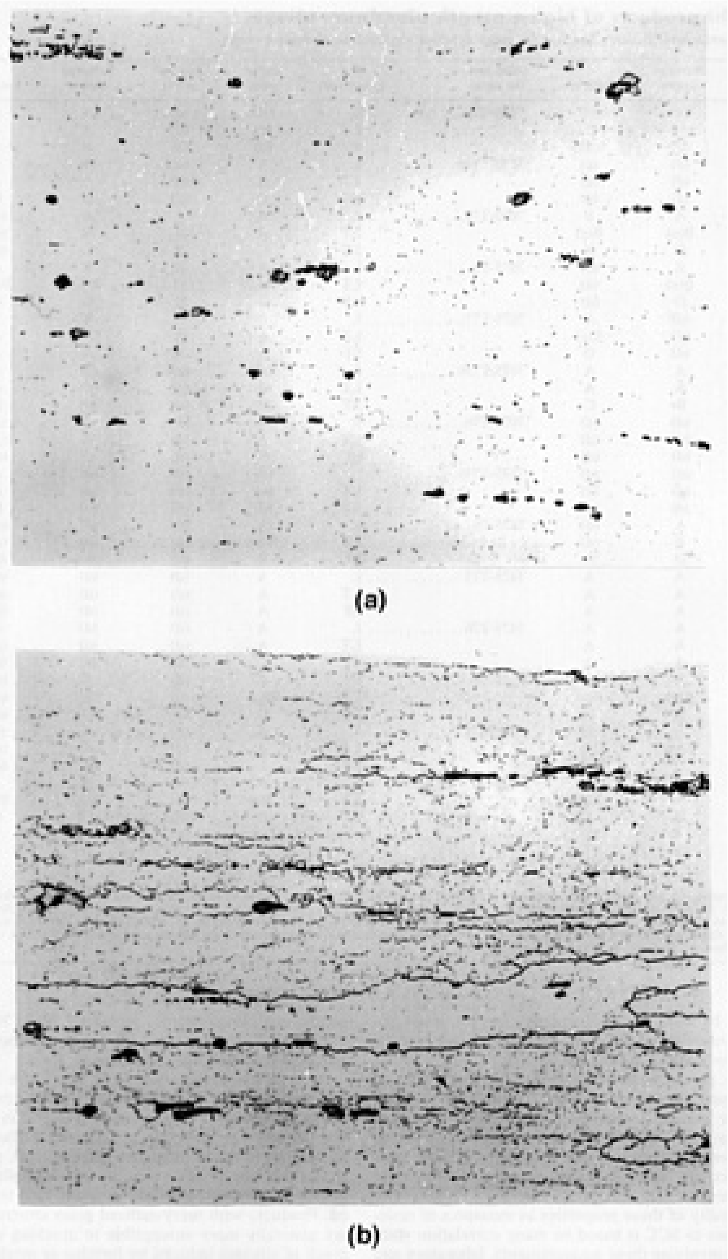

Fig. 12 Microstructures of alloy 5083-O plate stretched 1%. (a) As-stretched. (b) After heating 40 days at 120 °C (250 °F)

6*xxx* Alloys. The service record of 6*xxx* alloys shows no reported cases of SCC. In laboratory tests, however, at high stresses and in aggressive solutions, cracking has been demonstrated in 6*xxx* alloys of particularly high alloy content, containing silicon in excess of the Mg_2Si ratio and/or high percentages of copper.

7*xxx* Alloys Containing Copper. The 7*xxx* series alloy that has been used most extensively and for the longest period of time is 7075, an aluminum-zinc-magnesium-copper-chromium alloy. Introduced in 1943, this aircraft construction alloy was initially used for products with thin sections, principally sheet and extrusions. In these products, quenching rate is normally very high, and tensile stresses are not encountered in the short-transverse direction; thus, SCC is not a problem for material in the highest-strength (T6) tempers. When 7075 was used in products of greater size and thickness, however, it became apparent that such products heat treated to T6 tempers were often unsatisfactory. Parts that were extensively machined from large forgings, extrusions, or plate were frequently subjected to continuous stresses, arising from interference misfit during assembly or from service loading, that were tensile at exposed surfaces and aligned in unfavorable orientations. Under such conditions, SCC was encountered in service with significant frequency.

This problem resulted in the introduction (in about 1960) of the T73 tempers for thick-section 7075 products. The precipitation treatment used to develop these tempers requires two-stage artificial aging, the second stage of which is done at a higher temperature than that used to produce T6 tempers. During the preliminary stage, a fine high-density precipitation dispersion is nucleated, producing high strength. The second stage is then used to develop resistance to SCC and exfoliation. Extensive accelerated and environmental testing has demonstrated that 7075-T73 resists SCC even when stresses are oriented in the least favorable direction, at stress levels of at least 300 MPa (44 ksi). Under similar conditions, the maximum stress at which 7075-T6 resists cracking is about 50 MPa (7 ksi). The excellent test results for 7075-T73 have been confirmed by extensive service experience in various applications.

The additional aging treatment required to produce 7075 in T73 tempers, which have high resistance to SCC, reduces strength to levels below those of 7075 in T6 tempers. Alloy 7175, a variant of 7075, was developed for forgings. In the T736 temper, 7175 has strength nearly comparable to that of 7075-T6 and has better resistance to SCC. Other newer alloys--such as 7049 and 7475, which are used in the T73 temper, and 7050, which is used in the T736 temper--couple high strength with very high resistance and improved fracture toughness.

The T76 tempers, which also require two-stage artificial aging and which are intermediate to the T6 and T73 tempers in both strength and resistance to SCC, are developed in copper-containing 7*xxx* alloys for certain products. Comparative ratings of resistance for various products of all these alloys, as well as for products of 7178, are given in Table 6.

Table 6 Relative SCC ratings for wrought products of high-strength aluminum alloys

Resistance ratings are as follows: A, very high; B, high; C, intermediate; D, low. See text for more detailed explanation of these ratings.

(a) Ratings apply to standard mill products in the types of tempers indicated and also in T*x*5*x* and T*x*5*xx* (stress-relieved) tempers and may be invalidated in some cases by use of nonstandard thermal treatments, or mechanical deformation at room temperature, by the user.

(b) Test direction refers to orientation of direction in which stress is applied relative to the directional grain structure typical of wrought alloys, which for extrusions and forgings may not be predictable on the basis of the cross-sectional shape of the product: L, longitudinal; LT, long transverse; ST, short transverse.

(c) Sections with width-to-thickness ratios equal to or less than two, for which there is no distinction between LT and ST properties.

(d) Rating not established because product not offered commercially.

(e) Rating is one class lower for thicker sections: extrusions, 25 mm (1 in.) and thicker; plate and forgings, 38 mm (1.5 in.) and thicker

The microstructural differences among the T6, T73, and T76 tempers of these alloys are differences in size and type of precipitate, which changes from predominantly Guinier-Preston (GP) zones in T6 tempers to η', the metastable transition form of $\eta(MgZn_2)$, in T73 and T76 tempers. None of these differences can be detected by optical metallography. In fact,

even the resolutions possible in transmission electron microscopy are insufficient for determining whether the precipitation reaction has been adequate to ensure the expected level of resistance to SCC. For quality assurance, copper-containing 7*xxx* alloys in T73 and T76 tempers are required to have specified minimum values of electrical conductivity and, in some cases, tensile yield strengths that fall within specified ranges. The validity of these properties as measures of resistance to SCC is based on many correlation studies involving these measurements, laboratory and field stress-corrosion tests, and service experience.

Copper-free 7*xxx* Alloys. Wrought alloys of the 7*xxx* series that do not contain copper are of considerable interest because of their good resistance to general corrosion, moderate-to-high strength, and good fracture toughness and formability. Alloys 7004 and 7005 have been used in extruded form and, to a lesser extent, in sheet form for structural applications. More recently introduced compositions, including 7016, 7021, 7029, and 7146, have been used in automobile bumpers formed from extrusions or sheet.

As a group, copper-free 7*xxx* alloys are less resistant to SCC than other types of aluminum alloys when tensile stresses are developed in the short-transverse direction at exposed surfaces. Resistance in other directions may be good, particularly if the product has an unrecrystallized microstructure and has been properly heat treated. Products with recrystallized grain structures are generally more susceptible to cracking as a result of stresses induced by forming or mechanical damage after heat treatment. When cold forming is required, subsequent solution heat treatment or precipitation heat treatment is recommended. Applications of these alloys must be carefully engineered, and consultation among designers, application engineers and product producers, or suppliers is advised in all cases.

Casting Alloys. The resistance of most aluminum casting alloys to SCC is sufficiently high that cracking rarely occurs in service. The microstructures of these alloys are usually nearly isotropic; consequently, resistance to SCC is unaffected by orientation of tensile stresses.

Relative ratings of cast alloys, based primarily on accelerated laboratory tests, are listed in Tables 4(a), and 4(b). It has been indicated by accelerated and natural-environment testing and verified by service experience that alloys of the aluminum-silicon 4*xx.x* series, 3*xx.x* alloys containing only silicon and magnesium as alloying additions, and 5*xx.x* alloys with magnesium contents of 8% or lower have virtually no susceptibility to SCC. Alloys of the 3*xx.x* group that contain copper are rated as less resistant, although the numbers of castings of these alloys that have failed by SCC have not been significant.

Significant SCC of aluminum alloy castings in service has occurred only in the highest-strength aluminum-zinc-magnesium 7*xx.x* alloys and in the aluminum-magnesium alloy 520.0 in the T4 temper. For such alloys, factors that require careful consideration include casting design, assembly and service stresses, and anticipated environment exposure.

Specifications and Tests. Several aluminum alloy product specifications require defined levels of performance with respect to resistance to SCC. Standard tests used to measure such performance are described in the methods standards and are referenced in materials specifications. Among these are tests for evaluating resistance to SCC of 2*xxx* alloys and of 7*xxx* alloys that contain copper by alternate immersion in 3.5% NaCl solution (Ref 69, 70). Lot acceptance criteria for products of 7*xxx* copper-containing alloys in T76, T73, and T736 tempers are based on combined requirements for tensile strength and electrical conductivity.

Exfoliation Corrosion

In certain tempers, wrought products of aluminum alloys are subject to corrosion by exfoliation, which is sometimes described as lamellar, layer, or stratified corrosion. In this type of corrosion, attack proceeds along selective subsurface paths parallel to the surface. As shown in Fig. 13(a), layers of uncorroded metal between the selective paths are split apart and pushed above the original surface by the voluminous corrosion product formed along the paths of attack. Because it can be detected readily at an early stage and is restricted in depth, exfoliation does not cause unexpected structural failure, as does SCC.

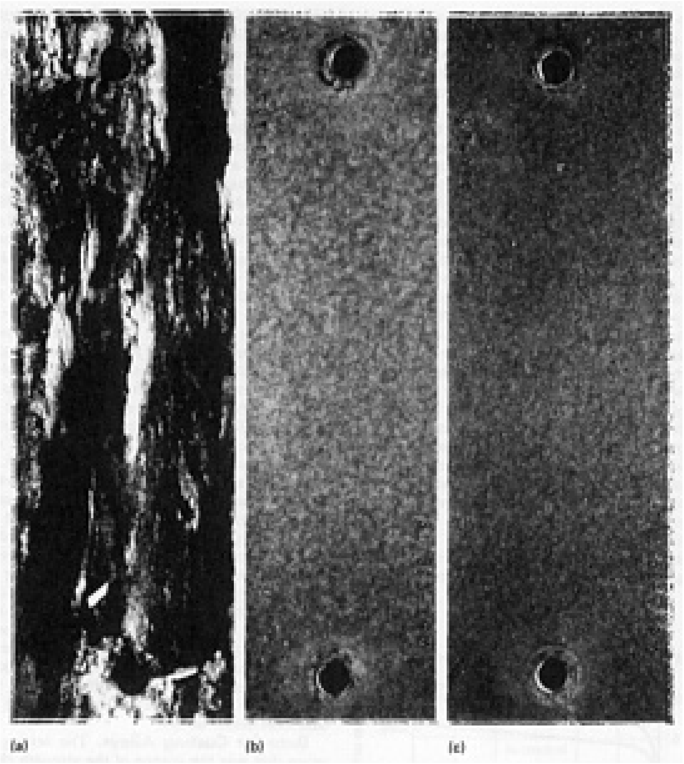

Fig. 13 Effect of temper on exfoliation resistance of an alloy 7075 extrusion exposed in a seacoast environment. Specimens were exposed for 4 years. (a) Specimen in the T6510 temper that developed exfoliation after only 5 months. (b) and (c) Specimens in the T76510 and T73510 tempers that were unaffected after 4 years

Exfoliation occurs predominantly in products that have markedly directional structures in which highly elongated grains form platelets that are thin relative to their length and width (Fig. 14). Susceptibility to this type of corrosion may result from the presence of aligned intergranular or subgrain boundary precipitates or from aligned strata that differ slightly in composition. The intensity of exfoliation increases in slightly acidic environments or when the aluminum is coupled to a cathodic dissimilar metal. Exfoliation is not accelerated by stress and does not lead to SCC.

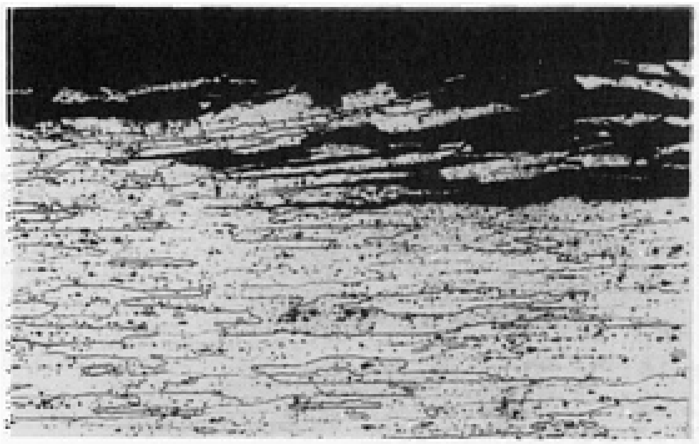

Fig. 14 Exfoliation corrosion in an alloy 7178-T651 plate exposed to a seacoast environment. Cross section of the plate shows how exfoliation develops by corrosion along boundaries of thin, elongated grains.

Alloys most susceptible to exfoliation are the heat-treatable 2*xxx* and 7*xxx* alloys and certain cold-worked 5*xxx* alloys, such as 5456-H321 boat hull plated. Exfoliation problems with 5*xxx* alloys led to the development of special boat hull plate tempers, H116 and H117, for alloys 5083, 5086, and 5456. In these alloys, exfoliation is primarily caused by unfavorable distribution of precipitate. The processing to eliminate this form of attack promotes either more uniform precipitation within grains or more advanced stage of precipitation. Thus, increases in the precipitation heat-treating time or temperature are as effective in reducing susceptibility to exfoliation as they are in reducing susceptibility to SCC.

During long-duration or high-temperature precipitation treatments, maximum resistance to exfoliation is usually achieved sooner than maximum resistance to SCC. Thus, precipitation treatments used to produce T76 tempers in 7*xxx* alloys, which use times and temperatures intermediate to those of T6 and T73 treatments, provide excellent resistance to exfoliation (Fig. 13b) but only intermediate resistance to SCC. The T73 tempers provide the highest resistance to both types of corrosion (Fig. 13c) but at a sacrifice in strength compared to T76 tempers.

Among the standard tests for evaluating resistance to exfoliation of 2*xxx*, 5*xxx*, and 7*xxx* alloys are those that require total immersion in aggressive acidified solutions of mixed salts or exposure to cyclic, acidified salt spray tests. Such tests are described in Ref 71 for 5*xxx* alloys and in Ref 72, 73, 74 for 2*xxx* and 7*xxx* alloys. Acceptability of aluminum-magnesium alloys 5083, 5086, and 5456 is based on a comparison of the microstructure disclosed by etching in a defined manner with a reference microstructure that is predominantly free from a continuous grain-boundary network of Al_8Mg_5 precipitate particles (Ref 75). Material containing such precipitate in amounts exceeding that shown by the reference standard is unacceptable unless it can be demonstrated by testing (Ref 71)that the material has acceptable resistance to exfoliation. References 76, 77, 78, 79, 80 compare the performance in these accelerated test methods to that in outdoor atmospheres.

Corrosion Fatigue

Fatigue strengths of aluminum alloys are lower in such corrosive environments as seawater and other salt solutions than in air, especially when evaluated by low-stress long-duration test (Ref 81, 82). As shown in Fig. 15, such corrosive environments produce smaller reductions in fatigue strength in the more corrosion-resistant alloys, such as the 5*xxx* and 6*xxx* series, than in the less resistant alloys, such as the 2*xxx* and 7*xxx* series.

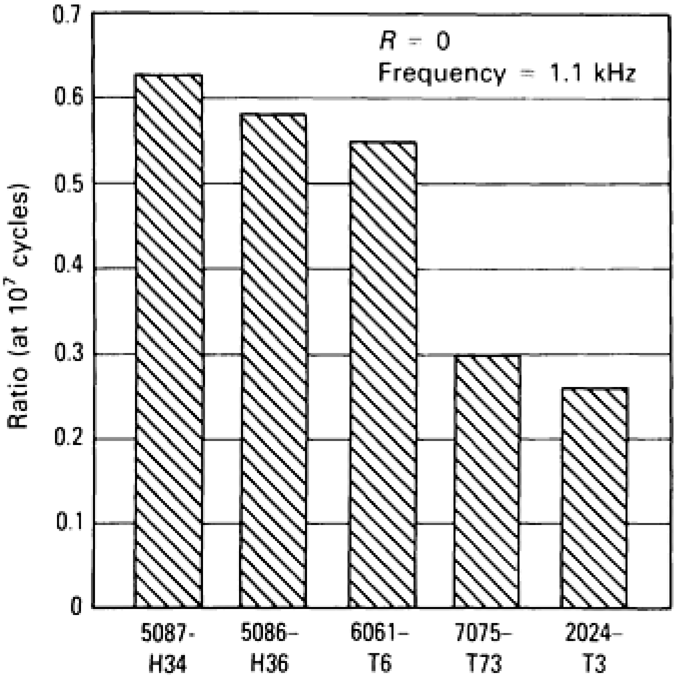

Fig. 15 Ratio of axial-stress fatigue strength of aluminum alloy sheet in 3% NaCl solution to that in air. Specimens were 1.6 mm (0.064 in.) thick.

Like SCC of aluminum alloys, corrosion fatigue requires the presence of water. In contrast to SCC, however, corrosion fatigue is not appreciably affected by test direction, because the fracture that results from this type of attack is predominantly transgranular.

Erosion-Corrosion

In noncorrosive environments, such as high-purity water, the stronger aluminum alloys have the greatest resistance to erosion-corrosion because resistance is controlled almost entirely by the mechanical components of the system. In a corrosive environment, such as seawater, the corrosion component becomes the controlling factor; thus, resistance may be greater for the more corrosion-resistant alloys even though they are lower in strength. Corrosion inhibitors and cathodic protection have been used to minimize erosion-corrosion, impingement, and cavitation on aluminum alloys (Ref 83).

Atmospheric Corrosion

Most aluminum alloys have excellent resistance to atmospheric corrosion (often called weathering), and in many outdoor applications, such alloys do not require shelter, protective coatings, or maintenance. Aluminum alloy products that have no external protection and therefore depend critically on this property include electrical conductors, outdoor lighting poles, ladders, and bridge railings. Such products often retain a bright metallic appearance for many years, but their surfaces may become dull, gray, or even black as a result of pollutant accumulation. Corrosion of most aluminum alloys by weathering is restricted to mild surface roughening by shallow pitting, with no general thinning. However, such attack is more severe for alloys with higher copper contents, and such alloys are seldom used in outdoor applications without protection.

Corrosivity of the atmosphere to metals varies greatly from one geographic location to another, depending on such weather factors as wind direction, precipitation and temperature changes, amount and type of urban and industrial pollutants, and proximity to natural bodies of water. Service life may also be affected by the design of the structure if weather conditions cause repeated moisture condensation in unsealed crevices or in channels with no provision for drainage. Laboratory exposure tests, such as salt spray, total-immersion, and alternate-immersion tests, provide useful comparative information, but have limited value for predicting actual service performance and sometimes exaggerate differences among alloys that are negligible under atmospheric conditions (Ref 84). Consequently, extensive long-term evaluations of the effects of exposure in different industrial, chemical, seacoast, tropical, and rural environments have been made (Ref 85, 86, 87, 88).

Data collected in these programs include measurements of maximum and mean depth of attack, weight loss, and changes in tensile properties. Because of the localized nature of the prevalent pitting corrosion, which leaves some (in many cases, most) of the original surface intact even after many years of weathering, weight loss or calculated average dimensional change based on weight loss may have limited significance. Changes in tensile strength, which reflect the effects of size, number, distribution, and acuity of pits, are generally most significant from a structural standpoint, while depth-of-attack determinations provide realistic measures of penetration rate.

Effect of Exposure Time. A very important characteristic of weathering of aluminum and of corrosion of aluminum under many other environmental conditions is that corrosion rate decreases with time to a relatively low, steady-state rate (Ref 85). This deceleration of corrosion (Fig. 16, 17, 18) occurs regardless of alloy composition, type of environment, or the parameter by which the corrosion is measured. However, loss in tensile strength, which is influenced somewhat by pit acuity and distribution but is basically a result of loss of effective cross section, decelerates more gradually than depth of attack (Fig. 16).

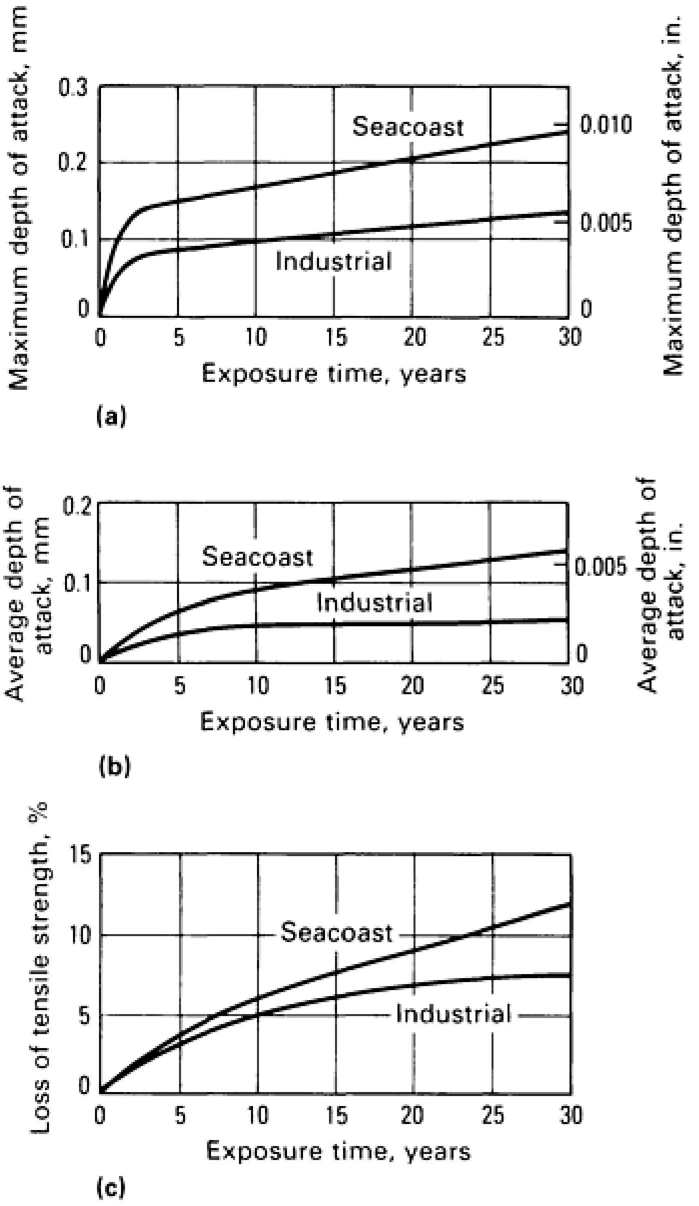

Fig. 16 Depth of corrosion and loss of tensile strength for alloys 1100, 3003, and 3004 (shown in graphs a, b, and c, respectively). Data are given for the average performance of the three alloys, all in the H14 temper. Seacoast exposure was at a severe location (Pt. Judith, RI); industrial exposure was at New Kensington, PA. Tensile strengths were computed using original cross-sectional areas, and loss in strength is expressed as a percentage of original tensile strength.

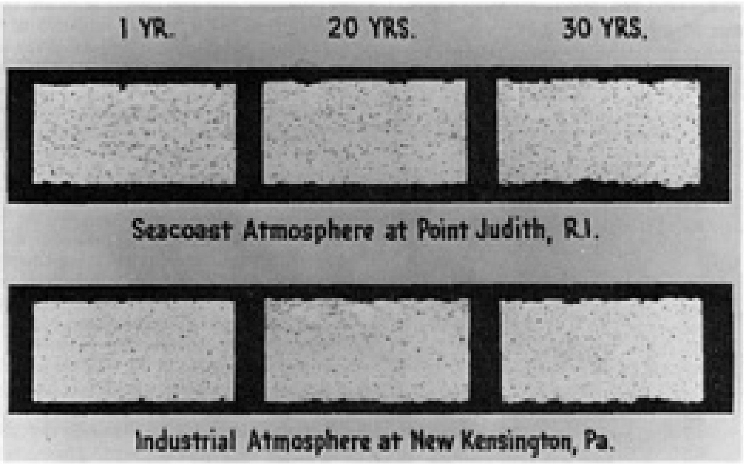

Fig. 17 Sectioned specimens cut from 1.6-mm (0.064-in.) thick alloy 3003-H14 panels after exposure in two environments

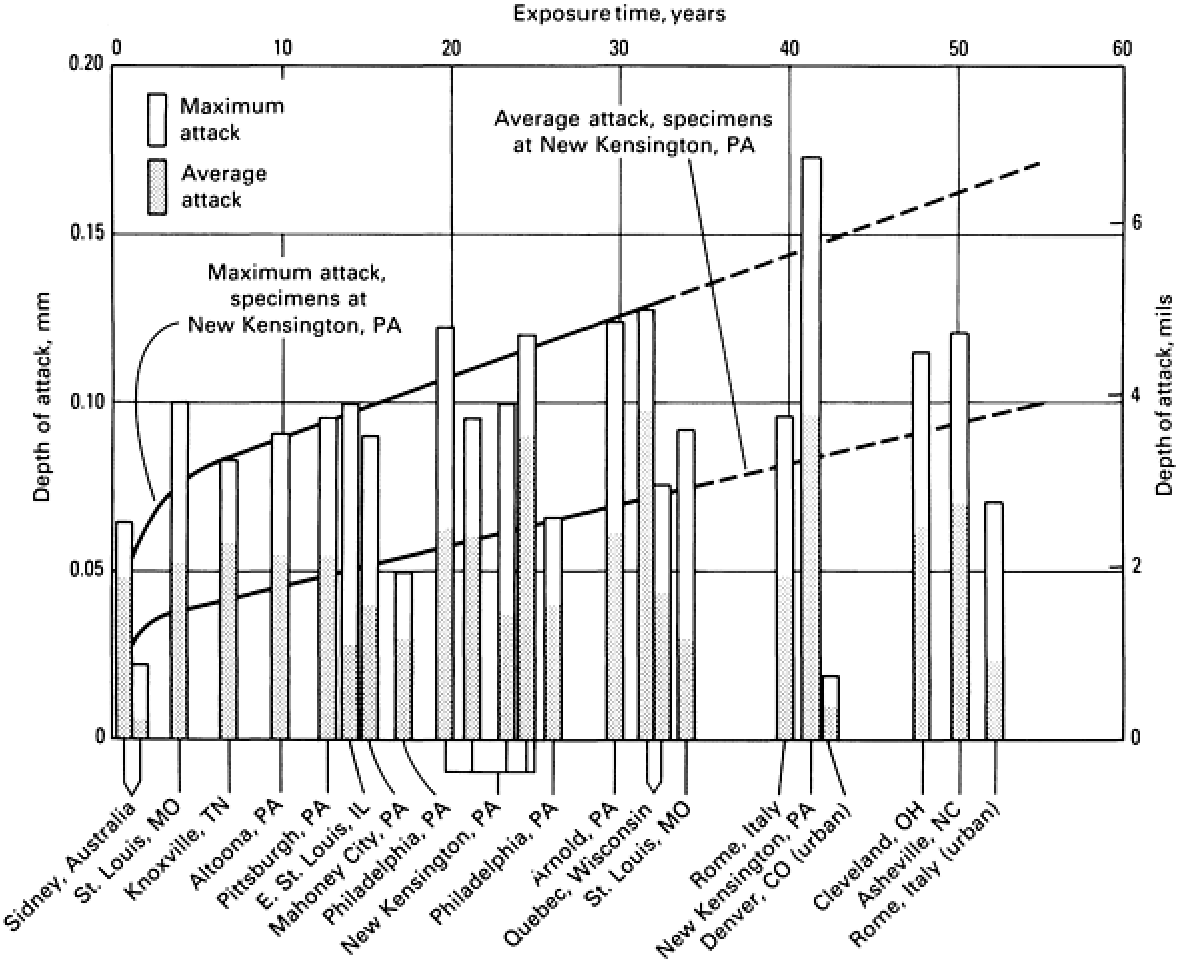

Fig. 18 Correlation of weathering data for specimens of alloys 1100, 3003, and 3004 (all in H14 temper) exposed to industrial atmosphere (curves) with service experience with aluminum alloys in various locations (bars)

The decrease in rate of penetration of corrosion is dramatic. In general, rate of attack at discrete locations, which is initially about 0.1 mm/yr (4 mils/yr), decreases to much lower and nearly constant rates within a period of about 6 months

to 2 years. For the deepest pits, the maximum rate after about 2 years does not exceed about 0.003 mm/yr (0.11 mil/yr) for severe seacoast locations and may be as low as 0.0008 mm/yr (0.03 mil/yr) in rural or arid climates. The dramatic deceleration in penetration is illustrated by the specimen cross sections shown in Fig. 17 and by the depth-of-attack curves shown in Fig. 18, both of which are from the same 30-year test program (Ref 89). Also shown in Fig. 18 are results (shown as vertical bars) from other test programs in which various articles made of aluminum alloys were continuously exposed for various periods and in different locations, many of which are less severe than the relatively aggressive industrial environment of New Kensington, PA.

Data for Wrought Alloys. Several major test programs have been conducted under the supervision of ASTM to investigate the weathering of aluminum alloy sheet. The first program, started in 1931, was limited in the variety of alloys tested, but included desert, rural, seacoast, and industrial exposures. Data obtained after 20 years of exposure are listed in Table 7. Corrosion rates were calculated from cumulative weight loss after 20 years, and average and maximum depths of attack were measured microscopically. In aggressive (seacoast and industrial) environments, the bare (nonalclad) heat-treated alloys--2017-T3 and, to a lesser extent, 6051-T4--exhibited more severe corrosion and greater resulting loss in tensile strength than the nonheat-treatable alloys. Alclad 2017-T3, although as severely corroded as the nonheat-treatable materials, did not show measurable loss in strength; in fact, some specimens of this alloy were 2 to 3% higher in strength after 20 years because of long-term natural aging.

Table 7 Weathering data for 0.89-mm (0.035-in.) thick aluminum alloy sheet after 20-year exposure (ASTM program started in 1931)

Data from a comprehensive program initiated in 1958 were compiled from examinations and tests performed after 7 years of exposure (Ref 89). Thirty-four combinations of alloy and temper in the form of 1.27-mm (0.050-in.) thick sheet were

exposed at four sites--two seacoast, one industrial, and one rural; Table 8 lists average values of measurements reported at two of the more aggressive sites. In another ASTM program, 10 years of weathering produced the changes in tensile strength reported in Tables 9(a), and 9(b).

(a) Average tensile strength values were below required minimum.

Data from these and other weathering programs (Ref 92, 93) demonstrate that differences in resistance to weathering among nonheat-treatable alloys are not great, that alclad products retain their strength well because corrosion penetration is confined to the cladding layer, and that corrosion and resulting strength loss tend to be greater for bare (nonalclad) heat-treatable 2*xxx* and 7*xxx* series alloys.

Data for Casting Alloys. The testing program that was the source of the strength change data for wrought alloys given in Tables 9(a) and 9(b) also provided weathering data for casting alloys exposed for the same period of time and at the same sites. Specimens were separately sand-cast and permanent mold cast tensile bars, each with a reduced section 12.7 mm (0.5 in.) in diameter. Strength change data for these alloys are summarized in Tables 10(a) and 10(b). Alloys with relatively high copper contents, such as 295.0-T6, 208.0-F, 319.0-T6, and 319.0-T61, showed the greatest losses. Alloys of the zinc-containing 7*xx.x* series generally exhibited larger strength losses than alloys having low zinc or copper contents. In all cases, as for wrought materials, severity of corrosion varied widely, depending on environmental conditions.

(a) Average tensile strength values were below required minimum.

Comparison with Other Metals. Other metals were exposed to the same weathering environments over the same time periods used to evaluate corrosion of aluminum alloys. Comparative corrosion rates (average loss in thickness per side calculated from weight losses measured after exposures of 10 and 20 years) are listed in Table 11 for aluminum, copper, lead, and zinc panels. Figure 19 compares losses in tensile strengths at several weathering sites for unprotected low-carbon steel (0.09C, 0.07Cu) and for aluminum alloys.

(a) Calculated from weight loss, assuming uniform attack, for 0.89-mm (0.035-in.) thick panels.

(b) Aluminum 1100-H14.

(c) Tough pitch copper (99.9% Cu).

(d) Commercial lead (99.92% Pb).

(e) Prime western zinc (98.9% Zn).

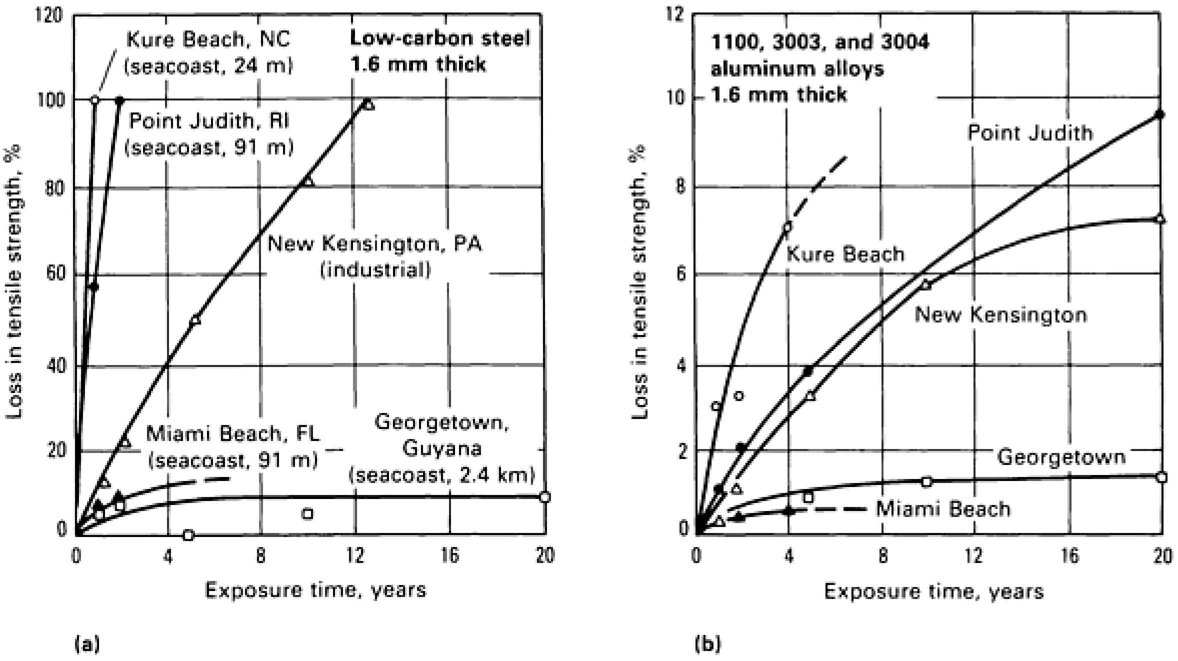

Fig. 19 Tensile-strength losses for low-carbon steel (a) and representative nonheat-treatable aluminum alloys (b) at several atmospheric exposure sites. Strength losses of the aluminum alloys are less than one-tenth that of the low-carbon steel.

Filiform Corrosion

Filiform corrosion, sometimes termed wormtrack corrosion, occurs on aluminum when it is coated with an organic coating and exposed to warm, humid atmospheres. The corrosion appears as threadlike filaments that initiate at defects in the organic coating, are activated by chlorides, and grow along the metal/coating interface at rates to 1 mm/d (0.04 in./d). The moving end of the filament is called the head, and the remainder of the track is called the tail. It is not clear why this type of corrosion forms tracks instead of circular spots of increasing diameter.

Filiform corrosion occurs only in the atmosphere, and relatively humidity is the single most important factor. This type of attack is rare on aluminum below about 55% relative humidity or above 95%. In natural atmospheres, it occurs most readily on aluminum at relative humidities between 85 and 95%. Although temperature and the thickness of the organic coating are minor factors, elevating the temperature increases the rate of filament growth if the relative humidity stays within the critical range.

The presence of oxygen is fundamental because it supplies the primary reactant for the cathodic reaction. Essentially, filiform corrosion is a type of oxygen concentration cell in which the anodic area is the head of the filament and the cathode is the area surrounding it, including the tail (Ref 95).

Considerable acidity is generated at the leading edge of the head. Measurements of pH as low as 1.5 to 2.5 have been reported, with the electrolyte in the head containing large concentrations of chloride (Ref 96). Such acidic solutions can be highly corrosive to aluminum alloys if the filament head should stop moving.

Phosphate coatings or chromium-containing conversion coatings applied to the metal surface before the organic coating are widely used to protect against filiform corrosion, but they are not completely successful. Perfect coatings, the absence of chlorides, or relative humidity below 30 to 40% would also be beneficial, but these conditions are not likely to be encountered outside the laboratory.

Corrosion in Waters

High-Purity Water. Suitability of the more corrosion-resistant aluminum alloys for use with high-purity water at room temperature is well established by both laboratory testing and service experience (Ref 97). The slight reaction with the water that occurs initially ceases almost completely within a few days after development of a protective oxide film of equilibrium thickness. After this conditioning period, the amount of metal dissolved by the water becomes negligible.

Corrosion resistance of aluminum alloys in high-purity water is not significantly decreased by dissolved carbon dioxide or oxygen in the water or, in most cases, by the various chemicals added to high-purity water in the steam power industry to provide the required compatibility with steel. These additives include ammonia and neutralizing amines for pH adjustment to control carbon dioxide, hydrazine and sodium sulfate to control oxygen, and filming amines (long-chain polar compounds) to produce nonwettable surfaces. Somewhat surprisingly, the effects of alloying elements on corrosion resistance of aluminum alloys in high-purity water at elevated temperatures are opposite to their effects at room temperature; elements (including impurities) that decrease resistance at room temperature improve it at elevated temperatures.

At 200 °C (390 °F), high-purity aluminum of sheet thickness disintegrates completely within a few days of reaction with high-purity water to form aluminum oxide. In contrast, aluminum-nickel-iron alloys have the best elevated-temperature resistance to high-purity water of all aluminum metals; for example, alloy X8001 (1.0Ni-0.5Fe) has good resistance at temperatures as high as 315 °C (600 °F) (Ref 98).

Natural waters. Aluminum alloys of the 1*xxx,* 3*xxx,* 5*xxx,* and 6*xxx* series are resistant to corrosion by many natural waters (Ref 99, 100, 101). The more important factors controlling the corrosivity of natural waters to aluminum include water temperature, pH, and conductivity; availability of cathodic reactant; presence or absence of heavy metals; and the corrosion potentials and pitting potentials of the specific alloys. Various correlations of the corrosivity of natural waters to aluminum have been attempted (Ref 102), but none predicts the corrosivity of all natural waters reliably.

Seawater. Service experience with 1*xxx,* 3*xxx,* 5*xxx,* and 6*xxx* wrought aluminum alloys in marine applications, including structures, pipeline, boats, and ships, demonstrates their good resistance and long life under conditions of partial, intermittent, or total immersion. Casting alloys of the 356.0 and 514.0 types also show high resistance to seawater corrosion, and these alloys are used widely for fittings, housings, and other marine parts.

Among the wrought alloys, those of the 5*xxx* series are most resistant and most widely used because of their favorable strength and good weldability. Alloys of the 3*xxx* series are also highly resistant and are suitable where their strength range is adequate. With the 3*xxx* and 5*xxx* series alloys, thinning by uniform corrosion is negligible, and the rate of corrosion based on weight loss does not exceed about 5 μm/yr (0.2 mil/yr), which is generally less than 5% of the rate for unprotected low-carbon steel in seawater. Corrosion is mainly of the pitting or crevice type, characterized by deceleration of penetration with time from rates of 3 to 6 μ/yr (0.1 to 0.2 mil/yr) in the first year to average rates over a 10-year period of 0.8 to 1.5 μm/yr (0.03 to 0.06 mil/yr).

The aluminum-magnesium-silicon 6*xxx* alloys are somewhat less resistant; although no general thinning occurs, weight loss may be two to three times that for 5*xxx* alloys. The more severe corrosion is reflected in larger and more numerous pits.

Alloys of the 2*xxx* and 7*xxx* series, which contain copper, are considerably less resistant to seawater that 3*xxx,* 5*xxx,* and 6*xxx* alloys and are generally not used unprotected. Protective measures, such as use of alclad products and coating by metal spraying or by painting, provide satisfactory service in certain situations.

Aluminum boats operating in salt water require antifouling paint systems because aluminum and its alloys do not inhibit growth of marine organisms. Aluminum is impervious to worms and borers, and the acids exuded from marine organisms are not corrosive to aluminum; but the accumulation of biofouling on the bottom of the boat impairs performance. Aluminum boats operating in both salt and fresh water, which alleviates fouling problems, have been able to leave underwater hull areas unpainted (Ref 103).

To make antifouling paint systems adhere properly to aluminum, careful surface preparation of the metal is necessary. A thorough precleaning and either a conversion coating or a washcoat primer are required, followed by a corrosion-inhibiting primer and a top coat. The antifouling paint is applied to the top coat. Primers containing red lead should not be used, because this substance may cause galvanic corrosion of the aluminum. For the same reason, copper-containing

antifouling paints should not be used on aluminum hulls. The preferred antifouling paints for aluminum are those containing organic tin compounds.

The literatue on corrosion testing of aluminum alloys in seawater is extensive. Summaries of information are provided in Ref 104 and 105, and in most of the selected references. Table 12 lists results of 10-year immersion testing of various alloys in the form of rolled plate exposed in three locations. The relationships among the types of alloys that have been discussed and a comparison with unprotected low-carbon steel are apparent. Similar data for extruded products of several 6*xxx* alloys and one 5*xxx* alloy are given in Table 13. Direct comparison of the data in Tables 12 and 13 is provided in Table 14, in which corrosion is expressed in terms of average weight loss, and in Fig. 20, which illustrates the deceleration of corrosion rate with time that is characteristic of aluminum alloys. Data on corrosion rates, maximum and average depth of pitting, and changes in tensile strength compiled during 10-year tidal and full-immersion exposure of seven 5*xxx* alloys and super-purity aluminum 1199 are summarized in Table 15. Full immersion generally resulted in more extensive corrosion than tidal exposure, although the reverse relationship has also been observed. Tensile-strength losses were 5% or less, and yield-strength losses were less than 5% in the panels completely immersed and generally lower in those exposed to tidal immersion.

Table 12 Average weight loss and maximum depth of pitting for aluminum alloy plate specimens after immersion in seawater

Specimens were 6.35 × 305 × 305 mm (0.250 × 12 × 12 in.) and weighed approximately 1.6 kg (3.5 lb).

(f) Average thickness of cladding on each surface, 307 μm (12.1 mils).

(g) Sand cast.

The corrosion behavior of aluminum alloys in deep seawater, judging from tests at a depth of 1.6 km (1 mile), is generally the same as at the surface except that the rate of pit penetration may be higher and the effect of crevices somewhat greater (Ref 107). The corrosivity of unpolluted full-strength seawater depends on several factors: dissolved oxygen content; pH, temperature, and velocity of the water flow; and the presence or absence of heavy-metal ions, particularly copper (Ref 48). The corrosion rate tends to be increased by decreasing temperature, pH, and flow velocity and by increasing dissolved oxygen (Ref 48, 108, 109, 110). The higher corrosion rate in deep water is not caused by low dissolved oxygen, as stated in the older literature, but is caused by the combination of low pH and low temperature.

Surface-water conditions at various tropical locations are benign to aluminum alloys because of their high temperature, high pH, and high oxygen concentrations and the virtual absence of heavy-metal contamination (Ref 111, 112, 113). A variety of aluminum alloys in the form of heat-exchanger tubing have been tested for up to 3 years in surface water off Keahole Point, HI, with no significant pitting or crevice corrosion (Ref 111).

Experience with seawater desalination units has demonstrated the high degree of resistance of aluminum alloys to deaerated seawater at temperatures to 120 °C (250 °F). For example, a 11 355-L/day (3000-gal./day) multiflash aluminum unit at the Office of Saline Water Materials Test Center at Freeport, TX, operated at 99% efficiency and with minimal corrosion for more than 3 years under process conditions selected to match those of a commercial installation. Such experience has shown, however, that galvanic attack of aluminum alloys in contact with dissimilar metals is more severe at elevated temperatures that at room temperature.

Corrosion in Soils

Soils differ widely in mineral content, texture and permeability, moisture, pH and aeration, presence of organic matter and microorganisms, and electrical resistivity. Because of these variations, the corrosion performance of buried aluminum varies considerably, and a clear understanding of its behavior has depended on the accumulation of many field corrosion tests and actual case histories over an extended period of time (Ref 2, 114, 115).

Corrosion of the copper-containing 2*xxx* and 7*xxx* series alloys in moist low-resistivity soils, measured by weight loss and pitting depth, is several times greater than corrosion of the more resistant 1*xxx,* 3*xxx,* 5*xxx,* and 6*xxx* series alloys, and applications of the copper-bearing alloys for buried service is limited accordingly. Use of cathodic protection or alclad products effectively reduces corrosion or limits penetration.

Aluminum alloys 3003, 6061, and 6063 are most frequently used for surface and underground pipelines for irrigation, petroleum, and mining applications. Most early installations used uncoated pipe (Ref 116). Hundreds of miles of pipe were installed, ranging in wall thickness from 1.5 to 19 mm (0.06 to 0.75 in.). Some of these have been in service for over 40 years. When used, coatings are usually bituminous products or tape wraps. Unprotected sections exhibited corrosion attack ranging from almost none to deep pitting. Cathodically protected sections of some of the same pipes in corrosive soil showed either no attack or only mild etching. Cathodic protection of buried aluminum was standardized in 1963 (Ref 117). In addition to pipelines, extensive experience was gained with aluminum culverts in various soils (Ref 118).

Soil resistivity provides a useful guideline to soil corrosivity; corrosion problems are usually limited to soils having resistivities less than 1500 $\Omega \cdot$ cm (Ref 119). Experience has shown that soils, at least to the depth normally used to bury pipelines, are noncorrosive to aluminum over large areas of North America. However, noncorrosive soils can be rendered corrosive if they become contaminated with certain substances, such as cinders, and variability of soils along a long pipeline can lead to galvanic corrosion of portions of the line.

Techniques for installing buried aluminum pipelines have improved, including better joining methods and the ability to plow in long lengths of pipe directly from coils. A high-energy joining technique has replaced conventional field welding (Ref 119). The technique does not require filler metal and is sufficiently rapid that it does not produce heat-affected zones in the metal.

It was concluded from early field experience that buried aluminum pipelines should be coated because the risk of pitting could not be eliminated, even in high-resistivity soils. In addition, and in keeping with similar requirements for buried steel lines, buried aluminum lines should be cathodically protected. The current density requirement for protecting aluminum is roughly 10% of that required for similarly coated steel. Because of the risk of alkaline corrosion, applied cathodic voltages should not be more negative than -1.20 V versus the saturated $Cu/CuSO_4$ electrode.

Resistance of Anodized Aluminum

Anodizing is an electrolytic oxidation process that produces on an aluminum surface an integral coating of amorphous aluminum oxide that is much thicker than the natural barrier layer. The anodic coatings used for decoration and/or protection of aluminum have a thin nonporous barrier-type layer adjacent to the metal interface and a porous outer layer that can be sealed by hydrothermal treatment in water or in a metal salt solution to increase its protective value. The entire coating adheres tightly to the aluminum substrate, resists abrasion, and, when adequate in thickness, provides greatly improved protection against weathering and other corrosive conditions (Ref 120).

For outdoor applications of aluminum parts, a coating thickness of 5 to 7.6 μm (0.2 to 0.3 mil) is normally specified for bright automotive trim and 17 to 30 μm (0.7 to 1.2 mils) for architectural product finishes. Dichromate sealing affords added protection in severe saline environments. Because coatings can be attacked and stained by alkaline building materials (such as mortar, cement, and plaster), a clear, nonyellowing lacquer is often applied to anodized aluminum architectural parts to protect the finish during construction. An added advantage of lacquer coatings is that they minimize soil accumulation during service.

In general, chemical resistance of anodic coatings is greatest in approximately neutral solutions, but such coatings are usually serviceable and protective if the pH is between 4 and 8.5. More acidic and more alkaline solutions attack anodic coatings.

Under atmospheric weathering, the number of pits developed in the base metal decreases exponentially with increasing coating thickness (Fig. 21). The pits may form at minute discontinuities or voids in the coating, some of which result from large second-phase particles in the microstructure. The pit density was determined by dissolving the anodic coating in a

stripping solution that does not attack the metal substrate. After the $8\frac{1}{2}$-year exposure, the pits were of pin-point size and had penetrated less than 50 μm (2.0 mils). Specimens with coatings at least 22 μm (0.9 mil) thick were practically free of pitting.

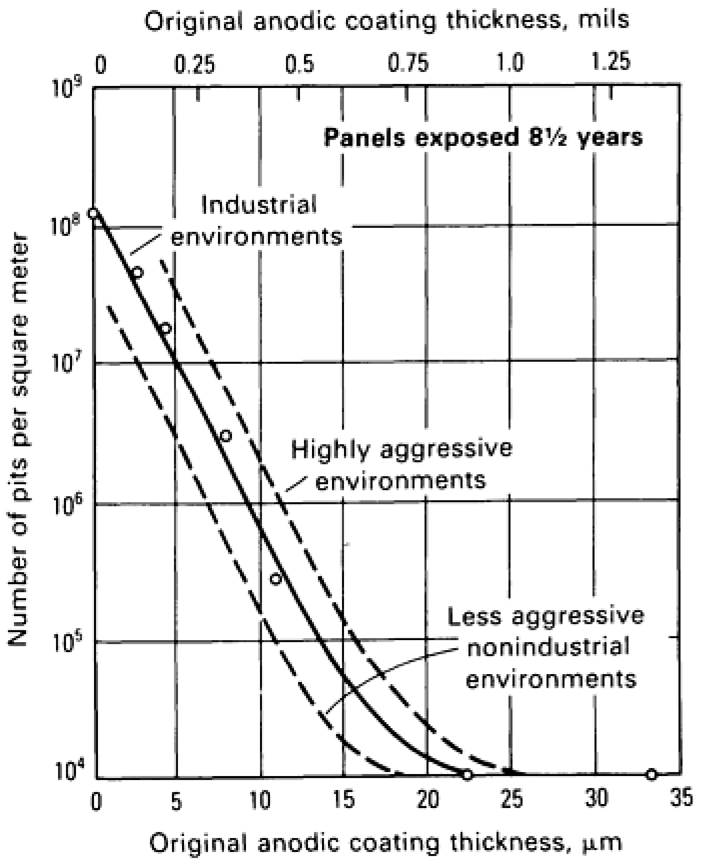

Fig. 21 Number of corrosion pits in anodized aluminum 1100 as a function of coating thickness. Source: Ref 121

Weathering of anodic coatings involves relatively uniform erosion of the coating by wind-borne solid particles, rainfall, and some chemical reaction with pollutants. The available information indicates that such erosion occurs at a reasonably constant rate, which averaged 0.33 μm/yr (0.013 mil/yr) for several alloys exposed to an industrial atmosphere for 18 years (Fig. 22).

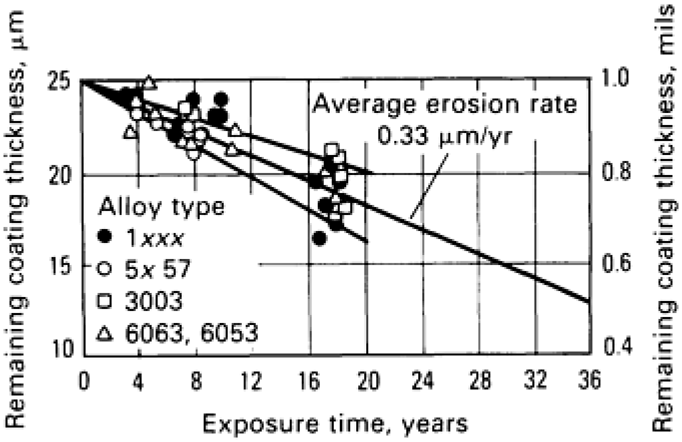

Fig. 22 Weathering data for anodically coated aluminum in an industrial atmosphere

A 3-year seacoast exposure of specimens of several alloys with 23-µm (0.9-mil) thick sulfuric acid coatings caused no visible pitting except in several alloys of the 7*xxx* series and in a 2*xxx* alloy (Table 17). Alloys that exhibited pitting where not protected any more effectively by 51-µm (2-mils) thick coatings. This confirms a general observation that optimum protection against atmospheric corrosion is achieved in the coating thickness range of 18 to 30 µm (0.7 to 1.2 mils) and that thicker coatings provide little additional protection.

Table 17 Results of 3-year seacoast exposure testing of anodized aluminum alloys(a)

Alloy and temper	Results
Sheet	
1100	No visible pitting
2024-T3, alclad	Edge pitting only
5456-H343	No visible pitting
5086-H34	No visible pitting
6061-T6	No visible pitting
7039-T6	No visible pitting
7075-T6	Edge pitting only
7075-F, alclad	Edge pitting only
7079-T6	Edge pitting only

Extrusions	
6351-T6	No visible pitting
6061-T6	No visible pitting
6063-T5	No visible pitting
6070-T6	No visible pitting
7039-T6	Scattered small pits

(a) H_2SO_4 anodic coatings 23 μm (0.9 mil) thick, sealed in boiling water on test panels 100 × 150 mm (4 × 6 in.) cut from sheet and extrusions

Anodized aluminum exterior automotive parts, such as bright trim and bumpers, exhibit good resistance to deicing salts and other ingredients of road splash despite the limited thickness applied to maintain brightness and image clarity. Development of a hazy coating appearance is considered more of a problem than pitting during service in these applications. The hazy appearance results from scattering of light from a coating surface that has been microroughened as a result of inadequate sealing or use of excessively harsh alkaline cleaners.

Anodic coatings, unless used as part of a protective system that includes such other measures as shot peening or painting, are not reliable for protection against SCC of susceptible alloys. Data obtained with short-transverse direction specimens from plate of alloy 7075-T651 and other susceptible alloys show that the anodic coating may retard, have no effect, or even accelerate SCC, depending on the level of stress and, to some extent, on whether or not the stress was present before anodizing. High stresses applied after anodizing crack the coating. The effects of several applied protective measures on lifetimes of specimens in industrial and seacoast environments under relatively high elastic strain are shown in Fig. 23, in which the relatively small protective value of anodic coatings is apparent (Ref 122).

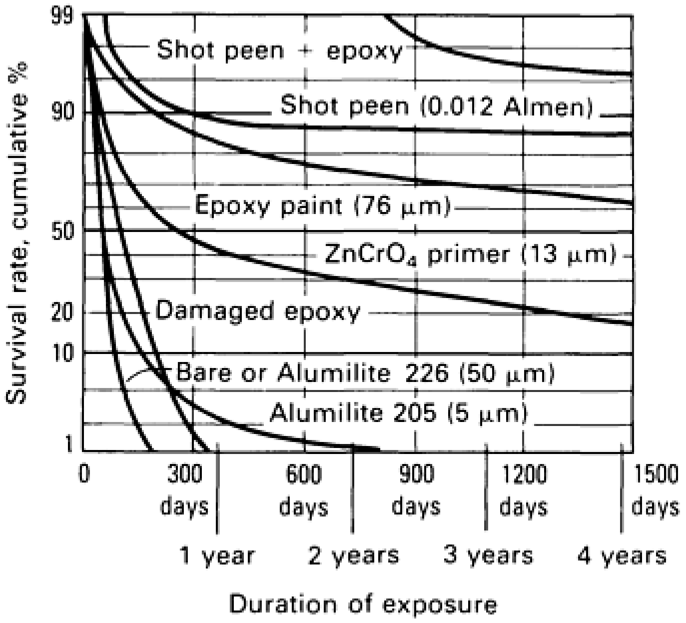

Fig. 23 Relative effectiveness of various protective systems in preventing SCC of susceptible aluminum alloys. Combined data for highly elastically strained specimens of alloys 2014-T651 and 7079-T651 exposed at Pt. Judith, RI; Comfort, TX; and New Kensington, PA

Effects of Nonmetallic Building Materials

Many nonmetallic building materials that contact aluminum during and after construction, either intentionally or accidentally, have been evaluated to determine their corrosive effects (Ref 123). Many of these materials that contain calcium or magnesium hydroxides are alkaline and, when wet, may cause overall surface attack of bare aluminum. This early reaction produces protective films of limited solubility that resist further corrosion. Such materials cause only superficial or mild surface attack, most of which occurs during initial stages of exposure.

Drainage from freshly applied concrete, plaster, mortar, or stucco is highly alkaline and causes slight attack and discoloration. This is most likely to occur during or shortly after construction, and leaching by subsequent rains, as well as conversion to carbonates, reduces the alkalinity and further attack. Staining can be effectively prevented by organic coatings.

Some insulating materials that are porous and absorbent may cause corrosion when wet. If more cathodic metals, such as steel or copper alloys, are electrically coupled with the aluminum through these materials, galvanic attack may occur. Protective paint films on the cathodic metal, moisture barriers, or chemical inhibition are required for optimum performance under these conditions.

Concrete, plaster, mortar, and cements also cause superficial etching of aluminum most of which occurs during the curing period. The surface attack involves dissolution of the natural oxide film and some of the metal, but a new film is formed that prevents further corrosion. Coupling with more cathodic metals has little effect on aluminum embedded in these materials except in those that contain certain curing or antifreeze additives.

When partly embedded in concrete, some metals undergo accelerated corrosion where the metal intersects the exposed surface of the concrete. This effect is usually not important for aluminum, but special consideration must be given to protection of faying surfaces or crevices between the aluminum and the concrete, which may entrap environmental contaminants. For example, highway railings and streetlight standards and stanchions are usually coated with a sealing compound where they are fastened to concrete in order to prevent entry of salt-laden road splash into crevices.

Contact with Foods, Pharmaceuticals, and Chemicals

The widespread use of aluminum in processing, handling, and packaging of foods, beverages, and pharmaceutical and chemical products is based on economic factors and the excellent compatibility of aluminum with many of these products (Ref 124). In addition to high corrosion resistance in contact with such products, many of these applications depend on the nontoxicity of aluminum and its salts, as well as its freedom from catalytic effects that cause product discoloration. Application of aluminum for packaging foods and pharmaceutical products has grown sharply since 1970; this application now accounts for about 26% of the aluminum marketed in the United States (Ref 125). The largest amount is used in beverage cans, and a smaller amount for foods. These cans generally have both internal and external organic coatings, primarily for decoration and for protection of product taste.

Large quantities of aluminum foil, either uncoated or with plastic coatings, are used in flexible packages. Coated foil is also used with fiber board in construction of rigid containers. The foil in such rigid containers, because of its extreme thinness, must be coated; only the slightest corrosion can be tolerated, and perforation must not occur even during long periods of storage. Packaging foils are produced from unalloyed aluminum corresponding to composition limits for aluminum 1230. Sheet for beverage can bodies is generally alloy 3004, food can bodies alloys 5352 or 5050, and can ends alloy 5182. These alloys have high corrosion resistance and are not normally subject to corrosion problems in such applications.

Aluminum alloy household cooking utensils, usually made of alloy 3003, have been used for many years. These utensils, as well as commercial food-processing equipment, do not require protective coatings; however, ceramic coatings are often applied to the exteriors of cooking utensils for aesthetic reasons, and polymeric coatings to the food-contacting surfaces for nonsticking characteristics. Alloys used in commercial food processing include alloy 3003, 5*xxx* alloys, and casting alloy 514.0. Unsatisfactory performance is sometimes caused by use of improper cleaners. Some alkaline cleaners cause excessive corrosion and should not be used unless they are inhibited effectively.

Aluminum alloys are used in processing, handling, and packaging a wide variety of chemical products (Ref 126, 127). Aluminum alloys are compatible with dry salts of most inorganic chemicals. Factors controlling compatibility of aluminum alloys with aqueous solutions have been discussed in earlier sections in this article. Within their passive pH range (about 4 to 9), aluminum alloys resist corrosion by solutions of most inorganic chemicals, but they are subject to pitting in aerated solutions, particularly halide solutions, in which they are polarized to their pitting potentials.

Figure 24 illustrates the corrosion behavior of aluminum in several acids and bases. Aluminum alloys are not suitable for handling mineral acids, with the exception of HNO_3 in concentrations above 82 wt% and H_2SO_4 from 98 to 100 wt%. Aluminum alloys resist most alcohols; however, some alcohols may cause corrosion when extremely dry and at elevated temperatures (Fig. 24d). The same characteristics are associated with phenol (Fig. 24f). Aldehydes have little or no action on aluminum (Fig. 24e). Under most conditions, particularly at room temperature, aluminum alloys resist halogenated organic compounds, but under some conditions, they may react rapidly or violently with some of these chemicals. If water is present, these chemicals may hydrolyze to yield mineral acids that destroy the protective oxide film of aluminum. Such corrosion by mineral acids may in turn promote further reaction with the chemicals themselves, because the aluminum halides formed by this corrosion are catalysts for some such reactions. To ensure safety, service conditions should be ascertained before aluminum alloys are used with these chemicals, and the most stringent precautions should be exercised before they are used in finely divided form.

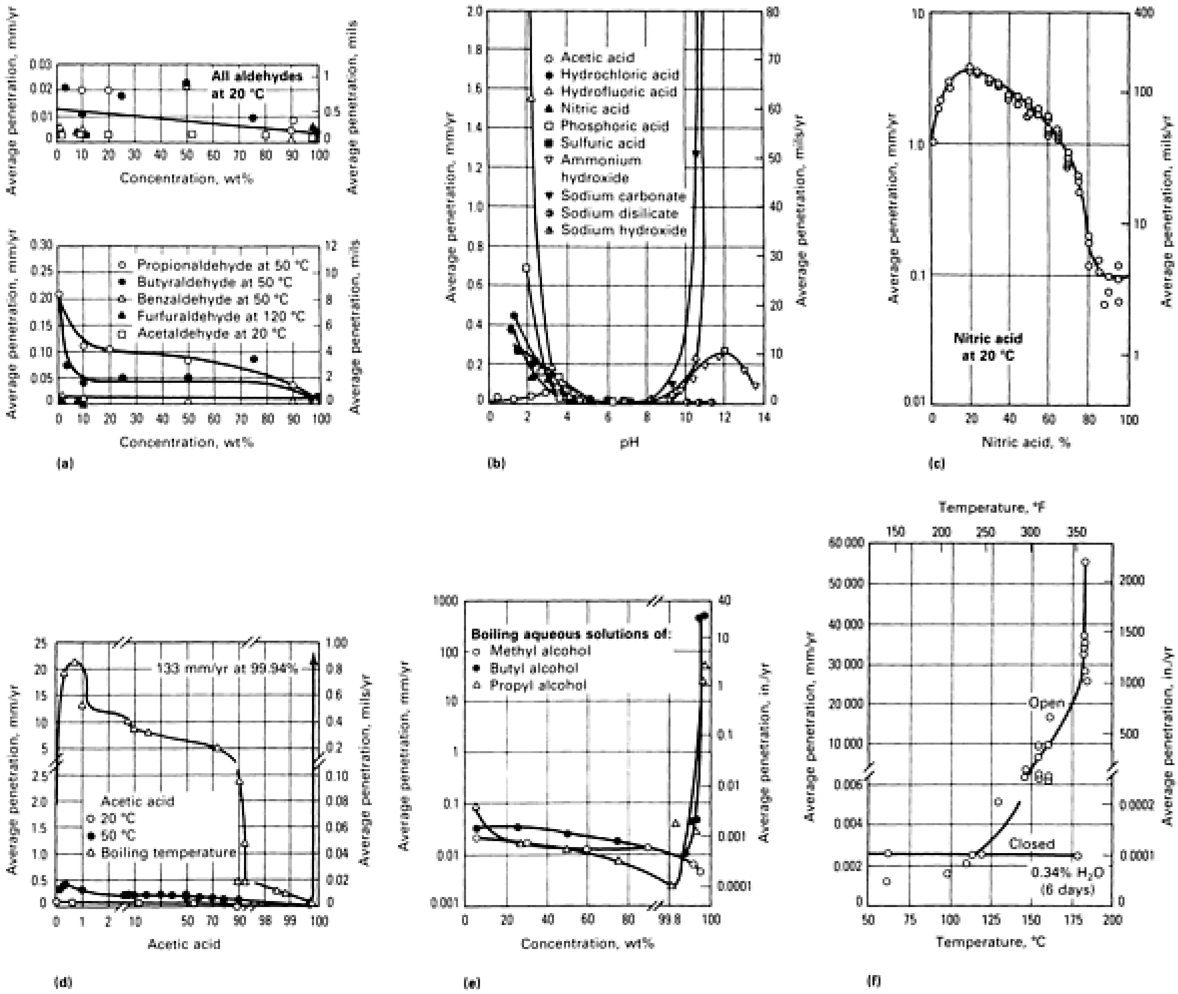

Fig. 24 Corrosion of aluminum 1100-H14 in various chemical solutions. Average penetration calculated from weight loss data in short-term tests. (a) Effect of concentration of aqueous solutions of several aldehydes. Rates of attack indicate that aluminum should be satisfactory for handling all these solutions. (b) Effect of pH. The concentration of all the solutions ranged from 0.00001 to 0.1 *N*, except acetic acid (0.00001 to 17.4 *N*), ammonium hydroxide (NH_4OH) (0.00001 to 15 *N*), and sodium disilicate ($Na_2Si_2O_5$) (0.00001 to 1 *N*). (c) Effect of concentration of HNO_3 solutions at room temperature. (d) Effect of concentration and temperature of acetic acid. (e) Effect of concentration of boiling aqueous solutions of three alcohols. (f) Effect of temperature of phenol. Rapid reaction above 120 °C (250 °F) can be stopped by small additions of steam or water.

Reactivity of aluminum alloys with halogenated organic chemicals is inversely related to the chemical stability of these reagents. Thus, they are most resistant to chemicals containing fluorine and are decreasingly resistant to those containing chlorine, bromine, and iodine. Aluminum alloys resist highly polymerized halogenated chemicals, reflecting the high degree of stability of these chemicals.

Resistance of aluminum and its alloys to many foods and chemicals, representing practically all classifications, has been established in laboratory tests and, in many cases, by service experience. Data are readily available from handbooks, proprietary literature, and trade association publications. Reference 128 is especially useful.

Much of the data from laboratory tests are for chemicals of high purity. Caution should be exercised in using these data to predict performance of aluminum alloys with commercial grades of chemicals. Corrosion of aluminum alloys by inorganic chemicals is frequently caused by such impurities as copper, lead, mercury, and nickel, and corrosion by organic chemicals often results from the presence of other organic chemicals. The combined effect of impurities may exceed the sum of their individual effects.

Care of Aluminum

Handling and Storage. Because of the excellent corrosion resistance of the 1*xxx*, 3*xxx*, 4*xxx*, 5*xxx*, and 6*xxx* series alloys, users occasionally have not employed good practice in the handling and storage of these alloys. This can result in water stains or in pitting. Methods to avoid these unsightly surface effects are described in the article "Surface Engineering of Aluminum and Aluminum Alloys" in *Surface Engineering,* Volume 5 of the *ASM Handbook.*

Water stain is superficial corrosion that occurs when sheets of bare metal are stacked or nested in the presence of moisture. The source of moisture may be condensation from the atmosphere that forms on the edges of the stack and is drawn between the sheets by capillary action. Aluminum should not be stored at temperatures or under atmospheric conditions conducive to condensation. When such conditions cannot be avoided, the metal sheets or parts should be separated and coated with oil or a suitable corrosion inhibitor. Once formed, water stain can be removed by either mechanical or chemical means, but the original surface brightness may be altered.

Outdoor storage of aluminum, even under a tarpaulin, is generally not desirable for long periods of time; this varies with the alloy, the end product, and the local environment. Moisture can collect on the surface, sometimes at relative humidities below the dew point, because of the hygroscopic nature of the dust or particles that deposit on the metal from the atmosphere. The resulting staining or localized pitting, although of little structural consequence in the 1*xxx*, 3*xxx*, 4*xxx*, 5*xxx*, and 6*xxx* alloys, is undesirable if the aluminum will be used for an end product for which surface finish is critical. The 2*xxx* and 7*xxx* bare alloys are susceptible to intergranular attack under these conditions, and for these alloys, use of strippable coatings, protective wrappers, papers, or inhibited organic films is advisable when adverse conditions cannot be avoided.

Mechanical damage can be easily avoided by good housekeeping practices, proper equipment, and proper protection during transportation. When transporting flat sheets or plates, the aluminum should be oiled or interleaved with approved paper to prevent traffic marks, where fretting action at points of contact causes surface abrasion. Practices to avoid these defects are described in Ref 129.

Cleaning and Deactivation of Corrosion. For many applications, minor surface corrosion is of little consequence, and no cleaning is necessary. Where corrosion occurs that is detrimental to strength or appearance if allowed to continue, aluminum can be cleaned by a number of methods (Ref 129). Removal of corrosion products can be followed by deoxidizing or brightening cleaners, if desired. Specifications for all cleaners should state that they are suitable for aluminum. For architectural aluminum products, aggressive or heavy-duty cleaners should be avoided in favor of more frequent use of mild cleaners. Other preventive and maintenance procedures are discussed in Ref 130.

Corrosion of Copper and Copper Alloys

By the ASM Committee on Corrosion of Copper*; Chairman: Ned W. Polan, Olin Corporation

Introduction

COPPER AND COPPER ALLOYS are widely used in many environments and applications because of their excellent corrosion resistance, which is coupled with combinations of other desirable properties, such as superior electrical and thermal conductivity, ease of fabricating and joining, wide range of attainable mechanical properties, and resistance to biofouling. Copper corrodes at negligible rates in unpolluted air, water, and deaerated nonoxidizing acids. Copper alloy artifacts have been found in nearly pristine condition after having been buried in the earth for thousands of years, and copper roofing in rural atmospheres has been found to corrode at rates of less than 0.4 mm (15 mils) in 200 years. Copper alloys resist many saline solutions, alkaline solutions, and organic chemicals. However, copper is susceptible to more rapid attack in oxidizing acids, oxidizing heavy-metal salts, sulfur, ammonia (NH_3), and some sulfur and NH_3 compounds. Resistance to acid solution depends mainly on the severity of oxidizing conditions in the solution. Reaction of copper with sulfur and sulfides to form copper sulfide (CuS or Cu_2S) usually precludes the use of copper and copper alloys in environments known to contain certain sulfur species.

Copper and copper alloys provide superior service in many of the applications included in the following general classifications:

- Applications requiring resistance to atmospheric exposure, such as roofing and other architectural uses, hardware, building fronts, grille work, hand rails, lock bodies, doorknobs, and kick plates
- Freshwater supply lines and plumbing fittings, for which superior resistance to corrosion by various types of waters and soils is important
- Marine applications--most often freshwater and seawater supply lines, heat exchangers, condensers, shafting, valve stems, and marine hardware--in which resistance to seawater, hydrated salt deposits, and biofouling from marine organisms is important
- Heat exchangers and condensers in marine service, steam power plants, and chemical process applications, as well as liquid-to-gas or gas-to-gas heat exchangers in which either process stream may contain a corrosive contaminant
- Industrial and chemical plant process equipment involving exposure to a wide variety of organic and inorganic chemicals
- Electrical wiring, hardware, and connectors; printed circuit boards; and electronic applications that require demanding combinations of electrical, thermal, and mechanical properties, such as semiconductor packages, lead frames, and connectors

Copper and its alloys are unique among the corrosion-resistant alloys in that they do not form a truly passive corrosion product film. In aqueous environments at ambient temperatures, the corrosion product predominantly responsible for protection is cuprous oxide (Cu_2O). This Cu_2O film is adherent and follows parabolic growth kinetics. Cuprous oxide is a *p*-type semiconductor formed by the electrochemical processes:

$$4Cu + 2H_2O \rightarrow 2Cu_2O + 4H^+ + 4e^- \text{ (anode)} \quad \textbf{(Eq 1)}$$

and

$$O_2 + 2H_2O + 4e^- \rightarrow 4(OH)^- \text{ (cathode)} \quad \textbf{(Eq 2)}$$

with the net reaction: $4Cu + O_2 \rightarrow 2Cu_2O$.

For the corrosion reaction to proceed, copper ions and electrons must migrate through the Cu_2O film. Consequently, reducing the ionic or electronic conductivity of the film by doping with divalent or trivalent cations should improve corrosion resistance. In practice, alloying additions of aluminum, zinc, tin, iron, and nickel are used to dope the corrosion product films, and they generally reduce corrosion rates significantly.

Effects of Alloy Compositions

Copper alloys are traditionally classified under the groupings listed in Table 1.

Table 1 Generic classification of copper alloys

Generic name	UNS numbers	Composition
Wrought alloys		
Coppers	C10100-C15760	>99% Cu
High-copper alloys	C16200-C19600	>96% Cu
Brasses	C205-C28580	Cu-Zn
Leaded brasses	C31200-C38590	Cu-Zn-Pb
Tin brasses	C40400-C49080	Cu-Zn-Sn-Pb
Phosphor bronzes	C50100-C52400	Cu-Sn-P
Leaded phosphor bronzes	C53200-C54800	Cu-Sn-Pb-P
Copper-phosphorus and copper-silver-phosphorus alloys	C55180-C55284	Cu-P-Ag
Aluminum bronzes	C60600-C64400	Cu-Al-Ni-Fe-Si-Sn
Silicon bronzes	C64700-C66100	Cu-Si-Sn
Other copper-zinc alloys	C66400-C69900	. . .

Copper-nickels	C70000-C79900	Cu-Ni-Fe
Nickel silvers	C73200-C79900	Cu-Ni-Zn
Cast alloys		
Coppers	C80100-C81100	>99% Cu
High-copper alloys	C81300-C82800	>94% Cu
Red and leaded red brasses	C83300-C85800	Cu-Zn-Sn-Pb (75-89% Cu)
Yellow and leaded yellow brasses	C85200-C85800	Cu-Zn-Sn-Pb (57-74% Cu)
Manganese and leaded manganese bronzes	C86100-C86800	Cu-Zn-Mn-Fe-Pb
Silicon bronzes, silicon brasses	C87300--C87900	Cu-Zn-Si
Tin bronzes and leaded tin bronzes	C90200-C94500	Cu-Sn-Zn-Pb
Nickel-tin bronzes	C94700-C94900	Cu-Ni-Sn-Sn-Zn-Pb
Aluminum bronzes	C95200-C95810	Cu-Al-Fe-Ni
Copper-nickels	C96200-C96800	Cu-Ni-Fe
Nickel silvers	C97300-C97800	Cu-Ni-Zn-Pb-Sn
Leaded coppers	C98200-C98800	Cu-Pb
Miscellaneous alloys	C99300-C99750	. . .

Coppers and high-copper alloys have similar corrosion resistance. They have excellent resistance to seawater corrosion and biofouling, but are susceptible to erosion-corrosion at high water velocities. The high-copper alloys are primarily used in applications that require enhanced mechanical performance, often at slightly elevated temperature, with good thermal or electrical conductivity. Processing for increased strength in the high-copper alloys generally improves their resistance to erosion-corrosion. A number of alloys in this category have been developed for electronic applications--such as contact clips, springs, and lead frames--that require specific mechanical properties, relatively high electrical conductivity, and atmospheric-corrosion resistance.

Brasses are basically copper-zinc alloys and are the most widely used group of copper alloys. The resistance of brasses to corrosion by aqueous solutions does not change markedly as long as the zinc content does not exceed about 15%;

above 15% Zn, dezincification may occur. Quiescent or slowly moving saline solutions, brackish waters, and mildly acidic solutions are environments that often lead to the dezincification of unmodified brasses.

Susceptibility to stress-corrosion cracking (SCC) is significantly affected by zinc content; alloys that contain more zinc are more susceptible. Resistance increases substantially as zinc content decreases from 15 to 0%. Stress-corrosion cracking is practically unknown in commercial copper.

Elements such as lead, tellurium, beryllium, chromium, phosphorus, and manganese have little or no effect on the corrosion resistance of coppers and binary copper-zinc alloys. These elements are added to enhance such mechanical properties as machinability, strength, and hardness.

Tin Brasses. Tin additions significantly increase the corrosion resistance of some brasses, especially resistance to dezincification. Examples of this effect are two tin-bearing brasses: uninhibited admiralty metal (no active UNS number) and naval brass (C46400). Uninhibited admiralty metal was once widely used to make heat-exchanger tubes; it has largely been replaced by inhibited grades of admiralty metal (C44300, C44400, and C44500), which have even greater resistance to dealloying. Admiralty metal is a variation of cartridge brass (C26000) that is produced by adding about 1% Sn to the basic 70Cu-30Zn composition. Similarly, naval brass is the alloy resulting from the addition of 0.75% Sn to the basic 60Cu-40Zn composition of Muntz metal (C28000).

Cast brasses for marine use are also modified by the addition of tin, lead, and, sometimes, nickel. This group of alloys is known by various names, including composition bronze, ounce metal, and valve metal. These older designations are used less frequently, because they have been supplanted by alloy numbers under the UNS or Copper Development Association (CDA) system. The cast marine brasses are used for plumbing goods in moderate-performance seawater piping systems or in deck hardware, for which they are subsequently chrome plated.

Aluminum Brasses. An important constituent of the corrosion film on a brass that contains a few percent aluminum in addition to copper and zinc is aluminum oxide (Al_2O_3), which markedly increases resistance to impingement attack in turbulent high-velocity saline water. For example, the arsenical aluminum brass C68700 (76Cu-22Zn-2Al) is frequently used for marine condensers and heat exchangers in which impingement attack is likely to pose a serious problem. Aluminum brasses are susceptible to dezincification unless they are inhibited, which is usually done by adding 0.02 to 0.10% As.

Inhibited Alloys. Addition of phosphorus, arsenic, or antimony (typically 0.02 to 0.10%) to admiralty metal, naval brass, or aluminum brass effectively produces high resistance to dezincification. Inhibited alloys have been extensively used for such components as condenser tubes, which must accumulate years of continuous service between shutdowns for repair or replacement.

Phosphor Bronzes. Addition of tin and phosphorus to copper produces good resistance to flowing seawater and to most nonoxidizing acids except hydrochloric (HCI). Alloys containing 8 to 10% Sn have high resistance to impingement attack. Phosphor bronzes are much less susceptible to SCC than brasses and are similar to copper in resistance to sulfur attack. Tin bronzes--alloys of copper and tin--tend to be used primarily in the cast form, in which they are modified by further alloy additions of lead, zinc, and nickel. Like the cast brasses, the cast tin bronzes are occasionally identified by older, more colorful names that reflect their historic uses, such as G Bronze, Gun Metal, Navy M Bronze, and steam bronze. Contemporary uses include pumps, valves, gears, and bushings. Wrought tin bronzes are known as phosphor bronzes and find use in high strength wire applications, such as wire rope. This group of alloys has fair resistance to impingement and good resistance to biofouling.

Copper Nickels. Alloy C71500 (Cu-30Ni) has the best general resistance to aqueous corrosion of all the commercially important copper alloys, but C70600 (Cu-10Ni) is often selected because it offers good resistance at lower cost. Both of these alloys, although well suited to applications in the chemical industry, have been most extensively used for condenser tubes and heat-exchanger tubes in recirculating steam systems. They are superior to coppers and to other copper alloys in resisting acid solutions and are highly resistant to SCC and impingement corrosion.

Nickel Silvers. The two most common nickel silvers are C75200 (65Cu-18Ni-17Zn) and C77000 (55Cu-18Ni-27Zn). They have good resistance to corrosion in both fresh and salt waters. Primarily because their relatively high nickel contents inhibit dezincification, C75200 and C77000 are usually much more resistant to corrosion in saline solutions than brasses of similar copper content.

Copper-silicon alloys generally have the same corrosion resistance as copper, but they have higher mechanical properties and superior weldability. These alloys appear to be much more resistant to SCC than the common brasses. Silicon bronzes are susceptible to embrittlement by high-pressure steam and should be tested for suitability in the service environment before being specified for components to be used at elevated temperature.

Aluminum bronzes containing 5 to 12% Al have excellent resistance to impingement corrosion and high-temperature oxidation. Aluminum bronzes are used for beater bars and for blades in wood pulp machines because of their ability to withstand mechanical abrasion and chemical attack by sulfite solutions.

In most practical commercial applications, the corrosion characteristics of aluminum bronzes are primarily related to aluminum content. Alloys with up to 8% Al normally have completely face-centered cubic (fcc) α structures and good resistance to corrosion attack. As aluminum content increases above 8%, α-β duplex structures appear. The β phase is a high-temperature phase retained at room temperature upon fast cooling from 565 °C (1050 °F) or above. Slow cooling for long exposure at temperatures from 320 to 565 °C (610 to 1050 °F) tends to decompose the β phase into a brittle $\alpha + \gamma_2$ eutectoid having either a lamellar or a nodular structure. The β phase is less resistant to corrosion than the α phase, and eutectoid structures are even more susceptible to attack.

Depending on specific environmental conditions, β phase or eutectoid structure in aluminum bronze can be selectively attacked by a mechanism similar to the dezincification of brasses. Proper quench-and-temper treatment of duplex alloys, such as C62400 and C95400, produces a tempered β structure with reprecipitated acicular α crystals, a combination that is often superior in corrosion resistance to the normal annealed structures.

Iron-rich particles are distributed as small round or rosette particles throughout the structures of aluminum bronzes containing more than about 0.5% Fe. These particles sometimes impart a rusty tinge to the surface, but have no known effect on corrosion rates.

Nickel-aluminum bronzes are more complex in structure with the introduction of the κ phase. Nickel appears to alter the corrosion characteristics of the β phase to provide greater resistance to dealloying and cavitation-erosion in most liquids. For C63200 and perhaps C95800, quench-and-temper treatments may yield even greater resistance to dealloying. Alloy C95700, a high-manganese cast aluminum bronze, is somewhat inferior in corrosion resistance to C95500 and C95800, which are low in manganese and slightly higher in aluminum.

Aluminum bronzes are generally suitable for service in nonoxidizing mineral acids, such as phosphoric (H_3PO_4) sulfuric (H_2SO_4), and HCl; organic acids, such as lactic, acetic (CH_3COOH), or oxalic; neutral saline solutions, such as sodium chloride (NaCI) or potassium chloride (KCl); alkalies, such as sodium hydroxide (NaOH), potassium hydroxide (KOH), and anhydrous ammonium hydroxide (NH_4OH); and various natural waters including sea, brackish, and potable waters. Environments to be avoided include nitric acid (HNO_3); some metallic salts, such as ferric chloride ($FeCl_3$) and chromic acid (H_2CrO_4); moist chlorinated hydrocarbons; and moist HN_3. Aeration can result in accelerated corrosion in many media that appear to be compatible.

Exposure under high tensile stress to moist NH_3 can result in SCC. In certain environments, corrosion can lower the fatigue limit to 25 to 50% of the normal atmospheric value.

Types of Attack

Coppers and copper alloys, like most other metals and alloys, are susceptible to several forms of corrosion, depending primarily on environmental conditions. Table 2 lists the identifying characteristics of the forms of corrosion that commonly attack copper metals as well as the most effective means of combating each.

Table 2 Guide to corrosion of copper alloys

Form of attack	Characteristics	Preventive measures
General thinning	Uniform metal removal	Select proper alloy for environmental conditions based on weight loss data.
Galvanic corrosion	Corrosion preferentially near a more cathodic metal	Avoid electrically coupling dissimilar metals; maintain optimum ratio of anode to cathode area; maintain optimum concentration of oxidizing constituent in corroding medium.
Pitting	Localized pits, tubercles; water line pitting; crevice corrosion; pitting under foreign objects or dirt	Alloy selection; design to avoid crevices; keep metal clean.
Impingement, Erosion-corrosion cavitation	Erosion attack from turbulent flow plus dissolved gases, generally as lines of pits in direction of fluid flow	Design for streamlined flow; keep velocity low; remove gases from liquid phase; use erosion-resistant alloy.
Fretting	Chafing or galling, often occurring during shipment	Lubricate contacting surfaces; interleave sheets of paper between sheets of metal; decrease load on bearing surfaces.
Intergranular corrosion	Corrosion along grain boundaries without visible signs of cracking	Select proper alloy for environmental conditions based on metallographic examination of corrosion specimens.
Dealloying	Preferential dissolution of zinc or nickel, resulting in a layer of sponge copper	Select proper alloy for environmental conditions based on metallographic examination of corrosion specimens.
Corrosion fatigue	Several transgranular cracks	Select proper alloy based on fatigue tests in service environment; reduce mean or alternating stress.
SCC	Cracking, usually intergranular but sometimes transgranular, that is often fairly rapid	Select proper alloy based on stress-corrosion tests; reduce applied or residual stress; remove mercury compounds or NH_3 from environment.

General Corrosion

General corrosion is the well-distributed attack of an entire surface with little or no localized penetration. It is the least damaging of all forms of attack. General corrosion is the only form of corrosion for which weight loss data can be used to estimate penetration rates accurately.

General corrosion of copper alloys results from prolonged contact with environments in which the corrosion rate is very low, such as fresh, brackish, and salt waters; many types of soil; neutral, alkaline, and acid salt solutions; organic acids; and sugar juices. Other substances that cause uniform thinning at a faster rate include oxidizing acids, sulfur-bearing compounds, NH_3, and cyanides. Additional information on this form of attack is available in the article "General Corrosion" in this Volume.

Galvanic Corrosion

An electrochemical potential almost always exists between two dissimilar metals when they are immersed in a conductive solution. If two dissimilar metals are in electrical contact with each other and immersed in a conductive solution, a potential results that enhances the corrosion of the more electronegative member of the couple (the anode) and partly or completely protects the more electropositive member (the cathode). Copper metals are almost always cathodic to other

common structural metals, such as steel and aluminum. When steel or aluminum is put in contact with a copper metal, the corrosion rate of the steel or aluminum increases, but that of the copper metal decreases. The common grades of stainless steel exhibit variable behavior; that is, copper metals may be anodic or cathodic to the stainless steel, depending on conditions of exposure. Copper metals usually corrode preferentially when coupled with high-nickel alloys, titanium, or graphite. Additional information on this subject is available in the section "Galvanic Corrosion." of the article "General Corrosion" in this Volume.

Corrosion potentials of copper metals generally range from -0.2 to -0.4 V when measured against a saturated calomel electrode (SCE); the potential of pure copper is about -0.3 V. Alloying additions of zinc or aluminum move the potential toward the anodic (more electronegative) end of the range; additions of tin or nickel move the potential toward the cathodic (less electronegative) end. Galvanic corrosion between two copper metals is seldom a significant problem, because the potential difference is so small.

Table 3 lists a galvanic series of metals and alloys valid for dilute aqueous solutions, such as seawater and weak acids. The metals that are grouped together can be coupled to each other without significant galvanic damage. However, the connecting of metals from different groups leads to damage of the more anodic metal; the larger the difference in galvanic potential between groups, the greater the corrosion. Accelerated damage due to galvanic effects is usually greatest near the junction, where the electrochemical current density is the highest.

Cathodic End

Another factor that affects galvanic corrosion is area ratio. An unfavorable area ratio exists when the cathodic area is large and the anodic area in small. The corrosion rate of the small anodic area may be several hundred times greater than if the anodic and cathodic areas were equal in size. Conversely, when a large anodic area is coupled to a small cathodic area, current density and damage due to galvanic corrosion are much less. For example, copper rivets (cathodic) used to fasten steel plates together lasted longer than 1.5 years in seawater, but steel rivets used to fasten copper plates were completely destroyed during the same period.

Five principal methods are available for eliminating or significantly reducing galvanic corrosion:

- Select dissimilar metals that are as close as possible to each other in the galvanic series
- Avoid coupling small anodes to large cathodes
- Insulate dissimilar metals completely wherever practicable
- Apply coatings and keep them in good repair, particularly on the cathodic member
- Use a sacrificial anode; that is, couple the system to a third metal that is anodic to both structural metals

Pitting

As with most commercial metals, corrosion of copper metals results in pitting under certain conditions. Pitting is sometimes general over the entire surface, giving the metal an irregular and roughened appearance. In other cases, pits are concentrated in specific areas and are of various sizes and shapes. Detailed information on this form of attack is available in the section "Pitting" in the article "Localized Corrosion" in this Volume.

Localized pitting is the most damaging form of corrosive attack because it reduces load-carrying capacity and increases stress concentration by creating depressions or holes in the metal. Pitting is the usual form of corrosive attack at

surfaces on which there are incomplete protective films, nonprotective deposits of scale, or extraneous deposits of dirt or other foreign substances.

Copper alloys do not corrode primarily by pitting, but because of metallurgical and environmental factors that are not completely understood, the corroded surface does show a tendency toward nonuniformity. In seawater, pitting tends to occur more often under conditions of relatively low water velocity, typically less than 0.6 to 0.9 m/s (2 to 3 ft/s). The occurrence of pitting is somewhat random regarding the specific location of a pit on the surface as well as whether it will even occur on a particular metal sample. Long-term tests of copper alloys show that the average pit depth does not continually increase with extended times of exposure. Instead, pits tend to reach a certain limit beyond which little apparent increase in depth occurs. Of the copper alloys, the most pit resistant are the aluminum bronzes with less than 8% Al and the low-zinc brasses. Copper nickels and tin bronzes tend to have intermediate pitting resistance, but the high-copper alloys and silicon bronzes are somewhat more prone to pitting.

Crevice corrosion is a form of localized corrosion that occurs near a crevice formed either by two metal surfaces or a metal and a nonmetal surface. Like pitting, crevice attack is a random occurrence, the precise location of which cannot always be predicted. Also, like pitting, the depth of attack appears to level off rather than to increase continually with time. This depth is usually less than that from pitting, and for most copper alloys, it will be less than 400 μm (15.8 mils).

For most copper alloys, the location of the attack will be outside but immediately adjacent to the crevice due to the formation of metal ion concentration cells. Classic crevice corrosion resulting from oxygen depletion and attack within crevices is less common in copper alloys. Aluminum- and chromium-bearing copper alloys, which form more passive surface films, are susceptible to differential oxygen cell attack, as are aluminum alloys and stainless steels. The occurrence of crevice attack is somewhat statistical in nature, with the odds of it occurring and its severity increasing if the area within a crevice is small compared to the area outside the crevice. Other conditions that will increase the odds of crevice attack are higher water temperatures or a flow condition on the surface outside the crevice.

Local cell action similar to crevice attack may also result from the presence of foreign objects or debris, such as dirt, pieces of shell, or vegetation, or it may result from rust, permeable scales, or uneven accumulation of corrosion product on the metallic surface. This type of attack can sometimes be controlled by cleaning the surfaces. For example, condensers and heat exchangers are cleaned periodically to prevent deposit attack.

Water line attack is a term used to describe pitting due to a differential oxygen cell functioning between the well-aerated surface layer of a liquid and the oxygen-starved layer immediately beneath it. The pitting occurs immediately below the water line.

Impingement

Various forms of impingement attack occur where gases, vapors, or liquids impinge on metal surfaces at high velocities, such as in condensers or heat exchangers. Rapidly moving turbulent water can strip away the protective films from copper alloys. When this occurs, the metal corrodes at a more rapid rate in an attempt to reestablish this film, but because the films are being swept away as rapidly as they are being formed, the corrosion rate remains constant and high. The conditions under which the corrosion product film is removed are different for each alloy and are discussed in the section "Corrosion of Copper Alloys in Specific Environments" in this article. Additional information on various types of impingement attack is available in the article "Mechanically Assisted Degradation" in this Volume.

Erosion-corrosion is characterized by undercut grooves, waves, ruts, gullies, and rounded holes; it usually exhibits a directional pattern. Pits are elongated in the direction of flow and are undercut on the downstream side. When the condition becomes severe, it may result in a pattern of horseshoe-shaped grooves or pits with their open ends pointing downstream. As attack progresses, the pits may join, forming fairly large patches of undercut pits. When this form of corrosion occurs in a condenser tube, it is usually confined to a region near the inlet end of the tube where fluid flow is rapid and turbulent. If some of the tubes in a bundle become plugged, the velocity is increased in the remaining tubes; therefore, the unit should be kept as clean as possible. Erosion-corrosion is most often found with waters containing low levels of sulfur compounds and with polluted, contaminated, or silty salt water or brackish water. The erosive action locally removes protective films, thus contributing to the formation of concentration cells and to localized pitting of anodic sites.

Cavitation is a phenomenon that occurs in moving water when the flow is disturbed so as to create a local pressure drop. Under these conditions, a vapor bubble will form and then collapse, applying a momentary stress of up to 1379 MPa (200

ksi) to the surface. The current theories of cavitation state that this repeated mechanical working of the surface creates a local fatigue situation that aids the removal of metal. This is in agreement with the observations that the harder alloys tend to have greater resistance to cavitation and that there is often an incubation period before the onset of cavitation attack. Of the copper alloys, aluminum bronze has the best cavitation resistance. Cavitation damage will be confined to the area where the bubbles collapse, usually immediately downstream of the low-pressure zone.

Impingement attack can be reduced, and the life of the unit extended, by decreasing fluid velocity, streamlining the flow, and removing entrained air. This is usually accomplished by redesigning water boxes, injector nozzles, and piping to reduce or eliminate low-pressure pockets, obstructions to smooth flow, abrupt changes in flow direction, and other features that cause local regions of high-velocity or turbulent flow. Condensers and heat exchangers are less susceptible to impingement attack if they are made of one of the aluminum brasses or copper nickels, which are more erosion resistant than the brasses or tin brasses. Erosion-resistant inserts at tube inlets and epoxy-type coatings are often effective repair methods in existing shell and tube heat exchangers. When contaminated waters are involved, filtering or screening the liquids and cleaning the surfaces can be very effective in minimizing impingement attack. The use of cathodic protection can lessen all forms of localized attack except cavitation.

Fretting

Another form of attack, called fretting or fretting corrosion, appears as pits or grooves in the metal surface that are surrounded or filled with corrosion product. Fretting is sometimes referred to as chafing, road burn, friction oxidation, wear oxidation, or galling.

The basic requirements for fretting are as follows:

- Repeated relative (sliding) motion between two surfaces must occur. The relative amplitude of the motion may be very small--motion of only a few tenths of a millimeter is typical
- The interface must be under load
- Both load and relative motion must be sufficient to produce deformation of the interface
- Oxygen and/or moisture must be present

Fretting does not occur on lubricated surfaces in continuous motion, such as axle bearings, but instead on dry interfaces subject to repeated, small relative displacements. A classic type of fretting occurs during shipment of bundles of mill products having flat faces. Fretting is not confined to coppers and copper alloys, but has been recognized on almost every kind of surface--steel, aluminum, noble metals, mica, and glass.

Fretting can be controlled, and sometimes eliminated, by:

- Lubricating with low-viscosity high-tenacity oils to reduce friction at the interface between the two metals and to exclude oxygen from the interface
- Separating the faying surfaces by interleaving an insulating material
- Increasing the load to reduce motion between faying surfaces; this may be difficult in practice, because only a minute amount of relative motion is necessary to produce fretting
- Decreasing the load at bearing surfaces to increase the relative motion between parts

Detailed information is available in the section "Fretting" of the article "Mechanically Assisted Degradation" in this Volume.

Intergranular Corrosion

Intergranular corrosion is an infrequently encountered form of attack that occurs most often in applications involving high-pressure steam. This type of corrosion penetrates the metal along grain boundaries--often to a depth of several grains--which distinguishes it from surface roughening. Mechanical stress is apparently not a factor in intergranular corrosion. The alloys that appear to be the most susceptible to this form of attack are Muntz metal, admiralty metal,

aluminum brasses, and silicon bronzes. Additional information is provided in the section "Intergranular Corrosion" of the article "Metallurgically Influenced Corrosion" in this Volume.

Dealloying

Dealloying is a corrosion process in which the more active metal is selectively removed from an alloy, leaving behind a weak deposit of the more noble metal. Copper-zinc alloys containing more than 15% Zn are susceptible to a dealloying process called dezincification. In the dezincification of brass, selective removal of zinc leaves a relatively porous and weak layer of copper and copper oxide. Corrosion of a similar nature continues beneath the primary corrosion layer, resulting in gradual replacement of sound brass by weak, porous copper. Unless arrested, dealloying eventually penetrates the metal, weakening it structurally and allowing liquids or gases to leak through the porous mass in the remaining structure.

The term plug-type dealloying refers to the dealloying that occurs in local areas; surrounding areas are usually unaffected or only slightly corroded. In uniform-layer dealloying, the active component of the alloy is leached out over a broad area of the surface. Dezincification is the usual form of corrosion for uninhibited brasses in prolonged contact with waters high in oxygen and carbon dioxide (CO_2). It is frequently encountered with quiescent or slowly moving solutions. Slightly acidic water, low in salt content and at room temperature, is likely to produce uniform attack, but neutral or alkaline water, high in salt content and above room temperature, often produces plug-type attack.

Brasses with copper contents of 85% or more resist dezincification. Dezincification of brasses with two-phase structures is generally more severe, particularly if the second phase is continuous; it usually occurs in two stages: the high-zinc β phase, followed by the lower-zinc α phase.

Tin tends to inhibit dealloying, especially in cast alloys. Alloys C46400 (naval brass) and C67500 (manganese bronze), which are α-β brasses containing about 1% Sn, are widely used for naval equipment and have reasonably good resistance to dezincification. Addition of a small amount of phosphorous, arsenic, or antimony to admiralty metal (an all-α 71Cu-28Zn-1Sn brass) inhibits dezincification. Inhibitors are not entirely effective in preventing dezincification of the α-β brasses, because they do not prevent dezincification of the β phase.

Where dezincification is a problem, red brass, commercial bronze, inhibited admiralty metal, and inhibited aluminum brass can be successfully used. In some cases, the economic penalty of avoiding dealloying by selecting a low-zinc alloy may be unacceptable. Low-zinc alloy tubing requires fittings that are available only as sand castings, but fittings for higher-zinc tube can be die cast or forged much more economically. Where selection of a low-zinc alloy is unacceptable, inhibited yellow brasses are generally preferred.

Dealloying has been observed in other alloys. Dealloying of aluminum occurs in some copper-aluminum alloys, particularly with those having more than 8% Al. It is especially severe in alloys with continuous γ phase and usually occurs as plug-type dealloying. Nickel additions exceeding 3.5% or heat treatment to produce an $\alpha + \beta$ microstructure prevents dealloying. Dealloying of nickel in C71500 is rare, have been observed at temperatures over 100 °C (212 °F), low flow conditions, and high local heat flux. Dealloying of tin in cast tin bronzes has been observed as a rare occurrence in hot brine or steam. Cathodic protection generally protects all but the two-phase copper-zinc alloys from dealloying. Additional information on this form of attack is available in the section "Dealloying Corrosion" of the article "Metallurgically Influenced Corrosion" in this Volume.

Corrosion Fatigue

The combined action of corrosion (usually pitting corrosion) and cyclic stress may result in corrosion fatigue cracking. Like ordinary fatigue cracks, corrosion fatigue cracks generally propagate at right angles to the maximum tensile stress in the affected region. However, cracks resulting from simultaneous fluctuating stress and corrosion propagate much more rapidly than cracks caused solely by fluctuating stress. Also, corrosion fatigue failure usually involves several parallel cracks, but it is rare for more than one crack to be found in a part that has failed by simple fatigue. The cracks shown in Fig. 1 are characteristic of service failures resulting from corrosion fatigue.

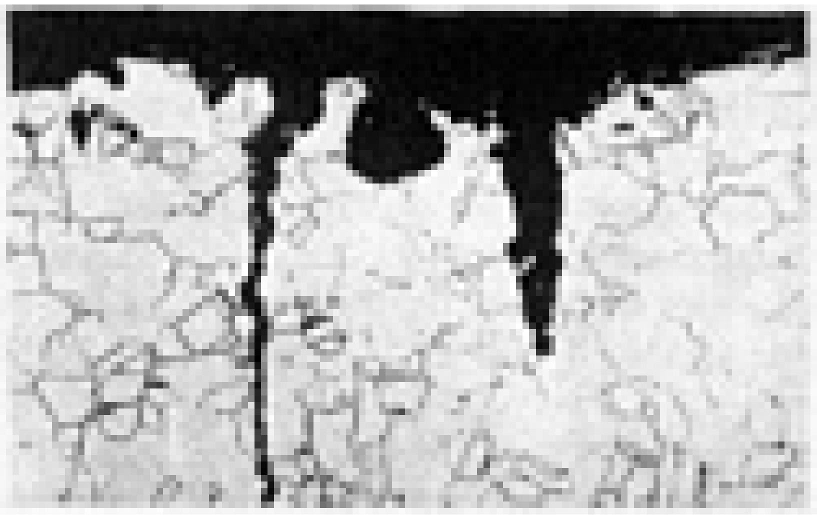

Fig. 1 Typical corrosion fatigue cracking of a copper alloy. Transgranular cracks originate at the base of corrosion pits on the roughened inner surface of a tube. Etched. About 150×

Ordinarily, corrosion fatigue can be readily identified by the presence of several cracks emanating from corrosion pits. Cracks not visible to the unaided eye or at low magnification can be made visible by deep etching or plastic deformation or can be detected by eddy-current inspection. Corrosion fatigue cracking is often transgranular, but there is evidence that certain environments induce intergranular cracking in copper metals.

In addition to effective resistance to corrosion, copper and copper alloys also resist corrosion fatigue in many applications involving repeated stress and corrosion. These applications include such parts as springs, switches, diaphragms, bellows, aircraft and automotive gasoline and oil lines, tubes for condensers and heat exchangers, and fourdrinier wire for the paper industry.

Copper alloys that are high in fatigue limit and resistance to corrosion in the service environment are more likely to have good resistance to corrosion fatigue. Alloys frequently used in applications involving both cyclic stress and corrosion include beryllium coppers, phosphor bronzes, aluminum bronzes, and copper nickels. More information on corrosion fatigue is available in the section "Corrosion Fatigue" of the article "Mechanically Assisted Degradation" in this Volume.

Stress-Corrosion Cracking

Stress-corrosion cracking and season cracking describe the same phenomenon--the apparently spontaneous cracking of stressed metal. Stress-corrosion cracking is often intergranular (Fig. 2), but transgranular cracking may occur in some alloys in certain environments. Stress-corrosion cracking occurs only if a susceptible alloy is subjected to the combined effects of sustained stress and certain chemical substances.

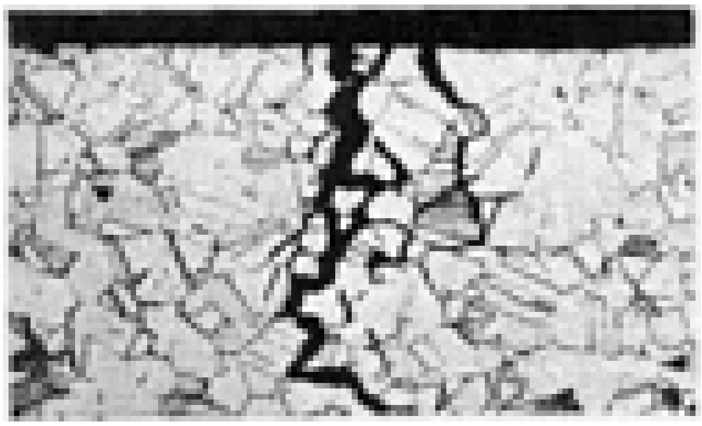

Fig. 2 Typical SCC in a copper alloy. Intergranular cracking in an etched specimen. About 60×

Mechanism. Copper alloys crack in a wide variety of electrolytes. In some cases, the crack surfaces have the distinctive brittle appearance that is associated with SCC. In other cases, the threshold stress for cracking may be close to that observed in air, and the fracture surfaces resemble those of samples fractured in air. It is also clear in many systems that cracking occurs at low threshold stresses only when certain environmental conditions exist. Variables that control this threshold stress in a specific environment include pH, potential of the metal, temperature, extent of cold work before the test, and minor alloying elements in the copper alloy.

The best nonquantitative interpretation of SCC is the following. Stress-corrosion cracking occurs in those environmental/metal systems in which the rate of corrosion is low; the corrosion that does occur proceeds in a highly localized manner. Intergranular attack, selective removal of an alloy component, pitting, attack at a metal/precipitate interface, or surface flaws, when they occur in the presence of a surface tensile stress, may lead to a surface defect at the base of which the stress intensity factor, K_I, exceeds the threshold stress intensity for SCC K_{Iscc}, for that specific environment/alloy system under the conditions selected for the test or encountered in service. Whether or not a crack propagates depends on the specimen geometry and how the magnitude of the stress field at the crack tip changes as the crack develops. The critical factor is how the metal reacts at the crack tip. If the metallurgical structure or the kinetics of chemical corrosion at the crack tip is such that a small radius of curvature (sharp crack tip) is maintained at the crack tip, the crack will continue to propagate because the local stress at the crack tip is high. High rates of corrosion at the crack tip, which lead to a large radius of curvature (blunt), will favor pitting rather than crack growth.

A sharp crack tip is favored by:

- Selective removal of one component of an alloy with the resulting development of local voids that provide a brittle crack path
- Brittle fracture of a corrosion product coating at the base of a crack that continually reforms
- Attack along the interface of two discrete phases
- Intergranular attack that does not spread laterally
- Surface energy considerations that encourage intrusion of the environment (a liquid metal in particular) into minute flaws

Since the discovery by E. Mattsson that a medium containing ammonium sulfate [$(NH_4)_2SO_4$], NH_4OH, and copper sulfate ($CuSO_4$) is an excellent one for studying the fundamentals of the SCC process caused by NH_3, many researchers have used this electrolyte, and the name Mattsson's solution has been given to this solution (Ref 1). Much of the knowledge of the specifics of SCC by NH_3 solutions has been obtained from brass exposed to this solution while under a tensile stress.

The chemistry and the electrochemistry of the brass-NH_3 system was recently reviewed and analyzed (Ref 2). Cupric (Cu^{2+}) ammonium complex was concluded to be necessary for the occurrence of SCC under open-circuit conditions in oxygenated NH_3 solutions. This complex becomes a component in the predominant cathodic reaction:

$$Cu(NH_3)_4^{2+} + e^- \rightarrow Cu(NH_3)_2^{+} + 2NH_3 \quad \textbf{(Eq 3)}$$

Equation 3 permits cracking by cyclic rupture of a Cu_2O film generated at the crack tip (Ref 3) or by a mechanism involving dezincification (Ref 4). Cracking can also occur in deoxygenated solutions in the absence of significant concentrations of the Cu^{2+} ions provided the cuprous (Cu^+) complexes are available. It was suggested that the role of the Cu^+ complex is to provide a cathodic reaction, in this case allowing dezincification to occur. These findings are consistent with the recognition that SCC failures of brass are not limited to environments containing NH_3.

The most damaging evidence against the film rupture model is given in Ref 5. In this study, the tarnish film that formed on unstressed 70Cu-30Zn brass during exposure for 48 h to an NH_4OH-$(NH_4)_2SO_4$-$CuSO_4$ electrolyte at pH 7.2 was shown to fracture transgranularly when fractured in air. The reported film rupture mechanism predicts that these films should fracture intergranularly. The transgranular cracks do not propagate when a stressed specimen is immersed in the electrolyte; instead, very rapid intergranular SCC is observed. These facts are also difficult to reconcile with the repeated film rupture model.

It was first shown in 1972 that dezincification of 70Cu-30Zn brass occurs in the crack during SCC in an ammonium salt environment (Ref 4). More recently, mechanical strain was found to lead to dezincification of both 85Cu-15Zn and 70Cu-30Zn alloys in an NH_4OH-$(NH_4)SO_4$-$CuSO_4$ electrolyte (Ref 6). Unstressed samples of the same alloys did not show dezincification. Strain-induced dealloying was further shown to occur in both intergranular (copper-zinc) and transgranular (copper-zinc-nickel) (Ref 7). These observations indicated that stress corrosion of copper alloys is integrally related to strain-induced dealloying.

Conditions Leading to SCC. Ammonia and ammonium compounds are the corrosive substances most often associated with SCC of copper alloys. These compounds are sometimes present in the atmosphere; in other cases, they are in cleaning compounds or in chemicals used to treat boiler water. Both oxygen and moisture must be present for NH_3 to be corrosive to copper alloys; other compounds, such as CO_2, are thought to accelerate SCC in NH_3 atmospheres. Moisture films on metal surfaces will dissolve significant quantities of NH_3, even from atmospheres with low NH_3 concentrations.

A specific corrosive environment and sustained stress are the primary causes of SCC; microstructure and alloy composition may affect the rate of crack propagation in susceptible alloys. Microstructure and composition can be most effectively controlled by selecting the correct combination of alloy, forming process, thermal treatment, and metal-finishing process. Although test results may indicate that a finished part is not susceptible to SCC, such an indication does not ensure complete freedom from cracking, particularly where service stresses are high.

Applied and residual stresses can both lead to failure by SCC. Susceptibility is largely a function of stress magnitude. Stresses near the yield strength are usually required, but parts have failed under much lower stresses. In general, the higher the stress, the weaker the corroding medium must be to cause SCC. The reverse is also true: the stronger the corroding medium, the lower the required stress.

Sources of Stress. Applied stresses result from ordinary service loading or from fabricating techniques, such as riveting, bolting, shrink fitting, brazing, and welding. Residual stresses are of two types: differential-strain stresses, which result from nonuniform plastic strain during cold forming, and differential-thermal-contraction stresses, which result from nonuniform heating and/or cooling.

Residual stresses induced by nonuniform straining are primarily influenced by the method of fabrication. In some fabricating processes, it is possible to cold work a metal extensively and yet produce only a low level of residual stress. For example, residual stress in a drawn tube is influenced by die angle and amount of reduction. Wide-angle dies (about 32°) produce higher residual stresses than narrow-angle dies (about 8°). Light reductions yield high residual stresses because only the surface of the alloy is stressed; heavy reductions yield low residual stresses because the region of cold working extends deeper into the metal. Most drawing operations can be planned so that residual stresses are low and susceptibility to SCC is negligible.

Residual stresses resulting from upsetting, stretching, or spinning are more difficult to evaluate and to control by varying tooling and process conditions. For these operations, SCC can be prevented more effectively by selecting a resistant alloy or by treating the metal after fabrication.

Alloy Composition. Brasses containing less than 15% Zn are highly resistant to SCC. Phosphorus-deoxidized copper and tough pitch copper rarely exhibit SCC, even under severe conditions. On the other hand, brasses containing 20 to 40% Zn are highly susceptible. Susceptibility increases only slightly as zinc content is increased from 20 to 40%.

There is no indication that the other elements commonly added to brasses increase the probability of SCC. Phosphorus, arsenic, magnesium, tellurium, tin, beryllium, and manganese are thought to decrease susceptibility under some conditions. Addition of 1.5% Si is known to decrease the probability of cracking.

Altering the microstructure cannot make a susceptible alloy totally resistant to SCC. However, the rapidity with which susceptible alloys crack appears to be affected by grain size and structure. All other factors being equal, the rate of cracking increases with grain size. The effects of structure on SCC are not sharply defined, primarily because they are interrelated with effects of both composition and stress.

Control Measures. Stress-corrosion cracking can be controlled, and sometimes prevented, by selecting copper alloys that have high resistance to cracking (notably those with less than 15% Zn); by reducing residual stress to a safe level by thermal stress relief, which can usually be applied without significantly decreasing strength; or by altering the environment, such as by changing the predominant chemical species present or introducing a corrosion inhibitor.

Residual and assembly stresses can be eliminated by recrystallization annealing after forming or assembly. Recrystallization annealing cannot be used when the integrity of the structure depends on the higher strength of strain-hardened metal, which always contains a certain amount of residual stress. Thermal stress relief (sometimes called relief annealing) can be specified when the higher strength of a cold-worked temper must be retained. Thermal stress relief consists of heating the part for a relatively short time at low temperature. Specific times and temperatures depend on alloy composition, severity of deformation, prevailing stresses, and the size of the load being heated. Usually, time is from 30 min to 1 h and temperature is from 150 to 425 °C (300 to 795 °F). Table 4 lists typical stress-relieving times and temperatures for some of the more common copper alloys.

Table 4 Typical stress-relieving parameters for some common copper alloys

Common name	UNS number	Temperature		Time, h
		°C	**°F**	
Commercial bronze	C22000	205	400	1
Cartridge brass	C26000	260	500	1
Muntz metal	C28000	190	375	$\frac{1}{2}$
Admiralty metal	C44300, C44400, C44500	300	575	1
Phosphor bronze, 5 or 10%	C51000, C52400	190	375	1
Silicon bronze	C65500	370	700	1
Aluminum bronze	C61300, C61400	400	750	1

The exact thermal treatment should be established by examining specific parts for residual stress. If such examination indicates that a thermal treatment is insufficient, temperature and/or time should be adjusted until satisfactory results are obtained. Parts in the center of a furnace load may not reach the desired temperature as soon as parts around the periphery. Therefore, it may be necessary to compensate for furnace loading when setting process controls or to limit the number of parts that can be stress relieved together.

Mechanical methods, such as stretching, flexing, bending, straightening between rollers, peening, and shot blasting, can also be used to reduce residual stresses to a safe level. These methods depend on plastic deformation to decrease dangerous tensile stresses or to convert them to less objectionable compressive stresses. Additional information on SCC is available in the section "Stress-Corrosion Cracking" of the article "Environmentally Induced Cracking" in this Volume.

Corrosion of Copper Alloys in Specific Environments

Selection of a suitably resistant material requires consideration of the many factors that influence corrosion. Operating records are the most reliable guidelines as long as the data are accurately interpreted. Some of the information in this article has been collected over a period of 20 years or more. Results of short-term laboratory and field testing are also described, but these data may not be as reliable for solving certain problems. Laboratory corrosion tests often do not duplicate such operating factors as stress, velocity, galvanic coupling, concentration cells, initial surface conditions, and contamination of the surrounding medium. If damage occurs by pitting, intergranular corrosion, or dealloying (as in dezincification) or if a thick adherent scale forms, corrosion rates calculated from a change in weight may be misleading. From these forms of corrosion, estimates of reduction in mechanical strength are often more meaningful. Corrosion fatigue and SCC are also potential sources of failure that cannot be predicted from routine measurements of weight loss or dimensional change.

Over the years, experience has been the best criterion for selecting the most suitable alloy for a given environment. The CDA has compiled much field experience in the form of the ratings shown in Table 5. Similar data for cast alloys are given in Table 6. These tables should be used only as a guide; small changes in the environmental conditions sometimes degrade the performance of a given alloy from "suitable" to "not suitable."

Table 5 Corrosion ratings of wrought copper alloys in various corrosive media

This table is intended to serve only as a general guide to the behavior of copper and copper alloys in corrosive environments. It is impossible to cover in a simple tabulation the performance of a material for all possible variations of temperature, concentration, velocity, impurity content, degree of aeration, and stress. The ratings are based on general performance; they should be used with caution, and then only for the purpose of screening candidate alloys.

The letters E, G, F, and P have the following significance:

E, excellent: resists corrosion under almost all conditions of service

G, good: some corrosion will take place, but satisfactory service can be expected under all but the most severe conditions.

F, fair: corrosion rates are higher than for the G classification, but the metal can be used if needed for a property other than corrosion resistance and if either the amount of corrosion does not cause excessive maintenance expense or the effects of corrosion can be lessened, such as by use of coatings or inhibitors.

P, poor: corrosion rates are high, and service is generally unsatisfactory.

(a) Copper and copper alloys are resistant to corrosion by most food products. Traces of copper may be dissolved and affect taste or color of the products. In such cases, copper alloys are often tin coated.

(b) Acetylene forms an explosive compound with copper when moisture or certain impurities are present and the gas is under pressure. Alloys containing less than 65% Cu are satisfactory; when the gas is not under pressure, other copper alloys are satisfactory.

(c) Precautions should be taken to avoid SCC.

(d) At elevated temperatures, hydrogen will react with tough pitch copper, causing failure by embrittlement.

(e) Where air is present, corrosion rate may be increased.

(f) Below 150 °C (300 °F), corrosion rate is very low; above this temperature, corrosion is appreciable and increases rapidly with temperature.

(g) Aeration and elevated temperature may increase corrosion rate substantially.

(h) Excessive oxidation may begin above 120 °C (250 °F). If moisture is present, oxidation may begin at lower temperatures.

(i) Use of high-zinc brasses should be avoided in acids because of the likelihood of rapid corrosion by dezincification. Copper, low-zinc brasses, phosphor bronzes, silicon bronzes, aluminum bronzes, and copper nickels offer good resistance to corrosion by hot and cold dilute H_2SO_4 and to corrosion by cold concentrated H_2SO_4. Intermediate concentrations of H_2SO_4 are sometimes more corrosive to copper alloys than either concentrated or dilute acid. Concentrated H_2SO_4 may be corrosive at elevated temperatures due to breakdown of acid and formation of metallic sulfides and sulfur dioxide, which cause localized pitting. Tests indicate that copper alloys may undergo pitting in 90 to 95% H_2SO_4 at about 50 °C (122 °F), in 80% acid at about 70 °C (160 °F), and in 60% acid at about 100 °C (212 °F).

(j) Wetting agents may increase corrosion rates of copper and copper alloys slightly to substantially when carbon dioxide or oxygen is present by preventing formation of a film on the metal surface and by combining (in some instances) with the dissolved copper to produce a green, insoluble compound.

Butane	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Calcium bisulfite	A	A	B	B	B	C	C	C	C	A	B	A	A	B
Calcium chloride (acid)	B	B	B	B	B	B	C	C	C	A	C	C	A	C
Calcium chloride (alkaline)	C	C	C	C	C	C	C	C	C	A	C	A	C	B
Calcium hydroxide	C	C	C	C	C	C	C	C	C	B	C	C	C	C
Calcium hypochlorite	C	C	B	B	B	C	C	C	C	B	C	C	C	C
Cane-sugar syrups	A	A	B	A	B	A	A	A	A	A	A	A	A	B
Carbonated beverages[(b)]	A	C	C	C	C	C	C	C	C	A	C	C	A	C
Carbon dioxide, dry	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Carbon dioxide, moist[(b)]	B	B	B	C	B	C	C	C	C	A	C	A	A	B
Carbon	A	A	A	A	A	A	A	A	A	A	A	A	A	A

tetrachloride, dry														
Carbon tetrachloride, moist	B	B	B	B	B	B	B	B	B	B	B	A	A	A
Chlorine, dry	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Chlorine, moist	C	C	B	B	B	C	C	C	C	C	C	C	C	C
Chromic acid	C	C	C	C	C	C	C	C	C	C	C	C	C	C
Citric acid	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Copper sulfate	B	A	A	A	A	C	C	C	C	B	B	B	A	A
Cottonseed oil[(b)]	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Creosote	B	B	B	B	B	C	C	C	C	A	B	B	B	B
Ethers	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Ethylene glycol	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Ferric chloride, sulfate	C	C	C	C	C	C	C	C	C	C	C	C	C	C
Ferrous chloride, sulfate	C	C	C	C	C	C	C	C	C	C	C	C	C	C
Formaldehyde	A	A	A	A	A	A	A	A	A	A	A	A	A	A

Formic acid	A	A	A	A	A	B	B	B	B	A	B	B	B	C
Freon	A	A	A	A	A	A	A	A	A	A	A	A	A	B
Fuel oil	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Furfural	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Gasoline	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Gelatin[(b)]	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Glucose	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Glue	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Glycerin	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Hydrochloric or muriatic acid	C	C	C	C	C	C	C	C	C	B	C	C	C	C
Hydrofluoric acid	B	B	B	B	B	B	B	B	B	A	B	B	B	B
Hydrofluosilicic acid	B	B	B	B	B	C	C	C	C	B	C	C	B	C
Hydrogen	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Hydrogen peroxide	C	C	C	C	C	C	C	C	C	C	C	C	C	C

Hydrogen sulfide, dry	C	C	C	C	C	C	C	C	C	B	C	C	B	C
Hydrogen sulfide, moist	C	C	C	C	C	C	C	C	C	B	C	C	C	C
Lacquers	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Lacquer thinners	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Lactic acid	A	A	A	A	A	C	C	C	C	A	C	C	A	C
Linseed oil	A	A	A	A	A	A	A	A	A	A	A	A	A	A
Liquors														
Black liquor	B	B	B	B	B	C	C	C	C	B	C	C	B	B
Green liquor	C	C	C	C	C	C	C	C	C	B	C	C	C	B
White liquor	C	C	C	C	C	C	C	C	C	A	C	C	C	B
Magnesium chloride	A	A	A	A	A	C	C	C	C	A	C	C	A	B
